Nine European case–control studies on tobacco use and colorectal cancer were identified. They were conducted in Yugoslavia (Jarebinski *et al*., 1988; 1989), Denmark (Olsen & Kronborg, 1993), Sweden (Baron *et al*., 1994), France (Tuyns *et al*., 1982; Boutron *et al*., 1995), Italy (Ferraroni *et al*., 1989; D'Avanzo *et al*., 1995; Tavani *et al*., 1998) and Germany (Nusko *et al*., 2000). Ten case–control studies were conducted in Asia, eight in Japan (Tajima & Tominaga, 1985; Kato *et al*., 1990a,b; Hoshiyama *et al*., 1993; Inoue *et al*., 1995; Kotake *et al*., 1995; Murata *et al*., 1996; Yamada *et al*., 1997) and one each in the Republic of Korea (Choi & Kahyo, 1991) and Hong Kong SAR (Lam *et al*., 2001). Eight case–control studies on tobacco use and colorectal cancer have been carried out in the USA; two of these were hospital-based (Williams & Horm, 1977; Dales *et al*., 1979). The population-based studies were conducted among whites in Los Angeles County (Peters *et al*., 1989), Utah (Slattery *et al*., 1990), Wisconsin (Newcomb *et al*., 1995), northern California, Utah and Minnesota (Slattery *et al*., 1997) and Iowa (Chiu *et al*., 2001) and among the multiethnic population in Hawaii (Le Marchand *et al*., 1997).

Of the case–control studies, statistically significant increased risks among former or current smokers or ever-smokers were reported in two studies each on colon cancer (Slattery *et al*., 1990, 1997; Chiu *et al*., 2001), rectal cancer (Inoue *et al*., 1995; Chiu *et al*., 2001) and colorectal cancer (Newcomb *et al*., 1995; Nusko *et al*., 2000). However, one investigator reported a statistically significant reduction in risk for cancer of the colon (Hoshiyama *et al*., 1993) and rectum among smokers (Vobecky *et al*., 1983). Because smokers may stop or reduce smoking because of disease-related symptoms, case–control studies that presented data on smoking status only without data on duration/intensity (i.e. ever-smoked only or former/current smoking only) (Dales *et al*., 1979; Tuyns *et al*., 1983; Vobecky *et al*., 1983; Kato *et al*., 1990a,b; Inoue *et al*., 1995; Ghadirian *et al*., 1998; Nusko *et al*., 2000) are of limited value.

(i) *Intensity of smoking*

The evidence for an association between cigarette smoking and colorectal cancer would be strengthened if dose–response relationships could be demonstrated. In only one cohort study, were parameters including number of cigarettes smoked, pack–years of smoking, duration of smoking and age at which smoking started investigated separately in current and former smokers (Chao *et al*., 2000). In most of the other cohort studies, one or two parameters of intensity of exposure were assessed. Number of cigarettes smoked per day was most frequently assessed (Hammond, 1966; Doll *et al*., 1980; Williams *et al*., 1981; Carstensen *et al*., 1987; Klatsky *et al*., 1988; Akiba & Hirayama, 1990; Doll *et al*.,

1994; Heineman *et al*., 1994; Chyou *et al*., 1996; Nyrén *et al*., 1996; Tulinius *et al*., 1997; Knekt *et al*., 1998; Chao *et al*., 2000; Terry *et al*., 2001). Statistically significant dose–response trends with amount smoked daily were reported for colon cancer (Heineman *et al*., 1994; Chyou *et al*., 1996), rectal cancer (Doll *et al*., 1994; Heineman *et al*., 1994; Chyou *et al*., 1996) and colorectal cancer (Chao *et al*., 2000; Stürmer *et al*., 2000).

Number of cigarettes smoked daily was evaluated in over half of the case–control studies (Williams & Horm, 1977; Jarebinski *et al*., 1989; Peters *et al*., 1989; Slattery *et al*., 1990; Choi & Kahyo, 1991; Kune *et al*., 1992; Hoshiyama *et al*., 1993; Baron *et al*., 1994; D'Avanzo *et al*., 1995; Kotake *et al*., 1995; Newcomb *et al*., 1995; Murata *et al*., 1996; Slattery *et al*., 1997; Yamada *et al*., 1997; Tavani *et al*., 1998; Chiu *et al*., 2001; Lam *et al*., 2001). Statistically significant positive trends of increasing risk with increasing number of cigarettes smoked daily were reported for colon cancer (Newcomb *et al*., 1995; Slattery *et al*., 1997), rectal cancer (Newcomb *et al*., 1995) and colorectal cancer (Yamada *et al*., 1997). In two studies, this pattern of increasing risks was apparent only in men (Slattery *et al*., 1990) or older men (aged ≥ 70 years) (Lam *et al*., 2001) but not among women in the same study.

(ii) *Duration of smoking*

Studies on colorectal cancer have been varied in their assessment of duration of smoking. Only a few studies actually evaluated years of smoking whereas others considered age at starting smoking, years since initiation of smoking or pack–years, combining duration and intensity of smoking. Five of the cohort studies have looked at years of smoking (Hsing *et al*., 1998; Chao *et al*., 2000), age at starting smoking (Heineman *et al*., 1994; Chao *et al*., 2000), years since initiation of smoking (Giovannucci *et al*., 1994a,b) and pack–years of smoking (Giovannucci *et al*., 1994a ; Heineman *et al*., 1994; Chao *et al*., 2000; Stürmer *et al*., 2000). Some evidence exists to suggest that risk for colorectal cancer increased with earlier age at initiation (Heineman *et al*., 1994; Chao *et al*., 2000) and with increasing number of years of smoking (Chao *et al*., 2000). In one study, risk increased with years since smoking initiation but this was observed among heavier smokers (i.e. subjects who smoked at least 10 cigarettes per day at starting smoking) only (Giovannucci *et al*., 1994a). Three studies showed a statistically significant trend of increasing risk with increasing pack–years of smoking (Heineman *et al*., 1994; Chao *et al*., 2000; Stürmer *et al*., 2000) but, in a fourth study, this association was limited to those who started smoking before the age of 30 years (Giovannucci *et al*., 1994b).

Some case–control studies have examined risk patterns in relation to years of smoking (Jarebinski *et al*., 1989; Choi & Kahyo, 1991; Olsen & Kronborg, 1993; Baron *et al*., 1994; D'Avanzo *et al*., 1995; Newcomb *et al*., 1995; Slattery *et al*., 1997; Tavani *et al*., 1998; Chiu *et al*., 2001), age at starting smoking (Tajima & Tominaga, 1985; Choi & Kahyo, 1991; D'Avanzo *et al*., 1995; Newcomb *et al*., 1995; Slattery *et al*., 1997; Tavani *et al*., 1998) and pack–years of smoking (Tajima & Tominaga, 1985; Kune *et al*., 1992; Hoshiyama *et al*., 1993; Baron *et al*., 1994; Boutron *et al*., 1995; D'Avanzo *et al*., 1995; Siemiatycki *et al*., 1995; Le Marchand *et al*., 1997; Slattery *et al*., 1997; Yamada

et al., 1997; Chiu *et al*., 2001). The risk for colon and rectal cancer increased significantly with increasing number of years of smoking in one study; this relationship was observed even after adjustment for other smoking variables including number of cigarettes smoked per day (Newcomb *et al*., 1995). In two studies, risk for colon cancer (Newcomb *et al*., 1995; Slattery *et al*., 1997) and rectal cancer (Newcomb *et al*., 1995) increased significantly with earlier age at initiation. In one study that included both sexes, this association was found in men only (Slattery *et al*., 1997) whereas in the study of women only (Newcomb *et al*., 1995), any effect of age at initiation was eliminated after adjusting for years of smoking for both colon and rectal cancer. In three studies, the risk for colon cancer (Slattery *et al*., 1997) and rectal cancer (Le Marchand *et al*., 1997; Yamada *et al*., 1997) increased significantly with increasing pack–years of smoking.

(iii) *Smoking cessation*

Modest differences in risk exist between former and current smokers (Tables 2.1.7.2 and 2.1.7.4). The benefit of smoking cessation by years since stopping was evaluated in two cohort studies (Wu *et al*., 1987; Chao *et al*., 2000). The risks in both men and women remained substantially elevated (relative risk, 1.6–1.7) even after 20 years of smoking cessation in one study (Wu *et al*., 1987) but the risk was substantially reduced (to near unity) in another (Chao *et al*., 2000).

Results from case–control studies are also somewhat inconsistent. Risk patterns by years of cessation (D'Avanzo *et al*., 1995; Newcomb *et al*., 1995; Slattery *et al*., 1997; Tavani *et al*., 1998) or age at stopping (Choi & Kahyo, 1991) have been investigated. Cessation was not associated with risk in two studies (Choi & Kahyo, 1991; Tavani *et al*., 1998), but was significantly associated with reduced risk in one (D'Avanzo *et al*., 1995). In one study, women who stopped smoking for 20 or more years still showed an elevation in risk of 10–30% compared with never-smokers (Newcomb *et al*., 1995). In another study, relative to never-smokers, former smokers who had stopped smoking within the first 15 years of starting smoking actually showed a higher risk than current smokers (Slattery *et al*., 1997).

(iv) *Length of follow-up*

Giovannuci *et al*. (1994a,b) proposed that smoking may act as an initiator of colorectal cancer and that a long induction period (i.e. 35–40 years) is needed before an effect on risk can be observed. However, the available results are not entirely compatible with their hypothesis. Of the cohort studies in which smoking was a significant risk factor for colon cancer (Heineman *et al*., 1994; Chyou *et al*., 1996), rectal cancer (Doll *et al*., 1994; Heineman *et al*., 1995; Chyou *et al*., 1996) or colorectal cancer (Wu *et al*., 1987 (men only); Giovannuci *et al*., 1994a; Chao *et al*., 2000; Stürmer *et al*., 2000), the length of follow-up was 6 years or less in two studies (Wu *et al*., 1987; Giovannuci *et al*., 1994a), between 13 and 14 years in two studies (Chao *et al*., 2000; Stürmer *et al*., 2000) and greater than 20 years in three studies (Doll *et al*., 1994; Heineman *et al*., 1994; Chyou *et al*., 1996). In the British Doctors' study, an elevated but non-significant risk for rectal cancer in smokers had

already been observed after the first 20 years of follow-up ($p = 0.09$). The magnitude of risk for rectal cancer in smokers was essentially the same after 20 years as after 40 years of follow-up (Doll & Peto, 1976; Doll *et al*., 1994) although the result became statistically significant with longer follow-up (Doll *et al*., 1994).

(*c*) *Population characteristics*

(i) *Sex*

There is some suggestion that the association between smoking and colorectal cancer may be stronger in men than in women although the evidence for this is far from consistent. Nine cohort studies showed sex-specific results (Hammond, 1966; Wu *et al*., 1987; Sandler *et al*., 1988; Akiba & Hirayama, 1990, Tverdal *et al*., 1993; Doll *et al*., 1994; Engeland *et al*., 1996; Tulinius *et al*., 1997; Chao *et al*., 2000). In one study, a significantly increased risk associated with smoking was observed only in women and not in men (Tulinius *et al*., 1997). In three other studies, an increased risk was more apparent in men than in women (Wu *et al*., 1987; Akiba & Hirayama, 1990; Tverdal *et al*., 1993). In another study, the association between smoking and colorectal cancer was equally strong in both sexes (Chao *et al*., 2000). Ten case–control studies also presented sex-specific results (Williams *et al*., 1977; Slattery *et al*., 1990; Kune *et al*., 1992; Boutron *et al*., 1995; D'Avanzo *et al*., 1995; Inoue *et al*., 1995; Le Marchand *et al*., 1997; Slattery *et al*., 1997; Chiu *et al*., 2001; Lam *et al*., 2001). Of the studies in which smoking was implicated as a risk factor, three showed no clear gender differences (Le Marchand *et al*., 1997; Slattery *et al*., 1997; Chiu *et al*., 2001) but in two studies, smoking was a risk factor only in men (Slattery *et al*., 1990) or older men (Lam *et al*., 2001).

(ii) *Ethnicity*

Almost all the cohort and case–control studies were conducted in Australia, Canada, Europe, the United Kingdom and the USA and included only Caucasian study subjects. One case–control study in the USA was conducted in African Americans (Dales *et al*., 1979) and another included Caucasians and various Asian groups (Le Marchand *et al*., 1997). Approximately one-fourth of the cohort studies (Kono *et al*., 1987; Akiba & Hirayama, 1990; Akiba, 1994) and of the case–control studies (Tajima & Tominaga, 1985; Kato *et al*., 1990a,b; Choi *et al*., 1991; Hoshiyama *et al*., 1993; Inoue *et al*., 1995; Kotake *et al*., 1995; Murata *et al*., 1996; Yamada *et al*., 1997; Lam *et al*., 2001) were conducted in Asia, mostly in native Japanese. There are no apparent differences in the association between smoking and colorectal cancer in members of different racial or ethnic groups.

(*d*) *Subsites of colorectal cancer*

Smoking and risk for cancer of the colon and for rectal cancer were investigated separately in the majority of cohort and case–control studies. Risk patterns are generally consistent between rectal and colon cancer in most of the cohort studies (Hammond & Horn, 1958a,b; Carstersen *et al*., 1987; Tverdal *et al*., 1993; Akiba, 1994; Heineman *et al*., 1994; Chyou *et al*., 1996; Nyren *et al*., 1996; Chao *et al*., 2000; Terry *et al*., 2001) and

case–control studies (Tuyns *et al*., 1982; Vobecky *et al*., 1983; Tajima & Tominaga, 1985; Peters *et al*., 1989, Kato *et al*., 1990a; Choi & Kahyo, 1991; Kune *et al*., 1992; Baron *et al*., 1994; D'Avanzo *et al*., 1995; Le Marchand *et al*., 1997; Tavani *et al*., 1998). However, in four cohort studies (Klatsky *et al*., 1988; Akiba & Hirayama, 1990; Doll *et al*., 1994; Engeland *et al*., 1996) and eight case–control studies (Williams *et al*., 1977; Kato *et al*., 1990b; Hoshiyama *et al*., 1993; Inoue *et al*., 1995; Kotake *et al*., 1995; Newcomb *et al*., 1995; Siemiatycki *et al*., 1995; Murata *et al*., 1996), any effect of smoking was more apparent for rectal cancer than for colon cancer. A stronger smoking association for colon cancer was found in two cohort studies (Hsing *et al*., 1998; Knekt *et al*., 1998) but in none of the case–control studies.

In three large population-based case–control studies and one cohort study (Heineman *et al*., 1994) in which smoking was also implicated as a cause of colon cancer, the effect of smoking by colon subsite was investigated. In two studies, there were no clear differences in the effects of smoking by colon subsite (Heineman *et al*., 1994; Slattery *et al*., 1997). In one case–control study, any effect of smoking was limited to the left colon (Newcomb *et al*., 1995). In another case–control study, the effects of smoking varied by colon subsite and were not consistent in men and women (Le Marchand *et al*., 1997).

(*e*) *Confounding*

It is of note that even among the 'positive' cohort and case–control studies, the magnitude of risk between the highest and lowest exposure (i.e. in people who have never used tobacco) was modest (20–60% increase in risk). The treatment of potential confounders is particularly important when evaluating the overall evidence on the association of smoking with colorectal cancer. Inadequate adjustment for various potential confounders (e.g. alcohol, physical activity, body size, dietary factors) or unidentified confounders could account for the small increase in risk found with smoking in some studies. For example, smokers are more likely than nonsmokers to be physically inactive (IARC, 2002), to use alcohol, to have poorer dietary habits (e.g. low consumption of fruits and vegetables and high consumption of fat and meat) and they are less likely to be screened for colorectal cancer (Margetts & Jackson, 1993). Each of these factors, in turn, is positively associated with colorectal cancer risk (Potter *et al*., 1993). Thus, smoking may appear to increase the risk for colorectal cancer even if it has no direct effect on risk, if these potential confounders are inadequately controlled for or not controlled for in the analysis.

Few potential confounders were adjusted in most of the cohort studies. In some one-third of the published studies, only age or other relevant demographic factors were considered (Hammond & Horn, 1958a,b; Hammond, 1966; Doll *et al*., 1980; Williams *et al*., 1981; Garland *et al*., 1985; Carstensen *et al*., 1987; Sandler *et al*., 1988; Akiba & Hirayama, 1990; Tverdal *et al*., 1993; Akiba, 1994; Doll *et al*., 1994; Engeland *et al*., 1996). Some studies adjusted only for demographic factors and alcohol use (Kono *et al*., 1987; Chyou *et al*., 1996; Hsing *et al*., 1998). Less than half of the studies considered two or more of the potential confounders mentioned above (Wu *et al*., 1987; Klatsky *et al*., 1988; Bostick *et al*., 1994; Giovannucci *et al*., 1994a,b; Heineman *et al*., 1994; Nyrén

et al., 1996; Knekt *et al*., 1998; Singh & Fraser, 1998; van Wayenburg *et al*., 2000; Chao *et al*., 2000; Stürmer *et al*., 2000; Terry *et al*., 2001). The extent to which residual effects of potential confounders can explain the small increase in risk associated with smoking cannot be determined for certain. In some studies, adjustment for alcohol (Hirayama, 1989) and other risk factors (Giovannucci *et al*., 1994a) substantially reduced the magnitude and the significance of the effect of smoking. In other studies, the risk estimate associated with smoking was reduced by up to 10% although the association remained statistically significant (Chao *et al*., 2000; Stürmer *et al*., 2000). None of the prospective studies has evaluated whether the association between smoking and colorectal cancer was modified by other characteristics such as alcohol intake, body size, and others.

In about half of the case–control studies, demographic factors and at least two of the potential confounders discussed above were adjusted for the analyses (Slattery *et al*., 1990; Choi & Kahyo, 1991; Kune *et al*., 1992; Olsen & Kronborg, 1993; Baron *et al*., 1994; D'Advanzo *et al*., 1995; Newcomb *et al*., 1995; Siemiatycki *et al*., 1995; Le Marchand *et al*., 1997; Slattery *et al*., 1997; Yamada *et al*., 1997; Ghadirian *et al*., 1998; Tavani *et al*., 1998; Chiu *et al*., 2001). In addition, two studies investigated whether the association between smoking and colorectal cancer was modified by other characteristics (Newcomb *et al*., 1995; Slattery *et al*., 1997). Newcomb and coworkers reported a significant interaction between body-mass index and risk for rectal cancer (but not colon cancer) such that the risk for cancer at this site was significantly greater among heavier women. In the study of colon cancer by Slattery *et al* (1997), smokers with a high body-mass index displayed higher risk than those with a low body-mass index. However, the influence of β-carotene and other antioxidants on risk appeared to vary by smoking levels, but the nature of the effect differed according to whether the sources of antioxidants were dietary or from supplements. Although no systematic confounding factor has been identified, limited results (Newcomb *et al*., 1995; Slattery *et al*., 1997) show that body size, dietary factors and other potential confounders need to be adequately controlled for in the analysis before any association between smoking and colorectal cancer can be accepted.

(*f*) *Colorectal polyps*

Twenty-seven informative studies have investigated the association between tobacco smoking and risk of colorectal polyps, mostly of the adenomatous type, a well-established precursor for colorectal cancer. These studies are presented in Table 2.1.7.5. Prevalent cases were investigated in most of the studies, although the risk of reccurrence was the end-point in two studies (Jacobson *et al.*, 1994; Baron *et al.*, 1998). In contrast to the weak and inconsistent findings on tobacco use and risk of colon and rectal cancer, the epidemiological evidence on the relationship between smoking and colorectal polyps is generally consistent and more compelling. A significant positive association between smoking and risk of polyps has been found in all but five studies (Kato *et al.*, 1990b; Kono *et al.*, 1990; Sandler *et al.*, 1993; Baron *et al.*, 1998; Breuer-Katschinski *et al.*, 2000). In five studies that presented results separately for men and women (Lee *et al.*, 1993; Jacobson *et al.*, 1994; Boutron *et al.*, 1995; Kahn *et al.*, 1998; Nagata *et al.*, 1999),

the association appeared equally strong in men and women. Significant positive dose–response trends with number of cigarettes smoked daily (Kikendall *et al.*, 1989; Monnet *et al.*, 1991; Zahm *et al.*, 1991; Kearney *et al.*, 1995; Kahn *et al.*, 1998), years of smoking (Monnet *et al.*, 1991; Zahm *et al.*, 1991; Olsen & Kronborg, 1993; Nagata *et al.*, 1999) and pack–years of smoking (Kikendall *et al.*, 1989; Monnet *et al.*, 1991; Zahm *et al.*, 1991; Honjo *et al.*, 1992; Lee *et al.*, 1993; Giovannucci *et al.*, 1994a,b; Jacobson *et al.*, 1994; Boutron *et al.*, 1995; Honjo *et al.*, 1995; Martínez *et al.*, 1995; Longnecker *et al.*, 1996; Nagata *et al.*, 1999; Almendingen *et al.*, 2000) have been found.

The benefit of smoking cessation has been evaluated. Point estimates for former smokers were calculated in 14 studies. Some studies found a decrease relative to current smokers to a non-significantly elevated risk (Zahm *et al.*, 1991; Kearney *et al.*, 1995; Longnecker *et al.*, 1996; Martínez *et al.*, 1997; Almendingen *et al.*, 2000), while the risk remained significantly elevated in others (Monnet *et al.*, 1991; Honjo *et al.*, 1992; Olsen & Kronborg, 1993; Martínez *et al.*, 1995; Kahn *et al.*, 1998).

A few studies also investigated trends, and the results are inconclusive. In one study, the risk for colorectal adenomas was higher than for current smokers after 10 years of smoking cessation (Monnet *et al.*, 1991), whereas in another study, the risk was close to unity after only 2 years of smoking cessation (Kikendall *et al.*, 1989).

Studies also varied in the potential confounders that were considered. In about half of the studies, demographic factors and several of the potential confounders discussed for colorectal cancer (physical activity, alcohol consumption, body size, dietary factors and screening history) were controlled for in the analysis (Olsen & Kronborg, 1993; Giovannucci *et al.*, 1994a,b; Jacobson *et al.*, 1994; Honjo *et al.*, 1995; Kearney *et al.*, 1995; Martínez *et al.*, 1995; Nelson *et al.*, 1995; Longnecker *et al.*, 1996; Martínez *et al.*, 1997; Kahn *et al.*, 1998; Almendingen *et al.*, 2000; Breuer-Katschinski *et al.*, 2000). Several studies adjusted for demographic factors and alcohol use only (Kikendall *et al.*, 1989; Kono *et al.*, 1990; Cope *et al.*, 1991; Zahm *et al.*, 1991; Honjo *et al.*, 1992; Sandler *et al.*, 1993; Boutron *et al.*, 1995), whereas only age was adjusted for in other studies (Hoff *et al.*, 1987; Demers *et al.*, 1988; Stemmermann *et al.*, 1988; Kato *et al.*, 1990b; Monnet *et al.*, 1991; Lee *et al.*, 1993; Manus *et al.*, 1997; Nagata *et al.*, 1999). In a study that examined the joint effect of smoking and alcohol, a statistically significant increase in risk was found only among subjects who were both smokers and drinkers (Cope *et al.*, 1991) although a non-significant twofold increase in risk was also found among smokers who were non-drinkers.

Most relative risk estimates for smoking and colorectal polyps range between 2 and 3, whereas the risk estimates for colorectal cancer range between 1.2 and 1.4. The reasons for the apparent paradox have stimulated considerable discussion (Boutron *et al.*, 1995; Terry & Neugut, 1998; Potter, 1998; Boutron-Ruault, 1999; Poole, 1999; Boutron-Ruault & Rabkin, 2000; Stürmer *et al.*, 2000; Terry *et al.*, 2000). The probable high prevalence of adenomas in most unscreened control groups selected for colorectal cancer studies may have diluted the association between colorectal cancer and smoking (Terry & Neugut, 1998). The strength of an association between a risk factor and a causal intermediate (e.g.

colorectal polyp) may be stronger than the association with the end-point of interest (e.g. colorectal cancer) if other pathways to that end-point exist (Poole, 1999; Terry *et al.*, 2000). Finally, because prevalences of colorectal polyps of at least 20% have been estimated for subjects aged 50 years or older in the USA, the rare disease assumption may not apply and the odds ratios reported would be inflated estimates of the relative risk (Terry *et al.*, 2000).

Table 2.1.7.1. Additional cohort studies on tobacco smoking and colorectal cancer: main characteristics of study design

Reference Country and years of study	Name of study (if available)	Cohort sample	Cases/deaths identification	Comments
Garland *et al*. (1985) USA 1957–77	Western Electric Health Study	1954 male employees at the Western Electric Company in Chicago, aged 40–55 years	Death certificates and medical and hospital records	Study primarily investigating dietary vitamin D and calcium intake and risk of colorectal cancer
Sandler *et al*. (1988) USA 1963–75		91 909 residents in Washington County, aged ≥ 25 years	County-wide cancer register or death certificates	
Kato *et al*. (1997) USA 1985–94	New York University Women's Health Study	15 785 women recruited from New York City and Florida, aged 34–65 years	Active follow-up and linkage to state cancer registries and National Death Index	Study mainly investigating diet and colorectal cancer
Stürmer *et al*. (2000) USA 1982–95	Physicians' Health Study	22 071 male physicians, aged 40–84 years	Yearly questionnaires	
Baron *et al*. (1998) USA 4 years		751 participants in a multi-centre clinical trial of β-carotene and vitamins C and E, with at least one recent large bowel adenoma	Cases ascertained by colonoscopy	Randomized intervention trial
Nagata *et al*. (1999) Japan 1992–95		31 552 (14 427 men, 17 125 women) residents of Takayama, aged ≥ 35 years	Cases ascertained by colonoscopy at two major hospitals	
Olsen & Kronborg (1993) Denmark 1986–90		17 284 residents of Funen Island, participating in a randomized control trial for colorectal cancer screening, aged 45–74 years	Cases ascertained by Haemoccult-II test	Nested case–control study; controls matched by age, sex and date of testing

Table 2.1.7.2. Cohort studies on smoking and risk of colorectal cancer

Reference Country and years of study	Cohort No. of subjects	No. of deaths from cancer of colon or rectum/incident cancers	Smoking categories	Relative risks (95% CI or *p* value)			Adjustment factors/ comments
				Colon cancer	Rectal cancer	Colorectal cancer	
Hammond & Horn (1958a,b) USA 1952–55	American Cancer Society Study 187 783 men	84 colon, 55 rectal deaths	Ever-smoker	0.8	0.9		Age
Hammond (1966) USA 1959–63	Cancer Prevention Study I 440 558 men, 562 671 women	Colorectal deaths 572 men, 349 women	*Men* Regular smoker Heavy smoker *Women* Regular smoker Heavy smoker			1.0 (age: 45–64 years) 1.2 (age: 65–79 years) 0.8 (age: 45–64 years) 0.7 (age: 45–64 years)	Stratified by age and sex. Baseline group included those who never smoked regularly
Kahn (1966) USA 1954–62	US Veterans' Study 248 195 men	513 colon, 216 rectal deaths	Former smoker Current smoker *Cigarettes/day* 10–20 21–39	1.3 1.2 1.1 1.3	1.0 0.9 0.7 1.0		A few cancers of the small intestines were included with colon cancers
Doll & Peto (1976) UK 1951–71	British Doctors' Study 34 440 men	195 colon, 78 rectal deaths	Former smoker Ever-smoker Current, any tobacco smoking *g tobacco/day* 1–14 15–24 ≥ 25 *p* for trend	1.0 1.3 1.3 1.3 1.2 1.2 > 0.05	1.0 2.3 2.3 1.7 2.3 4.5 0.09		Age, calendar year

Table 2.1.7.2 (contd)

Table 2.1.7.3. Case–control studies on tobacco smoking and colorectal cancer: main characteristics of study design

Reference Country and years of study	No. of cases and controls	Comments
Williams & Horm (1977) USA Early 1960s	Men: 333 colon, 185 rectum; women: 389 colon, 154 rectum; and about 4700 controls	Data from the Third National Cancer Survey personal interviews Controls included patients with all other cancers, excluding 'tobacco-related cancers' (lung, larynx, oesophagus, bladder and oral cavity).
Dales *et al*. (1979) USA 1973–76	Men and women: 99 colorectum cases and 280 controls	Hospital-based study among African Americans in the San Francisco Bay Area Cases with colon cancer (72), rectosigmoid cancer (5) and rectal cancer (22); response rate, 40% Controls were hospital patients matched 2:1 (189) and from multiphasic health check-ups matched 1:1 (91), all matched on age, sex and ethnicity; response rate, 50%
Tuyns *et al*. (1982) France 1973–80	Men: 80 colon, 104 rectum and 923 controls; women: 62 colon, 94 rectum and 1053 controls	Population-based study in Calvados Controls represented a random sample of 2% of the total adult population, aged ≥ 20 years,; response rate, 75%
Vobecky *et al*. (1983) Canada 1965–76	Men: 103 colorectum and 103 controls; women: 104 colorectum and 104 controls	Population-based study in St Laurent River Area Cases had 93% response rate. Controls randomly selected in area, individually matched 1:1 by age and sex
Tajima & Tominaga (1985) Japan 1981–83	Men: 27 colon, 25 rectume and 111 controls; women: 15 colon, 26 rectum and 75 controls	Hospital-based study in Aichi Cancer Centre Cases aged 40–70 years Controls were non-cancer patients
Jarebinski *et al*. (1988, 1989) Yugoslavia 1984–86	1988: men: 97 colorectum and 97 controls; women: 87 colorectum and 87 controls; 1989: men: 56 rectum and 112 controls; women: 42 rectum and 84 controls	Population- and hospital-based study in Belgrade Controls from case's neighbourhood (98) and hospital (98), individually matched by sex and age
Ferraroni *et al*. (1989) Italy 1985–88	Men: 221 colon, 170 rectum and 1334 controls; women: 234 colon, 125 rectum and 610 controls	Hospital-based study in northern Italy Cases aged < 75 years Controls were cancer-free (all subjects included in D'Avanzo *et al*., 1995)
Peters *et al*. (1989) USA 1974–82	Men: 106 colon, 41 rectum and 106 controls	Population-based study among young white men in Los Angeles County Cases aged 25–44 years; response rate, 63% Controls individually matched for neighbourhood, race, sex, date of birth; response rate, 63%

Table 2.1.7.3 (contd)

Reference Country and years of study	No. of cases and controls	Comments
Kato *et al*. (1990a) Japan 1986–90	Men: 79 colon, 60 rectum and 377 controls; women: 53 colon, 31 rectum and 201 controls	Population-based study in Aichi Cancer Centre among 1776 patients receiving colonoscopy; response rate for cases, 86% Controls from telephone directories matched by sex, age (5-year groups) and municipality; response rate, 91%
Kato *et al*. (1990b) Japan 1979–87	Men: 1716 colon, 1611 rectum and 16 600 controls	Hospital-based study in Aichi Cancer Centre among patients receiving colonoscopy Cases with cancer of the colon (445 proximal, 765 distal, 506 not specified), or rectum aged ≥ 20 years; response rate, 89% Controls with other cancers, excluding sites related to smoking (larynx, lung, pancreas, bladder) and alcohol consumption
Slattery *et al*. (1990) USA 1979–83	Men: 112 colon and 185 controls; women: 119 colon and 206 controls	Population-based study in Utah Cases of primary cancer, histologically confirmed, aged 40–79 years; response rate, 71% Controls selected by random-digit dialling; response rate, 74%
Choi & Kahyo (1991) Republic of Korea 1986–90	Men: 63 colon, 67 rectum, 189 controls for colon cases, 201 controls for rectal cases	Hospital-based study in Korea Cancer Centre Controls were cancer-free, matched 3:1 on birth years (± 5 years), sex and admission date.
Kune *et al*. (1992) Australia 1980–81	Men: 202 colon, 186 rectum; women: 190 colon, 137 rectum; and 727 controls	Population-based study in Melbourne Incident, histologically confirmed cases; response rate, 62% Controls from community, matched by age and sex; response rate, 71%
Hoshiyama *et al*. (1993) Japan 1984–90	Men: 37 colon, 61 rectum and 343 controls; women: 42 colon, 41 rectum and 310 controls	Population-based study in Saitama Prefecture Incident cases aged 40–69 years Controls from general population; response rate, 28%
Olsen & Kronborg (1993) Denmark 1986, 1988, 1990	Men: 21 colorectum and 156 controls; women 28 colorectum and 206 controls	Randomized control trial using Hemaoccult II as screening test for colorectal cancer 30 970 to screening and 30 968 to control group Cases tested positive for Hemaoccult II test and colonoscopy, aged 45–74 years (mean, 66.7 years) Controls tested negative for Hemaoccult II test, matched to cases on age and sex; mean age, 63.8 years

Table 2.1.7.3 (contd)

Reference Country and years of study	No. of cases and controls	Comments
Baron *et al*. (1994) Sweden 1986–88	Men and women: 352 colon, 217 rectum (262 men, 307 women) and 512 controls (236 men, 276 women)	Population-based study in Stockholm County All cases diagnosed in the area during that period identified through the regional cancer registry; age, 40–79 years; response rate, 79% Controls from population register; response rate, 82%
Boutron *et al*. (1995) France 1985	Men: 109 colorectum and 159 controls; women: 62 colorectum and 150 controls	Population-based study in a clinic in Côte d'Or Cases aged 30–79 years; response rate, 80% Controls selected from the 1975 census list; response rate, 54%
D'Avanzo *et al*. (1995) Italy 1985–91 (see also Ferraroni *et al*., 1989)	Men: 498 colon, 337 rectum and 1863 controls; women: 457 colon, 252 rectum and 1016 controls	Hospital-based study in northern Italy (Greater Milan and Pordenone Province) Cases aged 20–74 years; response rate, 95% Controls with a wide spectrum of acute non-malignant conditions, excluding diseases of the gastrointestinal tract or diseases related to coffee, alcohol or tobacco consumption; response rate, 95%
Inoue *et al*. (1995) Japan 1988–92	Men and women: 94 proximal and 137 distal colon, 201 rectum (257 men, 175 women) and 31 782 controls (8621 men, 23 161 women)	Hospital-based study in Aichi Cancer Centre; response rate for cases, 94% Controls were non-cancer outpatients on first hospital visit; response rate, 94%
Kotake *et al*. (1995) Japan 1992–94	Men and women: 187 colon, 176 rectum (214 men, 149 women) and 363 controls	Hospital-based study in 10 hospitals Controls included cancer (94), non-cancer (56) and screening controls (213) individually matched by age and sex
Newcomb *et al*. (1995) USA 1990–91	Women: 536 colon, 243 rectum and 2315 controls	Population-based study in Wisconsin Incident cases aged 30–74 years; response rate, 74% Controls randomly selected from driver's licences and Health Care Financing Administration listings; response rate, 90%
Siemiatycki *et al*. (1995) Canada 1979–85	Men: 505 colon, 256 rectum and 1492 controls	Study based in major hospitals in Montreal Cases aged 35–70 years; response rate, 82% (including next of kin) Controls selected among cancer patients (959) and from electoral lists (533); response rate, 72%
Le Marchand *et al*. (1997) USA 1987–92	Men: 698 colorectum and 698 controls; women: 494 colorectum and 494 controls	Population-based study among residents of Oahu, Hawaii Cases histologically confirmed, aged < 85 years; response rate, 66% Controls individually matched on sex, ethnicity and age; response rate, 71%

Table 2.1.7.3 (contd)

Reference Country and years of study	No. of cases and controls	Comments
Slattery *et al*. (1997) USA 1991–94	Men: 1097 colon and 1290 controls; women: 892 colon and 1220 controls	Population-based study in northern California, Utah and Minnesota Cases with first primary cancer, excluding rectosigmoid junction or rectum, aged 30–79 years; response rate, 76% Controls selected by random-digit dialling, Health Care Financing Administration and drivers' licence listings; response rate, 64%
Yamada *et al*. (1997) Japan 1991–93	Men: 108 cancers *in situ*, 55 colorectum; women: 21 cancers *in situ*, 11 colorectum; and 390 controls	Study based on a multiphasic health check-up in Tokyo Cases and controls selected among 79 082 persons receiving a faecal occult blood test Controls with no history of colorectal cancer or inflammatory bowel disease, matched 2:1 on sex, age and history of prior health check-up
Ghadirian *et al*. (1998) Canada 1989–93	Men: 200 colon and 239 controls; women: 202 colon and 429 controls	Population-based study in Greater Montreal Cases selected from five teaching hospitals, aged 35–79; response rate, 60% Controls selected by random-digit dialling, matched by age, sex, place of residence and language; response rate, 50%
Tavani *et al*. (1998) Italy 1991–96	Men: 688 colon, 437 rectum and 2073 controls; women: 537 colon, 219 rectum and 2081 controls	Hospital-based study in six centres in northern Italy Cases aged < 75 years Controls were non–cancer patients Response rate for cases and controls, > 95%
Nusko *et al*. (2000) Germany 1993–96	Men: 126 colorectum and 100 controls; women: 76 colorectum and 134 controls	Hospital-based study among patients undergoing colonoscopy Cases aged ≥ 40 years Controls were polyp-free patients
Chiu *et al*. (2001) USA 1986–89	Men: 317 colon, 362 rectum and 1503 controls; women: 338 colon, 267 rectum and 833 controls	Population-based study in Iowa Incident cases, histologically confirmed; aged 40–85 years; response rate, 86% Controls selected from driver's licence and Health Care Financing Administration listings, frequency-matched by sex and age; response rate, 80%
Lam *et al*. (2001) Hong Kong SAR 1997–99	Men: 636 colorectum; women: 563 colorectum; and 13 054 controls	Mortality study among 27 507 cancer deaths Cases aged ≥ 35 years; information retrieved from next of kin; response rate, 81% Controls were relatives of cases or other informants.

Table 2.1.7.4. Case–control studies on tobacco smoking and colorectal cancer

Reference Country and years of study	Smoking variables	Odds ratio (95% CI or *p* value)			Variables adjusted for and other comments
		Colon	Rectum	Colorectum	
Williams & Horm (1977) USA Early 1960s	Pack–years *Men* < 20 20–40 > 40 *Women* < 20 20–40 > 40	 0.7 ($p < 0.05$) 0.7 0.8 1.2 0.9 0.7	 1.6 ($p < 0.05$) 1.5 0.8 0.8 0.7 0.9		Age, race
Dales *et al*. (1979) USA 1973–76	Ever-smoker			58% cases versus 58% controls	Crude percentages
Tuyns *et al*. (1982) France 1973–80	Current smoker	1.0 (0.4–2.7)	1.1 (0.4–2.6)		Age, sex. Risks were non-significantly increased with alcohol intake; 44% of controls were younger than cases.
Vobecky *et al*. (1983) Canada 1965–76	*Men* Former smoker Current smoker *Women* Former smoker Current smoker	 0.5 (p >0.05) 2.0 ($p > 0.05$) Not available 1.3 ($p > 0.05$)	 0.2 ($p = 0.03$) 1.4 ($p > 0.05$) Not available 1.0 ($p > 0.05$)		Age, sex, city. Alcohol was not a risk factor for colon cancer but was for rectal cancer in men (not significant); information and selection bias

Table 2.1.7.4 (contd)

Table 2.1.7.5. Tobacco smoking and risk of colorectal polyps

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Hoff *et al.* (1987) Norway	400 individuals randomly selected from population registry, aged 50–59 years; 324 (81%) underwent sigmoidoscopy.	90 (55 M, 35 F) adenomas and/or hyperplastic polyps 71 (50 M, 21 F) adenomas and/or hyperplastic polyps	69 (32 M, 37 F) 38 (23 M, 15 F)	*Duration (years)* Men Women *Age at start (years)* Men Women	Cases vs non-cases 31.3 ± 1.7 vs 17.3 ± 2.8; $p < 0.01$ 17.6 ± 2.8 vs 8.9 ± 2.2; $p < 0.05$ 17.9 ± 0.6 vs 19.0 ± 1.2; $p > 0.05$ 23.1 ± 1.9 vs 27.7 ± 2.3; $p > 0.05$	Crude analysis. No significant differences in risk according to amount smoked daily
Demers *et al.* (1988) USA 1981–85	1380 male aerospace workers screened for colorectal cancer by sigmoidoscopy	246 polyps, including 94 adenomatous polyps	1134	Ever-smoker Adenomatous polyps Any polyp	 1.7 (1.3–2.3) 1.5 (1.2–1.8)	Adjusted for age
Stemmermann *et al.* (1988) USA 1966–83	American Men of Japanese Ancestry Study 163 deaths with detailed autopsy of the colon	79 adenomatous polyps	84	 Ever-smoker Current smoker	Cases vs non-cases 32.1 vs 30.7; $p = 0.74$ 13.2 vs 12.3; $p = 0.70$	
Kikendall *et al.* (1989) USA 1984–87	204 patients referred for colonoscopy; 185 with complete colonoscopy, adequate biopsy and smoking history	98 adenomas or adenocarcinomas	87	*Cigarettes/day* 1–19 ≥ 20 *Pack–years* 1–19 20–39 ≥ 40 *Years since quitting* > 2 < 2	 2.0 (1.3–3.2) 4.2 (1.7–10.3) 1.5 (1.1–2.0) 2.2 (1.3–3.9) 3.3 (1.4–7.8) 1.2 2.8	Adjusted for age, sex and beer consumption [number of cases and non-cases not clear; sex distribution not reported]

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Kato *et al.* (1990b) Japan 1986–90	2052 patients undergoing colonoscopy; 1776 (87%) responded to postal questionnaire.	525 adenomas[†] 163 proximal (124 M, 39 F) 351 distal (219 M, 132 F) 118 rectum (80 M, 38 F)	578 (377 M, 201 F) selected through telephone directories; 91% responded to postal questionnaire	 Former smoker Current smoker Former smoker Current smoker Former smoker Current smoker	Proximal colon 1.03 (0.6–1.9) 0.8 (0.4–1.3) Distal colon 0.9 (0.6–1.5) 0.8 (0.6–1.3) Rectum 0.95 (0.5–1.9) 1.1 (0.6–2.0)	Adjusted for age, sex and residence [†]Inconsistency between total number of adenomas and numbers at specific sites
Kono *et al.* (1990) Japan 1986–88	1348 male self-defence officials aged 49–56 years, undergoing colonoscopy for health check-up	86 adenomatous polyps of sigmoid colon	1184	*Pack–years* < 20 ≥ 20–< 40 ≥ 40	 0.8 (0.4–1.6) 0.9 (0.5–1.6) 0.8 (0.4–1.7)	Adjusted for rank, alcohol and rice consumption
Cope *et al.* (1991) UK	152 patients undergoing routine colonoscopy	66 (36 M, 30 F) adenomatous polyps	86 (38 M, 48 F)	Nonsmoker/non-drinker Smoker/non-drinker Nonsmoker/drinker Smoker/drinker	1.0 2.1 (0.5–8.3) 3.0 (1.1–8.2) 12.7 (3.0–53.4)	Adjusted for age and sex; categories refer to current alcohol drinkers and/or smokers.

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Monnet *et al.* (1991) France 1983–87	302 male inpatients or outpatients referred for colonoscopy; 211 (70%) responded to survey by phone or post.	103 adenomas	108	Former smoker Ever-smoker Current smoker *Cigarettes/day* 1–9 10–19 > 19 *p* for trend *Duration (years)* 1–19 > 19 *p* for trend *Pack–years* 1–19 > 19 *p* for trend *Years of cessation* > 10 < 10	2.7 (1.3–5.7) 2.2 (1.1–4.4) 1.9 (0.9–4.0) 1.5 (0.6–3.9) 2.0 (1.0–4.3) 3.4 (1.5–7.9) < 0.02 1.3 (0.5–3.6) 2.5 (1.3–4.9) < 0.02 1.4 (0.6–3.0) 3.0 (1.5–6.1) < 0.004 2.2 (0.9–5.3) 3.2 (1.3–7.7)	Adjusted for age; diagnosis of adenoma confirmed by biopsy

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)		Adjustment factors, comments
Zahm *et al.* (1991) USA 1981–83	1465 white male pattern makers examined by flexible sigmoidoscopy; 48% completed questionnaire; 549 with smoking history	76 polyps (adenomatous, hyperplastic or other not specified)	470	Former smoker Ever-smoker Current smoker *Cigarettes/day* ≤ 19 20–39 ≥ 40 *p* for trend *Duration (years)* ≤ 10 11–25 ≥ 26 *p* for trend *Pack–years* ≤ 20 21–40 ≥ 41 *p* for trend	1.4 (0.8–2.5) 1.7 (1.0–2.9) 2.2 (1.2–4.1) 5.5 (2.5–12.1) 1.5 (0.7–3.3) 5.7 (2.6–12.9) 0.0035 Not available 3.3 (1.3-8.3) 2.8 (1.4-5.5) 0.0006 2.4 (0.9–6.4) 4.5 (2.2–9.4) 2.1 (1.0–4.5) 0.0014		Adjusted for age and alcohol consumption; relative risks available for former smokers by number of cigarettes per day, years of smoking and pack–years, and for former and current smokers according to duration of employment
Honjo *et al.* (1992) Japan 1989–90	1296 male self-defence officials aged 48–54 years; 1203 received routine colonoscopy.	116 adenomatous polyps in sigmoid colon	930	Former smoker Current smoker *Cigarettes/day* < 25 ≥ 25 *Pack–years* < 20 20–< 40 ≥ 40	2.2 (1.1–4.3) 3.3 (1.8–6.3) 2.8 (1.3–5.9) 2.3 (1.1–4.6) 2.9 (1.5–5.4) 3.2 (1.6–6.5)		Adjusted for alcohol drinking, official rank and body-mass index
Kono *et al.* (1990); Honjo *et al.* (1992) Japan	Combined data from both studies 202 polyps with information on size	Adenomas 86 small (< 5mm) 72 large (≥ 5 mm)	2114	*Pack–years* < 20 20–< 40 ≥ 40	Small 1.5 (0.7–3.3) 2.1 (1.1–4.1) 2.5 (1.2–5.3)	Large 1.7 (0.8–3.8) 1.7 (0.8–3.4) 1.4 (0.6–3.3)	Adjusted for alcohol intake, official rank and body-mass index

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Lee *et al.* (1993) USA 1986–88	2879 patients referred for colonoscopy beyond splenic flexure, aged 35–84 years; 1892 (81%) interviewed	303 polyps 271 (153 M, 118 F) with smoking data	509 457 (202 M, 255 F) with smoking data	*Pack–years* ≤ 10 > 10–≤ 40 > 40 *p* for trend *Pack–years* ≤ 7.5 > 7.5–≤ 30 > 30 *p* for trend	Men 1.0 (0.5–1.9) 1.8 (0.3–3.3) 2.2 (1.2–3.8) 0.002 Women 0.9 (0.5–1.8) 1.2 (0.6–2.1) 1.4 (0.8–2.5) > 0.05	Adjusted for age. Significant trend by intensity of smoking for right side colon, severe atypia, multiplicity and polyps ≥ 10 mm
Olsen & Kronborg (1993) Denmark 1986	20 672 individuals randomly selected for Haemoccult II screening test; 397 (85%) with positive test had complete colonoscopy.	171 polyps (57 M, 114 F)	362 (157 M, 205 F)	Former smoker Current smoker *Duration (years)* 1–19 20–39 ≥ 40	2.1 (1.1–3.9) 2.0 (1.1–3.5) 2.1 (0.8–5.6) 2.0 (1.1–3.6) 2.7 (1.6–4.7)	Adjusted for age, sex and consumption of dietary fibre, coffee, tea and alcohol. Controls were participants with negative screening test result.
Sandler *et al.* (1993) USA 1988–91	2094 patients undergoing colonoscopy, aged ≥ 30 years; 645 eligible with reliable interviews	236 (105 M, 131 F) adenomatous polyps, including 39 adenomatous and hyperplastic polyps	409 (165 M, 244 F), including 46 with hyper-plastic polyps	Ever-smoker Ever-smoker[†] *Cigarettes/day* 1–10 11–20 ≥ 21 *Pack–years* 1–20 21–40 ≥ 41	1.1 (0.8–1.6) 1.2 (0.9–1.7) 1.3 (0.8–2.1) 1.00 (0.6–1.6) 0.96 (0.6–1.7) 1.2 (0.8–1.9) 0.9 (0.5–1.4) 1.4 (0.8–2.4)	Adjusted for age and sex. [†]Excluding controls with hyperplastic polyps. Similar results in men and women. Little change in results after adjusting for alcohol consumption. No difference between cases and controls for age at start, mean number of cigarettes per day, mean years of smoking and mean pack–years by sex. No difference between ever-smoker, former smoker and current smoker

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)		Adjustment factors, comments
Giovannucci *et al.* (1994a) USA 1980–90 (see also Kearney *et al.*, 1995)	Nurses' Health Study 12 143 women undergoing endoscopy (primarily sigmoido-scopy)	564 prevalent and incident adenomatous polyps of distal colon and rectum		Current smoker *Pack–years* 1–9 10–19 20–29 30–39 ≥ 40 *p* for trend	2.1 (1.7–2.6) 1.2 (0.9–1.7) 1.5 (1.1–2.0) 1.3 (0.9–1.8) 2.2 (1.6–3.1) 2.4 (1.8–3.1) < 0.0001		Adjusted for age, intake of dietary fat, fibre, folate and alcohol, body-mass index and family history of colorectal cancer. Diagnosis confirmed with histopathological reports. Significant trend for large (≥ 1 cm) adenomas with total pack–years ($p < 0.0001$), pack–years smoked before age 30 years ($p = 0.05$) and pack–years smoked after age 30 years ($p < 0.0001$) Significant trend for small (< 1 cm) adenomas with total pack–years ($p < 0.0001$) and pack–years smoked after age 30 years ($p < 0.0001$)
Giovannucci *et al.* (1994b) USA 1986–92 (see also Kearney *et al.*, 1995)	Health Professionals Follow-up Study 12 854 men undergoing endoscopy (primarily sigmoidoscopy)	499 prevalent adenomatous polyps of distal colon and rectum		Current smoker *Pack–years* 1–9 10–19 20–29 30–39 ≥ 40 *p* for trend *Pack–years ≥ 20 years ago* 1–4 5–9 10–15 ≥ 16 *p* for trend	1.6 (1.2–2.1) 1.5 (1.1–2.0) 1.3 (0.9–1.7) 1.4 (0.99–1.9) 1.9 (1.4–2.7) 1.7 (1.3–2.2) < 0.0001 Large 1.9 (0.9–3.8) 1.3 (0.8–2.4) 1.4 (0.7–2.7) 2.4 (1.6–3.6) 0.004	 Small 1.7 (1.03–2.9) 1.2 (0.8–1.9) 0.8 (0.5–1.5) 0.96 (0.7–1.4) 0.95	Adjusted for age, family history of colorectal cancer, body-mass index and intake of fat, fibre, folate and alcohol. Diagnosis confirmed by histopathological reports Significant trend for small ($p = 0.05$) and large ($p = 0.0002$) polyps by total pack–years

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Boutron *et al.* (1995) France	1232 patients undergoing colono-scopy, aged 30–79 years	208 (129 M, 79 F) large adenomas (≥ 10 mm) 154 (85 M, 69 F) small adenomas (< 10 mm)	427 (182 M, 245 F)	**Small adenomas** *Pack–years* 1–20 > 20 *p* for trend *Pack–years* 1–5 > 5 *p* for trend **Large adenomas** *Pack–years* 1–20 > 20 *p* for trend	 Men 1.9 (0.9–4.1) 3.6 (1.8–7.3) < 0.0001 Women 1.3 (0.5–3.1) 1.4 (0.6–3.2) > 0.1 Men 2.3 (1.2–4.5) 2.1 (1.1–4.2) < 0.01	Small adenomas: adjusted for age; large adenomas: adjusted for age and alcohol intake; data available for men only
Honjo *et al.* (1995) Japan 1986–92	4981 male self-defence officials undergoing sigmoidoscopy or colonoscopy, aged 48–56 years	429 sigmoid adenomas, 75 rectal adenomas	3101	*Pack–years* ≤ 22.5 > 22.5–≤ 33 > 33 *p* for trend *Pack–years* ≤ 22.5 > 22.5–≤ 33 > 33 *p* for trend	Sigmoid adenoma 1.7 (1.2–2.3) 2.3 (1.7–3.2) 2.3 (1.6–3.2) < 0.01 Rectal adenoma 0.6 (0.3–1.2) 1.7 (0.9–3.2) 1.0 (0.5–2.0) 0.28	Adjusted for body-mass index, official rank, hospital, study period and alcohol consumption. Seventeen patients had both sigmoid and rectal adenomas and were included in both groups.

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Kearney *et al.* (1995) USA 1986–92 (see also Giovannucci *et al.*, 1994a,b) 1980–90	Health Professionals Follow-up Study 12 922 men undergoing endoscopy Nurses' Health Study 15 984 women undergoing endoscopy	219 hyperplastic polyps of the distal colon and rectum 175 hyperplastic polyps of the distal colon and rectum		 Former smoker Current smoker *Cigarettes/day* 1–14 ≥ 15 Former smoker Current smoker *Cigarettes/day* 1–14 ≥ 15 *p* for trend	Men 1.1 (0.9–1.5) 2.5 (1.6–3.8) 2.3 (1.2–4.4) 2.1 (1.3–3.6) Women 1.3 (0.9–2.0) 2.0 (1.2–2.9) 2.2 (1.3–3.7) 2.4 (1.6–3.7) < 0.0001	Adjusted for age, energy intake, family history of colorectal cancer, previous endoscopy; [discrepancies in relative risks between text and table]
Martínez *et al.* (1995) USA 1991–93	4698 patients undergoing colonoscopy or sigmoidoscopy, identified by medical records; 200 eligible cases, 673 eligible controls (aged > 35 years)	157 (98 M, 59 F) adenomatous polyps	480 (229 M, 251 F)	Former smoker Current smoker *Pack–years* 1–10 11–20 > 20 *p* for trend	1.6 (1.03–2.5) 2.3 (1.3–4.1) 1.7 (0.5–5.7) 2.1 (0.6–6.5) 2.6 (1.3–5.1) = 0.008	Adjusted for age, sex, race, intake of dietary fibre, vitamin C and alcohol, body-mass index, family history of colorectal cancer, physical activity and non-steroidal anti-inflammatory drugs. Relative risks available for interaction with alcohol
Nelson *et al.* (1995) USA 1984–87 (see also Kikendall *et al.*, 1989)	Patients undergoing colonoscopy, aged 26–87 years [number not specified]	137 (109 M, 28 F) adenomas	136 (86 M, 50 F)	Smoker	2.0 (1.1–3.8)	Adjusted for age, sex, family history of cancer, race, alcohol consumption, serum ferritin, β-carotene, α-tocopheral and selenium. Controls included patients with hyperplastic polyps.

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Longnecker *et al.* (1996) USA 1991–93	1317 patients undergoing sigmoidoscopy, aged 50–74 years; 488 matched pairs with complete smoking and diet data	488 (325 M, 163 F) (response rate, 84%)	488 matched by age, sex, date of sigmoidoscopy and medical centre (response rate, 82%)	Former smoker Current smoker *Ever-smoker (pack–years)* Total 1–9 10–29 ≥ 30 *p* for trend *≤ 20 years ago* 1–9 10–30 > 30 *p* for trend *> 20 years ago* 1–9 10–30 > 30 *p* for trend	1.2 (0.9–1.7) 2.4 (1.6–3.8) 1.2 (0.8–1.8) 1.3 (0.9–1.9) 1.8 (1.2–2.5) 0.002 1.5 (1.00–2.3) 2.3 (1.4–3.7) 2.4 (1.02–5.6) 0.0007 1.2 (0.7–1.8) 0.7 (0.5–1.2) 1.1 (0.6–1.9) 0.65	Adjusted for race, alcohol intake, body-mass index, vigorous leisure-time activity, intake of energy, saturated fat and fruits and vegetables. Results by period of tobacco consumption similar for small (< 1 cm) and large (≥ 1cm) polyps 55% of cases and 54% of controls were whites.
Manus *et al.* (1997) Germany 1990–91	1166 patients in clinical rehabilitation centre, aged 50–60 years; 665 (57%) underwent sigmoidoscopy.	146 (97 M, 49 F) adenomatous polyps	519 (308 M, 211 F)	Ever-smoker	Cases vs non-cases 33.6% vs 24.1% ($p = 0.03$)	Large number of subjects with diabetes or hypertension
Martínez *et al.* (1997) USA 1991–93 (see also Martínez *et al.*, 1995)	4698 patients undergoing colonoscopy or sigmoidoscopy, identified by medical records; 113 eligible cases, 719 eligible controls (aged > 35 years)	81 (44 M, 37 F) hyperplastic polyps	480 (229 M, 251 F)	Former smoker Current smoker *Pack–years* ≤ 10 11–20 > 20	1.3 (0.8–2.3) 2.5 (1.2–5.0) 1.2 (0.6–2.3) 1.7 (0.8–3.7) 2.0 (1.02–3.8)	Adjusted for age, sex, race, intake of dietary fibre, energy and alcohol, body-mass index, physical activity and non-steroidal anti-inflammatory drugs

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Baron *et al.* (1998) USA 4 years	864 participants in an ongoing clinical trial with prior history of colorectal polypectomy; 751 subjects had colonoscopy 1 and 4 years after the excision	260 (212 M, 48 F) recurrent adenomas	449 (344 M, 105 F)	Former smoker Current smoker *Cigarettes/day* ≤ 20 21–40 > 40 *Duration (years)* ≤ 20 > 20–≤ 30 > 30– ≤ 40 > 40	1.1 (0.8–1.6) 0.95 (0.6–1.5) 1.2 (0.8–1.8) 0.8 (0.5–1.2) 1.6 (0.9–2.7) 1.5 (0.9–2.5) 0.7 (0.4–1.2) 1.1 (0.7–1.7) 0.97 (0.6–1.6)	Adjusted for age, sex, clinical centre, intake of fat, total dietary fibre, energy intake and colonoscopy interval. Similar results for polyp recurrence in right and left colon
Kahn *et al.* (1998) USA 1982–92	Cancer Prevention Study II 72 868 men and 81 356 women without polyps at baseline, aged 40–64 years	12 615 (7504 M, 5111 F) polyps		Former smoker Current smoker *(cigarettes/day)* 1–20 ≥ 21 Former smoker Current smoker *(cigarettes/day)* 1–20 ≥ 21	Men 1.25 (1.17–1.34) 1.30 (1.18–1.43) 1.34 (1.21–1.47) Women 1.21 (1.13–1.30) 1.37 (1.25–1.50) 1.50 (1.32–1.70)	Adjusted for age, education, race, gallbladder status, body-mass index, exercise, alcohol and coffee consumption, aspirin use, multivitamin use, family history of colorectal cancer, diet change, diet (intake of eggs, vegetables, meat, fibre, chicken, fish), and for women, parity, estrogen replacement therapy and menopausal status
Terry & Neugut (1998) USA 1986–88	3008 subjects undergoing complete colonoscopy beyond splenic flexure, aged 35–84 years; 2443 (81%) eligible; 2001 interviewed	269 (155 M, 114 F) polyps	508 (225 M, 283 F)	Ever-smoker *Pack–years* 1–19 20–39 ≥ 40	1.3 (0.97–1.8) 1.2 (0.8–1.8) 1.2 (0.7–1.9) 1.6 (1.1–2.4)	Adjusted for gender, age and Quetelet index. Study investigated the hypothesis that control groups in many studies on tobacco smoking and colorectal cancer included a high proportion of individuals with adenomatous polyps.

Table 2.1.7.5 (contd)

Reference Country and years of study	Initial study population	Case patients (M, F)	Polyp-free patients (M, F)	Smoking categories	Relative risk (95% CI)	Adjustment factors, comments
Nagata *et al.* (1999) Japan 1993–95	14 427 M, 17 125 F residents of Takayama, aged ≥ 35 years; 593 underwent colonoscopy	259 (181 M, 78 F) histologically proven adenomas			Men	Adjusted for age

2.1.8 *Cancer of the liver*

(*a*) *Overall risk*

An association between cigarette smoking and liver cancer was reported in two cohort studies, one in Japan and one in the USA, and in four case–control studies on the topic (IARC, 1986). In one of the cohort studies (Hirayama, 1981), the relative risks associated with smoking were statistically significant in each alcohol-specific stratum; in another (Trichopoulos *et al.*, 1980), a relative risk of 5.5 remained among hepatitis B surface antigen (HBsAg)-positive individuals who smoked > 20 cigarettes/day after adjustment for alcohol consumption. At the time, however, it was thought that the available data did not convincingly exclude residual confounding.

Twenty-eight additional cohort studies have been published since or after 1985, including 10 from Japan (Kono *et al*., 1987; Akiba & Hirayama, 1990; Hiyama *et al.*, 1990; Shibata *et al*., 1990; Kato *et al*., 1992; Goodman *et al*., 1995; Chiba *et al*., 1996; Murata *et al*., 1996; Mizoue *et al*., 2000; Mori *et al*., 2000), nine from China (Tu *et al.*, 1985; Ross *et al*., 1992; London *et al*., 1995; Yuan *et al*., 1996; Chen *et al*., 1997; Lam *et al.*, 1997; Gao *et al*., 1999; Sun *et al*., 1999; Evans *et al*., 2002), four from China, Province of Taiwan (Yu & Chen, 1993; Chang *et al*., 1994; Liaw & Chen, 1998; Yang *et al*., 2002), two each from the USA (Hsing *et al.*, 1990; McLaughlin *et al*., 1995) and Sweden (Carstensen *et al*., 1987; Nordlund *et al*., 1997) and one from the United Kingdom (Doll *et al*., 1994). In some studies, the cohort included patients with decompensated cirrhosis or post-transfusional hepatitis (Kato *et al*., 1992), persons with chronic hepatitis or cirrhosis (Chiba *et al*., 1996) or HBsAg-positive healthy patients (Hiyama *et al.*, 1990). The design of these cohort studies is described in Tables 2.1 and 2.1.8.1, and the results are summarized in Table 2.1.8.2.

Most of the new cohort studies show an increased relative risk among current smokers.

Twenty-six additional case–control studies (Tables 2.1.8.3 and 2.1.8.4) published after 1985 provide information on smoking and liver cancer: six were conducted in Japan (Hiyama *et al.*, 1990; Tsukuma *et al*., 1990; Tanaka *et al*., 1992; Pyong *et al.*, 1994; Tanaka *et al*., 1995; Mukaiya *et al*., 1998), three each in Africa (Kew *et al.*, 1990; Olubuyide & Bamgboye, 1990; Mohamed *et al*., 1992), China or Hong Kong SAR (Lin *et al*., 1991; Liu *et al*., 1998; Lam *et al.*, 2001) and the USA (Austin *et al.*, 1986; Yu, M.C. *et al.*, 1991; Chen *et al*., 2003), two each in Greece (Tzonou *et al*., 1991; Kuper *et al*., 2000), Italy (La Vecchia *et al*., 1988; Ferraroni *et al*., 1989), the Republic of Korea (Choi & Kahyo, 1991; Shin *et al*., 1996) and China, Province of Taiwan (Chen *et al*., 1991; Yu, M.W. *et al*., 1991) and one each in Canada (Siemiatycki *et al*., 1995), Germany (Peters *et al.*, 1994) and Spain (Vall Mayans *et al*., 1990). The majority of these studies used hospital controls. Five studies included community controls; two large Chinese studies (Liu *et al*., 1998; Lam *et al.*, 2001) include controls who had died of causes other than neoplastic respiratory or vascular diseases. Risks in current smokers that were higher than those in never-smokers were found in 17 studies and attained statistical significance in 10 studies. An association between smoking and increased risk of liver cancer is thus consistently demonstrated in nearly all cohort studies and in a number of case–control studies, particularly the largest

ones from Asia, Greece and the USA. These studies used different approaches to consider other established risk factors for liver cancer such as infection with hepatitis B virus (HBV) and with hepatitis C virus (HCV) infection and alcohol consumption.

(i) *Confounding and effect modification*

Covariates that may potentially confound and/or modify the relationship between smoking and liver cancer include chronic infection with HBV and HCV (IARC, 1994) and heavy alcohol consumption (IARC, 1988). Consideration of each of these factors presents a challenge, however, because analyses that adjust for alcohol consumption may over-control for cigarette smoking, and stratification on hepatitis infection status rather than adjustment may be the preferred approach for differentiating confounding from effect modification by HBV or HCV infection.

Heavy, although not moderate, intake of alcoholic beverages is associated with an increased risk for liver cancer (IARC, 1988). The excess of liver cancer in populations where drinking alcohol is common could thus reflect an insufficient adjustment for drinking habits (Doll *et al*., 1994; McLaughlin *et al*., 1995). However, several recent case–control and cohort studies have found an association between smoking and liver cancer after controlling for alcohol consumption (Yu, M.C. *et al*., 1991; Yuan *et al*., 1996; Chen *et al*., 1997; Liaw & Chen, 1998; Mizoue *et al*., 2000) and among persons who reported no alcohol consumption. Chen *et al.* (1991) showed that subjects who consumed no alcohol, but smoked 20 cigarettes or more daily had a relative risk of 2.7 of developing liver cancer relative to nonsmokers who drank no alcohol. Those who both drank and smoked heavily had a relative risk of 11.7. Further supportive evidence is provided by the association between smoking and liver cancer observed among Chinese women (Liu *et al*., 1998) and Japanese women (Tanaka *et al*., 1995), in whom heavy alcohol drinking is extremely rare.

Infection with HBV is the main cause of liver cancer worldwide, whereas HCV infection causes a large fraction of liver cancer in Japan, northern Africa and southern Europe (IARC, 1994). Infection with HCV is increasing in many countries. To distinguish the strong effect of infection with HBV and HCV (relative risks of the order of 20; IARC, 1994) from the association with smoking, stratification and/or adjustment for HBsAg and anti-HCV have been made in some studies (Yu, M.C. *et al*., 1991; Yu, M.W. *et al*., 1991; Liaw & Chen, 1998; Kuper *et al*., 2000). The association between smoking and liver cancer was not generally weakened by adjustment for HBV and HCV. Infection with HBV was less frequent among smokers than nonsmokers in a large population survey in China (Evans *et al*., 2002). The possibility that tobacco smoking may potentiate the progression of chronic HBV and HCV infections to liver cirrhosis (Yu *et al.*, 1997) and/or liver cancer (Tsukuma *et al.*, 1993) has been examined in relatively few studies. The increase in risk for liver cancer associated with cigarette smoking appears to be greater among HBV carriers than among uninfected persons in some studies (Tu *et al.*, 1985), but not in others (Kuper *et al.*, 2000).

No information on confounding from exposure to aflatoxin was available.

(ii) *Bias*

The most frequent bias that can arise in studies of associations between smoking and cancer are described in the General Remarks. Many of the case–control studies that have not found an association between smoking and liver cancer are hospital-based, so that the control series may include tobacco-related diseases. Morbidity and symptoms resulting from prevalent liver cirrhosis or undiagnosed liver cancer can lead to lifestyle changes, including a reduction in number of cigarettes smoked per day or cessation of smoking. This phenomenon would lead to underestimation of the relative risk for current smokers and to overestimation of the relative risk for former smokers. It can also distort the association of liver cancer with the number of cigarettes smoked per day. The detection of liver cancer in a cirrhotic liver presents substantial difficulties of under- or over-diagnosis in cohort studies. Differential ascertainment of liver cancer according to smoking status, however, is unlikely.

A varying, but often substantial, proportion of liver cancer cases in the studies considered in this section was not pathologically confirmed. Liver cancer is a common site for metastases. If a high proportion of liver cancer for which pathological confirmation was not acquired were in reality metastases from smoking-related cancers (e.g. of the lung, oesophagus or stomach), the association between smoking and liver cancer in some studies would be overestimated. In the vast majority of the examined studies, however, diagnosis of liver cancer was confirmed by cytological findings or by the combined presence of elevated concentrations of α-fetoprotein (> 400 ng/mL) and at least one positive image obtained by angiography, sonography, liver scan or computerize tomography scan.

(*b*) *Factors affecting risk*

(i) *Duration and intensity*

The US Veterans Study (Hsing *et al.*, 1990) found a substantial increase in the association with increased smoking duration. A clear trend of increasing risk of liver cancer with the increase in pack–years was reported by Chiba *et al.* (1996). Many more studies reported relative risk by number of cigarettes smoked per day. An increased risk in heavy smokers relative to light smokers was shown in several studies (Hiyama *et al.*, 1990; Hsing *et al.*, 1990; Chen *et al.*, 1991; Tzonou *et al.*, 1991; Yu, M.W. *et al.*, 1991; Tanaka *et al.*, 1992; Chiba *et al.*, 1996; Liu *et al*., 1998; Kuper *et al.*, 2000). In other studies, especially those from Asia, however, the relative risk among smokers did not vary by category of cigarettes smoked per day. The reasons for this are unknown but they may include the relatively low power of most studies to detect small relative risks, and the inclusion of persons who smoke up to 25 cigarettes per day in the referent group. Hsing *et al.* (1990) showed higher relative risk among smokers who started smoking earlier (generally before age 20 years) than in those who started at age 25 years or older.

(ii) *Smoking cessation*

Nine cohort and 10 case–control studies provided information on the relative risk for former smokers. Most studies showed a lower risk for liver cancer among former smokers than in current smokers. In four studies, however, the relative risk for former smokers was of similar magnitude or even higher than the relative risk for current smokers (Ferraroni *et al*., 1989; Tanaka *et al.*, 1992, 1995; Kuper *et al*., 2000). The only study that examined relative risks by number of years since quitting showed a decrease in risk with time since cessation (Goodman *et al*., 1995).

(iii) *Type of cigarettes*

No data were available to the Working Group.

(*c*) *Population characteristics*

(i) *Sex*

The absolute risk of liver disease (hepatitis, cirrhosis, and cancer) is substantially greater in men than women in all populations. The data available suggest, however, that the association between smoking and liver cancer is similar in men and women (Liu *et al*., 1998; Kuper *et al*., 2000), after taking into account different levels of smoking in the two sexes.

(ii) *Ethnicity*

Some disparities have been described in the relative risks observed in different racial and ethnic populations. [Such variations may reflect factors other than race such as different smoking and alcohol drinking patterns, variations in prevalence of HBV and HCV infection, and the greater probability of residual confounding from alcohol drinking in populations from Europe and North America.]

Table 2.1.8.1. Additional cohort studies on tobacco smoking and liver cancer

Reference Country and years of study	Hepatitis B virus (HBV) status	Cohort sample	Cases/deaths identification	Comments
Basa *et al.* (1977) Philippines 1968–73	HBV/HCV status unknown	16 492 cancer cases registered at the Central Tumour Registry of the Philippines	Registry	Retrospective study
Tu *et al*. (1985) China 1980–82	16% HBV-positive Stratified data	Male residents of Chongming Island, aged ≥ 40 years	Deaths ascertained by local Anti-Epidemic Station	
Hiyama *et a*l. (1990) Japan 1969–85 1972–92	Unknown status All HBsAg-positive	Male patients admitted to mental hospitals for alcoholism [age range not reported] 8646 men who donated blood in 1972–75	Deaths	Nested case–control study
Shibata *et al*. (1990) Japan 1958–86 1960–86	Status unknown	Men aged 40–69 years from: Farming areas (cohort I) Fishing areas (cohort II)	Deaths ascertained with resident's cards and other materials at municipal offices	
Kato *et al*. (1992) Japan 1987–90	Status known No adjustment No stratification	Patients with decompensated liver cirrhosis, 343 with post-transfusion hepatitis, aged ≥ 16 years	Cases	
Ross *et al.* (1992) China 1986–90	HBsAg-positive: 55% cases, 11% controls	All men aged 45–64 years living in 4 defined areas of metropolitan Shanghai	Cases of primary liver cancer identified through Shanghai municipality and Shanghai Cancer Registry	Nested case–control study; adjustment for HBsAg status in a multivariate regression model
Yu & Chen (1993) China, Province of Taiwan 1984–90	HBsAg-positive: 57% cases, 55% controls Anti-HCV: 20% cases, 3% controls No stratification	Men aged 30–85 years	Cases	Nested case–control study, adjustment for HBsAg and anti-HCV status in multivariate regression model

Table 2.1.8.1. (contd)

Reference Country and years of study	Hepatitis B virus (HBV) status	Cohort sample	Cases/deaths identification	Comments
Chang *et al*. (1994) China, Province of Taiwan 1984–92	HBsAg-positive: 63% cases, 7% controls Anti-HCV: 13% cases, 3% controls	Men aged 30–85 years	Cases	Same cohort as Yu & Chen (1993). Nested case–control study without adjustment for HBsAg or anti-HCV status
London *et al*. (1995); Evans *et al*. (2002) China 1992–2000	81% HBsAg-positive 11–15% HBsAg-positive, 1.5% HCV-positive No adjustment, no stratification	Residents of Haimen City, the world highest incidence area for hepatocellular carcinoma; aged 30–64 years	Deaths certificates confirmed by hospital records	London *et al.* (1995) conducted a nested case–control study with matching for HBV status.
Chiba *et al*. (1996) Japan 1977–93	HBsAg-negative, anti-HCV-positive	412 patients with chronic liver disease, including 232 chronic hepatitis and 180 cirrhosis	Cases ascertained by medical follow-up	
Sun *et al*. (1999) China 1987–98	16% HBsAg-positive, 7% HCV-positive	Men with chronic hepatitis B (72% of all men with hepatitis B in two townships)	Cases identified by twice-yearly examinations	
Mori *et al*. (2000) Japan 1992–97	1.8% HBsAg-positive 22% HCVAb-positive	Baseline survey during liver disorder screening	Cases	
Yang *et al*. (2002) China, Province of Taiwan 1991–2000	Known HBV and HCV status	Men aged 30–65 years	Cases ascertained by yearly mass screening	Nested case–control study

HCV, hepatitis C virus; HBsAg, hepatitis B surface antigen

Table 2.1.8.2. Cohort studies on tobacco smoking and liver cancer

Reference Country and years of study	Cohort No. of subjects	No. deaths/ incident cancers	Smoking categories and other variables	Relative risk (95% CI)		Adjustment factors/ comments
Hammond (1966) USA 1959–63	Cancer Prevention Study (CPS) I 440 558 men, 562 671 women		Ever-smoker Aged 45–64 years Aged 65–79 years	**Mortality ratio** 2.8 1.3		Mortality ratio of age-standardized death rates. Study based on examination of death certificates on which secondary liver cancers may have been included in the category 'liver cancer' (many smoking-related cancers metastasize to the liver).
Basa *et al*. (1977) Philippines 1968–73	16 492 cancer cases (6771 men, 9721 women)	541 men, 213 women	Ever-smoker Current smoker	**Men** 1.5 ($p = 0.01$) 1.3	**Women** 2.6 ($p = 0.001$) 1.9 ($p = 0.01$)	Adjusted for age
Hirayama (1981) Japan 1965–78	Six-prefecture Study 265 118 men and women	865 deaths	*Lifelong no. of cigarettes smoked* None 1–190 000 200 000–390 000 400 000	**Alcohol use** *Occasional, rare, none* 26.5 38.8 39.9 45.2	 *Daily* 24.0 49.4 45.8 66.9	Standardized mortality ratios
Tu *et al*. (1985) China 1980–82	12 222 men	70 deaths	*HBV carrier* Nonsmoker Current smoker ≤ 19 cigs/day ≥ 20 cigs/day *HBV non-carrier* Nonsmoker Current smoker ≤ 19 cigs/day ≥ 20 cigs/day	**Mortality rate** 332.8 737.9 660.1 1519 ($p < 0.05$) 115.1 99.9 96.3 145.2		Adjusted for age and alcohol consumption

Table 2.1.8.2 (contd)

Reference Country and years of study	Cohort No. of subjects	No. deaths/ incident cancers	Smoking categories and other variables	Relative risk (95% CI)		Adjustment factors/ comments
Carstensen *et al*. (1987) Sweden 1963–79	Swedish Census Study 25 129 men	54 deaths	Former smoker Current smoker *Cigarettes/day* 1–7 8–15 > 15	1.7 3.0 1.6 3.3 4.1		Relative death rates Categories in grams of any tobacco/day combined: 1 cigarette = 1 g; 1 small cigar = 3 g; 1 large cigar = 5 g
Kono *et al*. (1987) Japan 1965–83	Japanese Physicians' Study 5130 men	51 deaths	1–19 cigarettes/day ≥ 20 cigarettes/day	1.1 (0.6–2.2) 1.0 (0.5–2.2)		Adjusted for age and alcohol
Akiba & Hirayama (1990) Japan 1965–81	Six-prefecture Study 122 261 men, 142 857 women ~3 975 000 person–years	1060 deaths (662 men, 398 women)	Current smoker *Cigarettes/day* **Men** 1–4 5–14 15–24 25–34 ≥ 35 **Women** 1–4 5–14 ≥ 15	1.5 (1.2–1.9) 1.1 (0.5–2.0) 1.6 (1.3–2.0) 1.4 (1.2–1.8) 1.6 (1.1–2.4) 1.9 (1.1–3.2) [p for trend = 0.002] 1.4 (0.7–2.5) 1.4 (1.0–2.0) 2.5 (1.3–4.1) [p for trend = 0.001]		Adjusted for prefecture, occupation, age and observation period. No trend observed in the relative risk in relation to calendar period. Unclear whether former smokers were included in analysis or not
Hiyama *et al*. (1990) Japan 1969–85	13 171 men	93 cases		*Ratio observed/expected* 1.4 (1.1–1.7)		
1972–92	8646 men	22 cases, 44 controls	*Cigarettes/day* 10–29 ≥ 30	*Crude odds ratio* 1.7 (0.4–6.4) 5.8 (1–34.2)	*Adjusted for alcohol* 1.2 6.3	Nested case–control study; controls matched by age

Table 2.1.8.2 (contd)

Reference Country and years of study	Cohort No. of subjects	No. deaths/ incident cancers	Smoking categories and other variables	Relative risk (95% CI)	Adjustment factors/ comments
Hsing *et al*. (1990) USA 1954–80	US Veterans' Study 293 916 men	289 deaths	Former smoker Current smoker *Cigarettes/day* < 10 10–20 21–39 > 39 *Duration (years)* < 35 35–39 > 39 *Age at starting smoking (years)* < 20 20–24 > 24	1.9 (1.2–2.9) 2.4 (1.6–3.5) 2.2 (1.2–3.8) 2.0 (1.3–3.0) 2.9 (1.8–4.5) 3.8 (1.9–8.0) 0.9 (0.4–2.1) 2.6 (1.4–4.9) 2.7 (1.5–4.9) 2.9 (1.6–5.3) 2.3 (1.2–4.3) 1.0 (0.4–2.3)	Adjusted for age and calendar period
Shibata *et al*. (1990) Japan 1958–86 (I) 1960–86 (II)	Cohort I 639 men 17 480 person–years Cohort II 677 men 17 172 person–years	11 deaths 22 deaths	Current smoker *Cigarettes/day* 1–9 ≥ 10 Former smoker Current smoker *Cigarettes/day* 1–9 10–19 20–29 ≥ 30 1–19 ≥ 20	1.1 (0.2–4.7) 0.6 (0.1–3.7) 1.2 (0.2–5.7) [*p* for trend ~0.6] 2.9 (0.3–29.0) 3.6 (0.6–22.3) 11.9 (1.5–96.8) 1.1 (0.1–10.6) 2.7 (0.4–19.2) 3.2 (0.4–23.7) [*p* for trend ~0.5] 2.1 (0.4–10.0) 1.9 (0.4–9.4)	Adjusted for age. Calculations based on small number of liver cancer cases. No information on HBV/HCV Adjusted for age and alcohol

Table 2.1.8.2 (contd)

Reference Country and years of study	Cohort No. of subjects	No. deaths/ incident cancers	Smoking categories and other variables	Relative risk (95% CI)	Adjustment factors/ comments
Kato *et al*. (1992) Japan 1987–90	1441 patients with decompensated liver cirrhosis, 343 with post-transfusion hepatitis 4386 person–years	122 cases	Former smoker Current smoker *Pack–years* < 30 ≥ 30	0.9 (0.4–2.0) 1.0 (0.5–1.8) 0.8 (0.4–1.7) 0.9 (0.5–1.9) p for trend = 0.824	Adjusted for sex and age. Record linkage study. Patients at high risk for development of hepatocellular carcinoma
Ross *et al*. (1992) China 1986–89	18 244 men 35 299 person–years	22 cases, 140 controls	Ever-smoker *Cigarettes/day* 1–19 ≥ 20 *Duration (years)* 1–29 ≥ 30 Ever-smoker	2.6 (0.9–7.2) 3.1 (1.0–10.3) 2.1 (0.6–6.9) 2.6 (0.7–9.4) 2.5 (0.9–7.6) 1.8 (0.6–5.6)	No adjustment; nested case–control study. Population-based controls matched on age, sample collection and residence Adjusted for HBV, alcohol consumption, aflatoxin exposure and education
Yu & Chen (1993) China, Province of Taiwan 1987–90	9691 men	35 cases, 140 controls	Current smoker	1.2 (0.4–3.1)	Nested case–control study; controls matched by age, date of interview and residence. Adjusted for testosterone, alcohol consumption, HCV status, HBsAg status, vegetable consumption and history of liver disease
Chang *et al*. (1994) China, Province of Taiwan 1984–92	9775 men	38 cases, 152 controls	Ever-smoker	1.2 (0.6–2.7)	Nested case–control study; controls matched for age, residence and date of recruitment. Cases confirmed pathologically or α-fetoprotein ≥ 400 mg/mL and ultrasound

Table 2.1.8.2 (contd)

Reference Country and years of study	Cohort No. of subjects	No. deaths/ incident cancers	Smoking categories and other variables	Relative risk (95% CI)	Adjustment factors/ comments
Doll *et al*. (1994) UK 1951–91	British Doctors' Study 34 439 men	76 deaths		**Mortality rate**	Annual mortality rate per 100 000 men
			Never-smoker	7	
			Former smoker	9	
			Current smoker	11	
			Cigarettes/day		
			1–14	17	
			15–24	3	
			≥ 25	15 [*p* for trend = 0.7]	
Goodman *et al*. (1995) Japan 1980–89	Life Span Study 36 133 men and women 311 086 person–years	252 cases (156 men, 86 women)	**Men**		Adjusted for city, age at time of bombing and radiation dose to liver. Relative risk among non-drinkers of alcohol for ever smoking, 1.9 (95% CI, 1.2–2.9); among men, 7.2 (95% CI, 1.0–53.3); among women, 1.3 (95% CI, 1.0–1.7). [CIs calculated by the Working Group]
			Former smoker	4.2 (2.0–10.7)

Sun *et al*. (1999) China 1987–98	145 men	22 cases, 45% histologically confirmed	 Never-smoker Current smoker	**Incidence rate** 2.3 1.6 $p = 0.5$	Rate per 100 person–years
Mizoue *et al*. (2000) Japan 1986–96	Fukuoka Study 4050 men 35 785 person–years	59 deaths	Former smoker Current smoker *Cigarettes/day* 1–24 ≥ 25	2.9 (1.0–8.4) 3.3 (1.2–9.5) 3.5 (1.2–10.2) 2.8 (0.8–9.6)	Adjusted for age, alcohol consumption and area of residence
Mori *et al*. (2000) Japan 1992–97	974 men, 2078 women 13 984 person–years	22 (14 men, 8 women)	Former smoker *Pack–years* < 10 ≥ 10	2.1 (0.6–7.2) 3.3 (0.4–28.2) 2.0 (0.6–6.9) p for trend = 0.3	Adjusted for age and sex

Table 2.1.8.2 (contd)

Reference Country and years of study	Cohort No. of subjects	No. deaths/ incident cancers	Smoking categories and other variables	Relative risk (95% CI)	Adjustment factors/ comments
Evans *et al*. (2002) China 1992–2000	48 454 men, 25 430 women	977 deaths (900 men, 77 women)	*Current smoker* Men Women	 0.9 (0.8–1.1) 2.0 (0.9–4.2)	Smoking was not significantly associated with liver cancer as assessed by present consumption, duration of smoking or pack–years
Yang *et al*. (2002) China, Province of Taiwan 1991–2000	11 83 men 92 359 person–years	111 cases, 222 controls	Current smoker	1.5 (1.0–2.2)	Nested case–control study; population-based controls matched on age, date of enrolment and township. Adjusted for HBV and HCV status, age and alcohol consumption

HBV, hepatitis B virus; HCV, hepatitis C virus

Table 2.1.8.3. Case–control studies on tobacco smoking and liver cancer: main characteristics of study design

Reference Country and years of study	No. of cases and controls	Source of cases and controls
Williams & Horm (1977) USA 1969–71	Men: 31 cases and 1739 controls; women: 14 cases and 3164 controls	Study with the Third National Survey Cases and controls aged ≥ 35 years; response rate, 57% Controls were patients with other cancers, excluding lung, larynx, oral cavity, oesophagus and bladder
Trichopoulos *et al*. (1980) Greece 1976–77	Men: 35 cases and 169 controls; women: 5 cases and 35 controls	Hospital-based study among HBsAg-negative Cases histologically confirmed (58%); mean age, 62 years Controls matched on age and sex
Lam *et al*. (1982) Hong Kong SAR 1977–80	Men: 17 cases and 94 controls; women: 2 cases and 13 controls	Hospital-based study among HBsAg-negative patients Cases histologically confirmed (99%); mean age, 50 years Controls matched on age and sex
Stemhagen *et al*. (1983) USA 1975–80	Men: 178 cases and 356 controls; women: 87 cases and 174 controls	Hospital-based study Cases histologically confirmed; mean age, 64 years Controls matched on age, race, sex and area of residence
Yu *et al*. (1983) USA 1975–79	Men and women: 78 cases and controls	Population-based study among black and white non-Asians Incident cases histologically confirmed (70.6%); aged ≥ 70 years Controls matched on age, sex, race and neighbourhood
Hardell *et al*. (1984) Sweden 1974–81	Men: 98 cases and 200 controls	Population-based study Deceased cases of hepatocellular carcinoma (83) or cholangiocarcinoma (15), 100% histologically confirmed; aged 25–80 years Controls randomly selected from population
Austin *et al*. (1986) Cuba, USA (years of study not specified)	Men: 60 cases; women: 26 cases; 172 controls	Hospital-based study Cases confirmed histologically (93%); aged 19–84 years Controls matched by age, sex and race
La Vecchia *et al*. (1988) Italy 1984–87	Men: 115 cases and 776 controls; women: 36 cases and 275 controls	Hospital-based study Cases aged 24–74 years Controls with acute conditions excluding malignant disorders, digestive tract diseases and conditions related to tobacco or alcohol; aged 22–74 years
Ferraroni *et al*. (1989) Italy 1983–88	Men: 115 cases and 1334 controls; women: 36 cases and 610 controls	Hospital-based study Cases histologically confirmed (100%); aged < 75 years Controls with no cancer, digestive tract disorders or conditions related to coffee, alcohol and tobacco consumption; comparable catchment areas

Table 2.1.8.3 (contd)

Reference Country and years of study	No. of cases and controls	Source of cases and controls
Hiyama *et al*. (1990) Japan 1984–87	Men: 192 cases and 192 controls; women: 37 cases and 74 controls	Population-based study (in Japanese)
Kew *et al*. (1990) South Africa (years of study not specified)	Women: 46 cases and 92 controls	Hospital-based study Cases aged 19–54 years Controls with various medical disorders, excluding diseases related to contraceptive steroids, matched on sex, race, exact tribe, place of birth (rural/urban), migration, hospital and ward
Vall Mayans *et al*. (1990) Spain 1986–88	Men: 67 cases and 133 controls; women: 29 cases and 57 controls	Hospital-based study Cases histologically confirmed (77%) Controls were diagnosed with 76 different conditions (including other cancers, AIDS, liver disease, stomach ulcer, pancreatitis), all unrelated to study exposure, matched on age and sex
Olubuyide & Bamgboye (1990) Nigeria 1987–88	Men: 85 cases and 85 controls; women: 15 cases and 15 controls	Hospital-based study Cases of primary hepatocellular carcinoma, 100% histologically confirmed; aged 42–55 years Controls were patients admitted to orthopaedic clinic, matched for sex and age
Tsukuma *et al*. (1990) Japan 1983–87	Men: 192 cases and 192 controls; women: 37 cases and 74 controls	Hospital-based study Cases histologically confirmed (38%); aged < 74 years Controls from gastroenterology department, excluding liver disease and smoking- or alcohol-related diseases
Chen *et al*. (1991) China, Province of Taiwan 1985–87	Men: 200 cases and 200 controls	Population-based study Cases recruited at teaching hospitals Controls selected from household registration offices, with no history of hepatocellular carcinoma, matched on age, sex, ethnic group and area of residence
Choi & Kahyo (1991) Republic of Korea 1986–90	Men: 216 cases and 648 controls	Hospital-based study Cases; average age, 49 years Controls matched on age and date of admission to hospital
Lin *et al*. (1991) China 1984–86	Men: 200 cases and 200 controls	Hospital-based study in a polyclinic Cases with primary hepatoma; aged ≥ 20 years Controls were patients with conditions unrelated to smoking

Table 2.1.8.3 (contd)

Reference Country and years of study	No. of cases and controls	Source of cases and controls
Tzonou *et al*. (1991) Greece 1976–84	Men: 166 cases and 381 controls; women: 19 cases and 51 controls	Hospital-based study in nine major hospitals Cases histologically confirmed (58%) Controls were patients without cancer or liver disease
Yu, M.C. *et al*. (1991b) USA 1984–90	Men: 49 cases and 104 controls; women: 25 cases and 58 controls	Population-based study Cases histologically confirmed (100%); aged 18–74 years Controls from neighbourhood, matched by age, sex and race
Yu, M.W. *et al*. (1991) China, Province of Taiwan 1986–87	Men: 121 cases and 121 controls; women: 6 cases and 6 controls	Population-based study Cases histologically confirmed (80%); aged 38–62 years Health community controls from household registration offices, individually matched for sex, age, ethnicity and area of residence
Mohamed *et al*. (1992) South Africa (years of study not specified)	Men: 77 cases and 77 controls; women: 24 cases and 24 controls	Hospital-based study in a major teaching hospital Cases histologically confirmed (95%); aged 20–87 years Controls with conditions unrelated to alcohol consumption, matched for age, sex and ethnicity
Tanaka *et al*. (1992) Japan 1985–89	Men: 168 cases and 291 controls; women: 36 cases and 119 controls	Hospital-based study Cases histologically confirmed (40%); aged 40–69 years
Peters *et al*. (1994) Germany 1986–93	Men: 72 cases and 72 controls; women: 14 ccases, and 14 controls	Hospital-based study Cases histologically confirmed (74%) Controls with cirrhosis, matched on age and sex (mean age: men, 62.8 years; women 65.0 years)
Pyong *et al*. (1994) Japan 1989–92	Men: 68 cases and 109 controls; women: 22 cases and 140 controls	Study among Koreans Cases aged 40–89 years Controls matched by age
Siemiatycki *et al*. (1995) Canada 1979–86	Men: 48 cases and 2238 controls	Hospital-based study Cases histologically confirmed (100%); aged 35–70 years Controls were hospital controls with other cancers (1705) and population controls (533)
Tanaka *et al*. (1995) Japan 1983–89	Women: 120 cases and 257 controls	Hospital-based study Cases aged 35–74 years

Table 2.1.8.3 (contd)

Reference Country and years of study	No. of cases and controls	Source of cases and controls
Shin *et al*. (1996) Republic of Korea 1990–93	Men: 159 cases and 318 controls; women: 44 cases and 88 controls	Hospital-based study Cases histologically confirmed (53%) Controls were healthy patients from check-up at hospital (159 men, 44 women) and in-patients (159 men, 44 women), individually matched for sex and age
Liu *et al*. (1998) China 1989–91	Men and women: 28 187 cases and 87 315 controls	Population-based study in rural and urban areas of China Cases: 17 523 (13 478 men, 4045 women) from urban and 10 664 (7979 men, 2685 women) from rural areas Controls: 51 880 (30 709 men, 21 171 women) from urban and 35 435 (22 046 men, 13 389 women) from rural areas
Mukaiya *et al*. (1998) Japan 1991–93	Men: 104 cases and 104 controls	Hospital-based study Cases with chronic liver disease; aged 51–69 years Controls with chronic disease but no hepatocellular carcinoma, matched for age
Kuper *et al*. (2000) Greece 1995–98	Men: 283 cases and 298 controls; women: 50 cases and 62 controls	Hospital-based study Cases histologically confirmed (47%) Non-cancer controls with injuries, eye/ear/nose/throat conditions, unrelated to smoking, alcohol or coffee consumption
Lam *et al*. (2001) Hong Kong SAR 1998	Men: 15 296 cases and 3918 controls; women: 12 211 cases and 9136 controls	Population-based study among ethnic Chinese Cases from death registries; aged ≥ 35 years Controls were spouses or relatives; aged ≥ 60 years
Chen *et al*. (2003) China 1986–88	Men: 26 294 cases and 11 321 controls; women: 9642 cases and 5619 controls	Retrospective population-based study in 24 cities and 74 rural counties Cases aged ≥ 35 years Controls with cirrhosis

Table 2.1.8.4. Case–control studies on tobacco smoking and liver cancer

Reference Country and years of study	No. of cases and controls	Smoking categories	Relative risk (95% CI)		Adjustment/comments
Williams & Horm (1977) USA 1969–71	40/204	*Pack–years* < 20 20–39 ≥ 40	Men 0.6 2.3 3.1	Women 0.3 – 1.6	Adjusted for age and sex. Non-significant odds ratios
Trichopoulos *et al*. (1980) Greece 1976–77	19/107	*Cigarettes/day* 1–10 11–20 21–30 ≥ 31	 1.3 2.5† 3.7† 8.4†		Persistence of effect after adjusting for alcohol consumption †significantly higher than 1
Lam *et al*. (1982) Hong Kong 1977–80	265/530	≥ 20 cigarettes/day	3.3 (1.0–13.4)		Overall, no significant association between alcohol consumption and liver cancer. Peanuts not considered as important source of aflatoxin
Stemhagen *et al*. (1983) USA 1975–80	78/78	Ever-smoker	Men 0.7 (0.5–1.1)	Women 1.0 (0.6–1.7)	No difference when adjusted for alcohol consumption. No dose–response
Yu *et al*. (1983) USA 1975–79		Former smoker ≤ 20 cigarettes/day > 20 cigarettes/day	1.1 (0.3–4.0) 1.2 (0.6–2.5) 2.6 (1.0–6.7)		Adjusted for alcohol. Nonsmokers and former smokers combined. [The Working Group considered that because only 4 controls drank ≥ 80 g/day ethanol, there were insufficient data to study the effect of smoking among heavy drinkers. Among lighter drinkers, the effect does not reach significance, is lower in magnitude that the unstratified effect and may be influenced by residual confounding.]
Hardell *et al*. (1984) Sweden 1974–81	98/200				The small positive association between HCC and smoking disappeared after controlling for alcohol consumption. Strong association between smoking and cholangiocarcinoma

Table 2.1.8.4 (contd)

Reference Country and years of study	No. of cases and controls	Smoking categories	Relative risk (95% CI)	Adjustment/comments
Austin *et al*. (1986) USA	86/172	Ever-smoker	1.3 (NS)	Unadjusted
		Current smoker	1.5 (0.7–3.7)	
		Former smoker	0.9 (NS)	Adjusted for alcohol consumption
		Ever-smoker	1.0 (0.5–1.8)	
		Current smoker	1.1 (0.5–2.4)	
		Pack–years		Adjusted for HBsAg status and alcohol consumption
		1–24	0.9 (NS)	
		25–49	2.6 (NS)	
		≥ 50	0.8 (NS)	
La Vecchia *et al*. (1988) Italy 1984–87	151/1051	Former smoker	0.7 (0.4–1.0)	Adjusted for age, sex, geographical area, hepatitis, cirrhosis and alcohol consumption
		Current smoker	0.9 (0.6–1.5)	
Ferraroni *et al*. (1989) Italy 1983–88	151/1944	Former smoker	0.9	Adjusted for age, sex, alcohol, education, marital status and coffee consumption. No difference when adjusted for age and sex only
		Cigarettes/day		
		< 15	0.9 (NS)	
		15–24	0.7 (NS)	
		≥ 25	0.8 (NS)	
Hiyama *et al*. (1990) Japan 1984–87	229/266	*Pack–years*		Adjusted for HBsAg status, age, sex, alcohol consumption and family history of liver cancer
		< 20	1.0 (baseline)	
		20–39	1.9 (1.1–3.3)	
		40–59	2.0 (1.1–3.6)	
		≥ 60	1.0 (0.5–1.9)	
Kew *et al*. (1990) South Africa	46/92	Current smoker	2.2 (0.8–6.1)	
		Cigarettes/day		
		< 10	2.1 (0.8–7.1)	
		≥ 10	2.1 (0.4–10.7)	
Vall Mayans *et al*. (1990) Spain 1986–88	96/190	*Cigarettes/day*		χ^2 for trend = 0.01. No difference after adjustment for HBV or alcohol consumption
		1–20	1.4	
		> 20	1.1	

Table 2.1.8.4 (contd)

Reference Country and years of study	No. of cases and controls	Smoking categories	Relative risk (95% CI)			Adjustment/comments

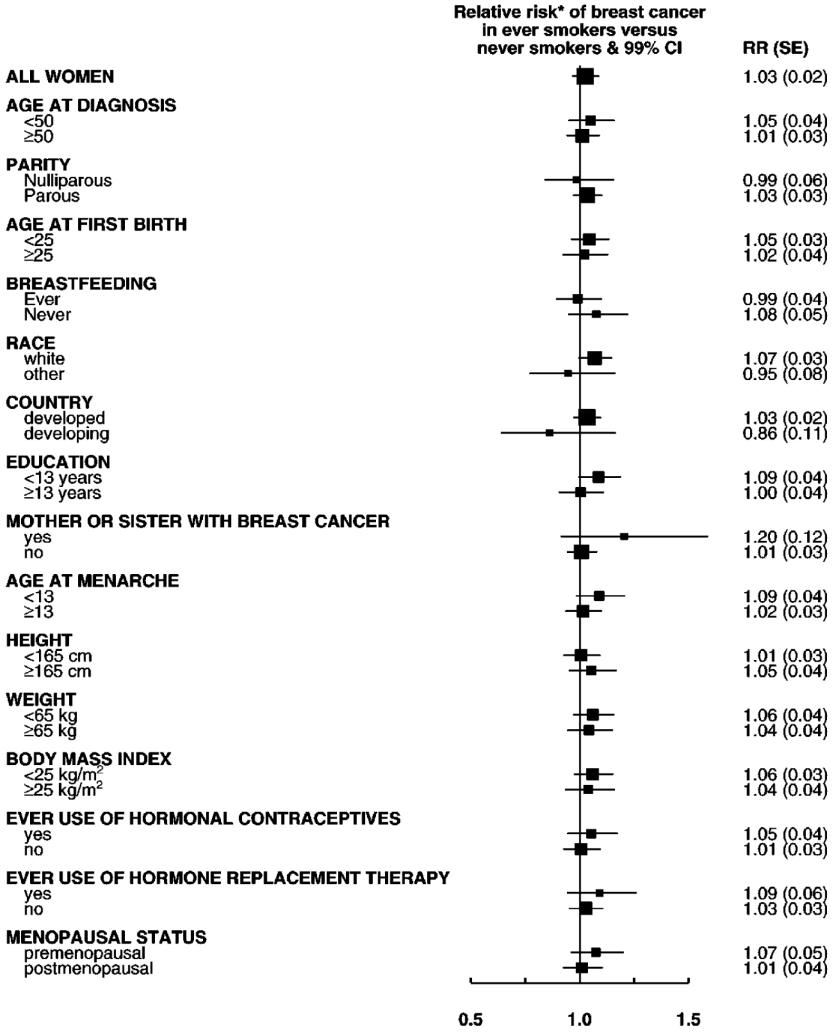
2.1.9 *Breast cancer*



Indirect evidence suggests that smoking could conceivably reduce the risk for breast cancer. It is recognized that high levels of estrogens, particularly of estrone and estradiol, contribute to an increased risk for breast cancer and smoking is thought to have an anti-estrogenic effect. The occurrence of menopause at an earlier age among smokers than among nonsmokers is also well established, and late age at menopause has been consistently related to an increased risk for breast cancer. Conversely, cigarette smoke contains carcinogens that could plausibly affect the breast (US Department of Health and Human Services, 2001). Research is in progress to determine whether some population groups are placed genetically at a higher risk for breast cancer associated with smoking (see Section 4).

A total of 18 case–control and cohort studies that addressed the association of tobacco smoke with breast cancer were reviewed by the IARC Working Group on Tobacco Smoke in 1986 (IARC, 1986). A suggestion of a decreased risk was noted, but the reported relative risks were distributed on both sides of unity, ranging from 0.7 to 1.4. While the epidemiological evidence was consistent with a decrease in risk, it could not be concluded that this had been demonstrated.

Thirty-six case–control studies and eight cohort studies as well as one large pooled analysis of data from 10 cohort and 29 case–control studies from the Collaborative Group on Hormonal Factors in Breast Cancer Study (2002) were examined to assess the relationship between smoking and breast cancer risk. The characteristics of the case–control studies and the principal findings relative to the association with smoking are shown in Tables 2.1.9.1 and 2.1.9.2, respectively. Descriptions of all cohort studies are presented at the beginning of Section 2 and in Tables 2.1 and 2.1.9.3, and the results for breast cancer are given in Table 2.1.9.4. The studies included in the analysis by the Oxford Collaboration and the results of the pooled analysis are shown in Table 2.1.9.5 and Figure 2.1.9.1 (Collaborative Group on Hormonal Factors in Breast Cancer, 2002).

The Oxford Collaborative Study included over 80% of the worldwide epidemiological data on breast cancer and on alcohol and tobacco consumption. Overall, the analyses for tobacco exposure included 58 515 women with invasive breast cancer and 95 067 controls from 53 studies, in which individual data on both alcohol and tobacco consumption had been recorded. Case–control and cohort studies were eligible for the collaborative analysis if they included at least 100 women with incident invasive breast cancer and had information on reproductive factors and on use of hormonal therapies. Cohort studies were included using a nested case–control design, in which four controls were selected at random, matched on follow-up to the age of the case at diagnosis and, where appropriate, matched on broad geographical region. Only active smoking was considered and no attention was given to the reported associations with passive exposures, nor was information obtained on the age when women started or stopped smoking, or the amount smoked. Relative risks of breast cancer were estimated, after stratifying by study, age, parity and, when indicated, women's age at time of first birth and their consumption of alcohol and tobacco.

Figure 2.1.9.1. Relative risk of breast cancer in relation to tobacco consumption in various subgroups of women

*Stratified by study, age, parity and age at first birth; analyses restricted to women who reported drinking no alcohol

RR, relative risk; SE, standard error

The collaborative analysis examined the relationship between smoking and breast cancer and found it to be substantially confounded by the effect of alcohol consumption. When the analyses were restricted to 22 255 cases and 40 832 controls reported to drink no alcohol, smoking was not associated with breast cancer (compared with never-smokers, the relative risk for ever-smokers was 1.03 (95% CI, 0.98–1.07) and the relative

risk for current smokers was 0.99 (95% CI, 0.92–1.05)). The findings for tobacco were not substantially confounded by any other factors, including family history of breast cancer, race, height, weight, age at menarche, menopause or use of hormonal preparations. Furthermore, the results for tobacco exposure and breast cancer did not vary substantially between studies, study designs or by the 15 personal characteristics of the women that were examined (Figure 2.1.9.1).

Among women who reported drinking alcohol, it was difficult to distinguish the independent effects of smoking (Collaborative Group on Hormonal Factors in Breast Cancer Study, 2002). For example, when ever-smokers were compared with never-smokers, the relative risk for breast cancer was 1.09 before stratification by alcohol consumption and was reduced to 1.05 after stratification. Moreover, the corresponding χ^2 (Chi squared) value declined by 75% from 23.4 to 6.4. Among ever-smokers in the 48 studies that gave information on current and past smoking, 54% were current smokers and 46% were past smokers. Compared with never-smokers, the relative risk for breast cancer was 0.99 for current smokers and 1.07 for past smokers.

Eleven studies, comprising a total of 4781 cases and 12 713 controls, contributed data on tobacco consumption for each woman, but no data on alcohol consumption, and were not included in the pooled analysis. The relative risk for breast cancer in ever-smokers compared with never-smokers in this subset of 11 studies was 1.05.

The results of some individual studies, particularly hospital-based case–control studies, must be interpreted cautiously (see General Remarks). Furthermore, questions have been raised about the results of some studies of women who participated in breast cancer screening programmes because the extent to which early detection methods are used may be correlated with smoking behaviour. Population-based case–control studies are generally believed to provide the most valid results.

Confounding

The most serious constraint in the interpretation of results from most studies that have attempted to evaluate the association of exposure to tobacco smoking with breast cancer risk results from the strong correlation of alcohol consumption, an established risk factor for breast cancer, with smoking behaviour, and the imprecision in estimates of the amount of alcohol consumed, especially those based on self-reports. The Oxford Collaborative analysis addressed this constraint by limiting the analysis of the association of breast cancer with tobacco consumption to study subjects who reported never drinking alcohol.

Table 2.1.9.1. Case–control studies on tobacco smoking and breast cancer: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Rosenberg *et al.* (1984) USA and Canada 1976–82	2160 cases diagnosed in the last 6 months, and 717 controls, aged 30–69 years	Case–control surveillance programme in medical centers Controls admitted for cancers unrelated to smoking and to age at menopause (e.g. endometrium)
Smith *et al.* (1984) USA 1980–82	429 cases and 612 controls, aged 20–54 years, matched by age	National population-based study conducted by the CDC Cases histologically confirmed Controls with no previous cancer of the breast, endometrium and ovary 95% response rate for both cases and controls
Schechter *et al.* (1985) Canada Up to 1982	123 cases and 369 controls, aged 40–59 years, matched by age group and screening center	Multicenter randomized controlled trial (National Breast Screening Study) Criteria for eligibility: no history of breast cancer, not pregnant, no mammogram in the last 12 months Cases histologically confirmed Controls selected among women allocated to mammography
Brinton *et al.* (1986) USA 1973–1980	1547 cases and 1930 controls, matched by center, ethnicity, age group, time of entry and length of participation in the programme	Multicenter screening programme (Breast Cancer Detection Demonstration Project) Controls selected among women not having received a biopsy 74% response rate for cases and 90% for controls
McTiernan *et al.* (1986) USA 1981–82	329 cases and 332 controls, aged 25–54 years, matched by age	Population-based study (CDC Cancer and Steroid Hormone Study) Controls selected among women of the county by Waxberg's random-digit dialling method 79% response rate for cases and 87% for controls
O'Connell *et al.* (1987) USA 1977–78	276 cases and 1519 controls, aged 30 years or older	Population-based study Cases (patients admitted to North Carolina hospitals) histologically confirmed Controls selected from a stratified sample of households within the catchment area of the hospitals where the cases were identified 93% response rate for cases and 88% for controls
Stockwell & Lyman (1987) USA 1981	5246 cases and 3921 controls	Population-based study Controls were residents of the state of Florida diagnosed with colon or rectal cancers, or melanoma, or endocrine neoplasms

Table 2.1.9.1 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Stanford *et al.* (1987) USA 1980–82	458 cases and 568 controls, aged 20–54 years, matched by age group	Population-based study (Cancer and Steroid Hormone Study) Cases histologically confirmed Controls selected by random-digit dialling in the same geographical area as cases 85% response rate for cases and 90% for controls
Adami *et al.* (1988) Sweden & Norway 1984–85	422 cases and 527 controls, aged less than 45 years (Sweden) and less than 40 years (Norway), matched by age (Sweden) and day and year of birth (Norway)	Population-based study Cases histologically confirmed Controls with no history of cancer selected from population registers 89% response rate for cases and 81% for controls
Brownson *et al.* (1988) USA 1979–86	456 cases (88% prevalent) and 1693 controls, matched by age group and county of residence	Screening programme (Columbia Women's Cancer Control Programme) Cases histologically confirmed Controls randomly selected from participants to the programme Near 100% response rates for cases [controls not specified]
Cooper *et al.* (1989); Rohan & Baron (1989) Australia 1982–84	451 case–control pairs, aged 20–74 years, matched by age	Population-based study Cases histologically confirmed Controls randomly selected from the electoral roll of the Adelaide area 81% response rate for cases; 648 controls approached to achieve a final number of 451
Kato *et al.* (1989) Japan 1980–86	1740 cases and 8920 controls, aged 20 years and older	No detailed information on study design Cases selected from cancer registry Controls with cancers of known primary site, unrelated to alcohol
Meara *et al.* (1989) UK 1980–84	998 cases (hospital study) and 118 cases (screening), aged 25–59 years (hospital study) and 45–69 years (screening), and 998 controls matched by age group	Hospital-based study and mammographic screening Controls selected among patients from the same hospital with conditions unrelated to breast cancer or contraceptive practice, and among normal screenees Near 100% response rates in both studies for cases and controls
Schechter *et al.* (1989) Canada 1982–85 (prevalence study) 1981–87 (incidence study)	254 prevalent cases and 762 controls; 317 incident cases and 951 controls; age 40–59 years	Multicentre randomized controlled trial (National Breast Screening Study) Criteria for eligibility: no history of breast cancer, not pregnant, no mammogram in the last 12 months Cases histologically confirmed Controls selected among women allocated to mammography

Table 2.1.9.1 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Chu *et al.* (1990) USA 1980–82	4720 cases and 4682 controls, aged 20–54 years, matched by age group and geographic location	Population-based study (CDC Cancer and Steroid Hormone Study) Controls selected among women of the county by Waxberg's random-digit dialling method 80% response rate for cases and 88% for controls
Ewertz (1990) Denmark 1983–84	1480 cases and 1332 controls, aged less than 70 years, matched by age	Population-based study Controls with no history of breast cancer identified from the Central Population Register 87% response rate for cases and 78% for controls
Palmer *et al.* (1991) Canada and USA 1982–86	**Canada** 607 cases and 1214 controls under age 70, matched by age and neighbourhood **USA** 1955 cases and 805 controls, aged 30–69 years	**Population-based study in Canada** English-speaking women with no history of cancer were eligible Controls identified from tax assessment rolls 76% response rate for cases and 65% for controls **Hospital-based study in the USA** Controls admitted to hospital for cancers unrelated to smoking (colon, rectum, melanoma, lymphoma, bone or connective tissues) diagnosed in the last 6 months and having no previous history of cancer
Field *et al.* (1992) USA 1982–84	1617 case–control pairs aged 20–79 years, matched by year of birth and county of residence	Population-based study Cases histologically confirmed Controls selected using state driver's licence files 79% response for cases and 72% for controls
Smith *et al.* (1994) UK 1984–88	755 case–control pairs (cases under age 36 at date of diagnosis), matched by date of birth (within 6 months)	Population-based study Cases diagnosed in 1982–85 Controls randomly chosen from each case's general practioner list of patients 72% response rate for cases and 89% for controls
Ranstam & Olsson (1995) Sweden 1981–84	177 premenopausal and 216 postmenopausal cases; 195 premenopausal and 254 postmenopausal controls	Population-based study Controls randomly selected from the national population register 90% response rate for cases and 80% for controls
Baron *et al.* (1996) USA 1988–91	6888 cases and 9529 controls, aged less than 75 years	Population-based study Controls randomly selected from state driver's licence lists (aged < 65 years) and among women enrolled in Medicare in the participating state (aged 65–74 years) 81% response rate for cases and 84% for controls

Table 2.1.9.1 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Braga *et al.* (1996) Italy 1991–94	2569 cases and 2588 controls, aged 23–74 years (cases) and 20–74 years (controls)	Multicentre hospital-based study in six Italian areas Cases histologically confirmed Controls with no history of cancer admitted to hospitals for acute, non-neoplastic, non-hormonal, non-gynaecological diseases, smoking-related conditions excluded > 96% response rate for both cases and controls
Haile *et al.* (1996) Canada and USA 1970–89 (Los Angeles) 1975–89 (Quebec) 1935–89 (Connecticut)	144 cases and 232 controls, aged less than 50 years	Population-based study Cases histologically confirmed Controls were cases' sister(s) who were alive in 1989 (≥ 1 sister by case) and unaffected by breast cancer ~70% response rate for cases and controls combined
Morabia *et al.* (1996) Switzerland 1992–93	244 cases and 1032 controls, aged less than 75 years	Population-based study Cases histologically confirmed Controls were residents of Geneva, aged 30–74 years 71% response rate for cases and 70% for controls
Yoo *et al.* (1997) Japan 1988–92	1154 cases and 21714 controls, aged 25 years or older	Hospital-based study Cases histologically confirmed Controls were cancer-free hospital patients with no history of cancer
Brunet *et al.* (1998) Canada and USA [years of study not specified]	186 case–control pairs, mean age 49.7 years, matched by age and mutation in the same BRCA gene	Study involving genetic counselling centers Cases with past diagnosis of invasive breast cancer and no previous diagnosis of ovarian cancer Controls: women with no history of breast cancer, carriers of BRCA1 or BRCA2 mutations
Ghadirian *et al.* (1998) Canada 1989–93	414 cases and 429 controls, aged 35–79 years, matched by age and residence	Population-based study in the Francophone Community of greater Montreal Cases histologically confirmed Controls selected by random-digit dialling 77% response rate for cases
Gammon *et al.* (1998) USA 1990–92	2199 cases and 2009 controls, under 45 years, matched by age group and geographic area	Population-based study (Women's Interview Study of Health) Controls identified by random-digit dialling 86% response rate for cases and 71% for controls

Table 2.1.9.1 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Millikan *et al.* (1998) USA 1993–96	498 cases and 473 controls	Population-based study (Carolina Breast Cancer Study) Cases histologically confirmed Controls selected from lists from the North Carolina Division of Motor Vehicles (aged 20–64 years) and the Health Care Financing Administration (aged 65–74 years) Randomized recruitment among cases and controls to have equivalent numbers of white and African Americans as well as < 50 and ≥ 50 years of age 77% response rate for cases and 68% for controls
Gammon *et al.* (1999) USA 1990–92	378 cases (168 TP53-positive and 210 TP53-negative) and 462 controls, under the age of 45 years, matched by age group	Multicentre population-based study Cases histologically confirmed Controls identified by random-digit dialling 83% response rate for cases and 77% for controls
Lash & Aschengrau (1999) USA 1983–86	265 cases and 763 controls	Population-based study Controls identified by random-digit dialling (aged < 65 years); from the Health Care Financing Administration lists (aged ≥ 65 years); and from the Massachusets Department of Vital Statistics lists (deceased subjects 1983–89) 79% response rate for cases and 77% for controls
Johnson *et al.* (2000) Canada 1994–97	2617 cases (805 premenopausal and 1512 postmenopausal) and 2438 controls, aged 25–74 years	Population-based study Cases histologically confirmed Controls randomly selected from provincial health insurance plans; or random-digit dialling; or population research laboratory 77% response rate for cases and 71% for controls
Marcus *et al.* (2000) USA 1993–96	864 cases and 790 controls, aged 20–74 years	Population-based study (Carolina Breast Cancer Study) see Millikan *et al.* (1998) 77% response rate for cases and 68% for controls
Innes & Byers (2001) USA 1989–95	319 cases and 768 controls, aged 26–45 years	Record-linkage study Cases had completed a first pregnancy after 1987 Primiparous controls who resided and delivered in the same county as the case and were not subsequently diagnosed with breast or endometrial cancer were identified from infants' birth records
Kropp & Chang-Claude (2002) Germany 1992–95 and 1999–2000	468 mostly premenopausal cases and 1093 controls, matched by age and region	Population-based study Cases histologically confirmed Controls selected from regional population registries 70% response rate for cases and 61% for controls

	≥ 20	1.04 (0.6–1.9)	
	High exposure to active and passive smoking	1.8 (1.2–2.7)	

Table 2.1.9.3. Additional cohort studies on tobacco smoking and breast cancer: main characteristics of study design

Reference	Cohort sample	Cases/deaths identification	Comments
Bennicke *et al.* (1995) Denmark 1989–91	All women referred for mammography to the radiology department of a large public hospital, aged 15–92 years	Diagnosis of breast cancer from mammography and clinical examination	Former smokers were included in the 'smoker' category.
van den Brandt *et al.* (1995) Netherlands 1986–89	62 573 women aged 55–69 years (all menopausal); cases taken from entire cohort; controls taken from a subcohort of 1716 randomly sampled subjects	Incident cases	Case–control approach without matching; controls excluded cancers other than skin cancer.
Thomas *et al.* (1997) China 1989–91	267 040 women working in the Shanghai Textile Industry Bureau, recruited for a randomized trial of breast self-examination, born 1925–58	Cases identified primarily by trial workers during visits to the factory's medical clinic	
Million Women Study Group (1999) UK 1996–99	121 000 women aged 50–64 years recruited nationwide when invited for routine breast screening; response rate, 71%	Cases identified by linkage with screening centres	Study designed primarily to investigate use of hormone replacement therapy and risk of breast cancer

Table 2.1.9.4. Cohort studies on tobacco smoking and breast cancer

Reference Country and years of study	Name of study No. of subjects	No. of cases	Smoking categories	Relative risk (95% CI)	Comments
Hiatt & Fireman (1986) (USA) 1964–80	Kaiser Permanente Medical Care Program Study 84 172 women	1363 cases		Incidence rate	Annual age-adjusted rate per 1000 person–years Relative risks are comparable for pre- and post-menopausal women.
			Current smoker	1.4	
			Former smoker	1.6	
			Nonsmoker	1.3	
				RR	
			Former smoker	1.2 (1.0–1.4)	
			Current smoker		
			Light	1.0 (0.8–1.1)	
			Moderate	1.2 (1.1–1.4)	
			Heavy	1.2 (0.9–1.6)	
Vatten & Kvinnsland (1990) (Norway) 1974–88	Norwegian Screening Study 24 329 women	242 cases		Incidence rate ratio	Adjusted for age at entry, age at diagnosis, occupation and body-mass index
			Cigarettes/day		
			1–9	1.2 (0.9–1.7)	
			≥ 10	0.9 (0.6–1.2)	
			Cases < 51 years		
			1–9 cigarettes/day	1.1 (0.7–1.7)	
			≥ 10 cigarettes/day	0.8 (0.5–1.2)	
			Cases ≥ 51 years		
			1–9 cigarettes/day	1.0 (0.6–1.7)	
			≥ 10 cigarettes/day	0.8 (0.5–1.3)	
Tverdal *et al.* (1993) (Norway) 1972–88	Norwegian Screening Study 24 535 women	70 deaths		Mortality rate	Annual mortality rate per 100 000 women Adjusted for age and area
			Never-smoker	19.9	
			Former smoker	18.8	
			Current smoker	28.0	
			1–9 cigarettes/day	29.4	
			≥ 10 cigarettes/day	24.8	

Table 2.1.9.4 (contd)

Reference Country and years of study	Name of study No. of subjects	No. of cases	Smoking categories	Relative risk (95% CI)	Comments
Calle *et al.* (1994) (USA) 1982–88	CPS II 604 412 women	880 deaths		Rate ratio	Adjusted for family history of breast cancer, body-mass index, education, alcohol consumption, breast cysts, age at first birth, age at menarche and age at menopause
			Former smoker	0.9 (0.7–1.03)	
			Ever-smoker	1.0 (0.9–1.19)	
			Current smoker	1.3 (1.1–1.5)

2.1.10 *Cervical cancer*

A positive correlation between the incidence of cervical cancer and other cancers known to be related to cigarette smoking across populations prompted the hypothesis that smoking may affect the risk for cervical cancer (Winkelstein, 1977). Excess risk for cervical cancer among smokers has been observed in a number of case–control studies. However, the extent to which the relationship between smoking and cervical cancer reflected a causal association independent of infection with human papillomavirus (HPV) remained a cause for concern. It was believed that the association of smoking with cervical cancer may be causal, may reflect confounding or risk modification among women with HPV infection, or may even reflect causality via an effect of smoking on risk for HPV infection.

In the earlier IARC evaluation of tobacco smoking (IARC, 1986), the Working Group noted that the effect of smoking is confounded by sexual behaviour variables, but the data were not adequate to remove the confounding effect, and that a reasonable conclusion from the available studies of invasive cervical cancer is that the results, although they indicate a positive effect of smoking, are compatible with the residual effects of variables that play a fundamental role in the etiology of cervical cancer (IARC, 1986). At the time of the 1986 review, a specific causal agent had not been identified, but was proposed to be an infective agent related to sexual activity.

Infection with HPV is now recognized as the main etiological factor for invasive and pre-invasive cervical neoplasia worldwide (IARC, 1995). Persistent infection with certain high-risk types of HPV, i.e. HPV 16, 18, 31, 33, 45, 52 and 58, is considered to be a necessary cause of invasive cervical cancer (IARC, 1995). Using the most sensitive polymerase chain reaction-based assays, HPV DNA has been found in 99.7% of approximately 1000 cervical cancer specimens from 22 countries worldwide (Walboomers *et al*., 1995) and odds ratios close to 100.0 for high-risk HPV types have been obtained in numerous case–control studies (IARC, 1995). Co-factors acting in conjunction with HPV, however, could be important for the development of cervical neoplasia or invasive cervical cancer. In order to investigate the possibility that smoking acts as a co-factor in conjunction with HPV in the production of cervical cancer, it is important to account accurately for the presence of HPV infection. Less than 10% of invasive cervical cancers have a histology of adenocarcinoma or adenosquamous-cell carcinoma, whereas squamous-cell types account for over 90%. This review, therefore, focuses on squamous-cell invasive cervical cancer; data for adenocarcinoma and adenosquamous-cell carcinoma are used for comparative purposes.

Ten cohort studies and 31 case–control studies have provided information about the association of cigarette smoking with the incidence of invasive squamous-cell cervical cancer and six cohort studies and 22 case–control studies evaluated the association of tobacco smoking with preinvasive neoplasms (cervical intraepithelial neoplasia (CIN) and cervical cancer *in situ*). In addition, seven case–control studies evaluated the association of adenocarcinoma and adenosquamous-cell carcinoma with tobacco smoking. The charac-

teristics of and the main results from these studies are shown in Tables 2.1.10.1–2.1.10.12 (see Tables 2.1, 2.1.10.1 and 2.1.10.2 for details on study design). These tables are organized by type of disease and level of control for HPV status. HPV status was controlled for in data analysis or by restriction of analyses to HPV-positive cases and controls. Twenty-eight of the earliest case–control studies of invasive squamous-cell cervical cancer and 25 case–control studies and one cohort study on the association of CIN with smoking did not control for HPV status (Tables 2.1.10.3–2.1.10.6). Four case–control studies of invasive cervical cancer (Peng *et al*., 1991; Chichareon *et al*., 1998; Ngelangel *et al*., 1998; Lacey *et al*., 2001), and one cohort study (Moscicki *et al*., 2001) and four case–control studies (Muñoz et *al*., 1993; Ho *et al*., 1998; Yoshikawa *et al*., 1999; Kjellberg *et al*., 2000) of CIN controlled for HPV status by adjustment in the data analysis (Tables 2.1.10.7–2.1.10.9). More recent studies controlled for HPV status by restricting analyses to HPV-positive cases and controls. The results of eight case–control studies of invasive squamous-cell cervical cancer (Bosch *et al*., 1992; Eluf-Neto *et al*., 1994; Chaouki *et al*., 1998; Chichareon *et al*., 1998; Ngelangel *et al*., 1998; Rolon *et al*., 2000; Hildesheim *et al*., 2001; Santos et al., 2001) and two case–control studies of CIN (Olsen *et al*., 1998; Deacon *et al*., 2000) are shown in Tables 2.1.10.10 and 2.1.10.11. In addition, the results of six case–control studies that examined the association of adenocarcinoma and adenosquamous-cell carcinoma with tobacco (Brinton *et al*., 1986; Ursin *et al*., 1996; Chichareon *et al*., 1998; Ngelangel *et al*., 1998; Lacey *et al*., 2001; Madeleine *at al*., 2001) are shown in Table 2.1.10.12.

In these studies, the association between cervical cancer and smoking was not eliminated, even though most studies controlled for several well-established risk factors for cervical cancer, including early age at first sexual intercourse, history of multiple sexual partners, low socioeconomic status and, in the recent studies, infection with HPV. Most studies in which the risk values were not adjusted for HPV infection reported a relative risk of approximately 2.0 among smokers compared with nonsmokers. Women who had smoked for a long period or at high intensity generally had the highest risk. In several studies, the relationship was restricted to, or strongest among, recent or current smokers. Some studies reported that the highest risk occurred among women who had started smoking late in life, but other studies reported the opposite effect, namely a higher risk among women who had begun smoking at young ages (La Vecchia *et al*., 1986; Daling *et al*., 1996). In the studies that assessed the association of adenocarcinoma and adenosquamous-cell carcinoma of the cervix with smoking, there was generally no significant association noted for adenocarcinoma or adenosquamous-cell carcinoma of the cervix.

Recent studies have chosen to control for the confounding effect of HPV as indicated by either the presence of HPV DNA in cervical cells or of anti-HPV serum antibodies in multivariate analytical models, or have restricted their analyses to HPV-positive cases and controls.

Several of the studies reviewed, including the IARC multicentre pooled analysis of 10 studies of invasive cervical cancer (Plummer *et al*., 2003), examined tobacco smoking as a co-factor to HPV infection by restricting the analysis to HPV DNA-positive study participants, a decision justified by the necessity of HPV infection in the causation of invasive

cervical cancer (Hildesheim *et al*., 2001). The results from these analyses showed no significant alteration in risk whether or not the study participants were HPV DNA-positive. Similarly, other studies that investigated the effect of smoking among HPV-seropositive cases and controls found that the effect of smoking remained, and there was evidence of a dose–response relationship. The association between smoking and invasive cervical cancer was not notably reduced by adjustment for a woman's reported number of lifetime sexual partners, age at first sexual intercourse or other potential confounding factors (Hildesheim *et al*., 2001). Thus, the effect of smoking is unlikely to represent a surrogate marker for a woman's sexual behaviour.

Cervical infection with HPV has not been found to be consistently associated with tobacco smoking in cross-sectional studies (Plummer *et al*., 2003). Therefore, it would appear that HPV is not a significant confounding factor for the association between cervical cancer and smoking.

The detection of HPV DNA has a different meaning for cases and control participants. In cases, HPV DNA-positivity indicates a persistent HPV infection, whereas some control participants may have a transient HPV infection or have been infected with HPV in the past and have cleared their infection. Given that the ascertainment of overall HPV prevalence and the relative distribution of HPV types may differ according to status as case or control, careful account of the type of HPV infection (such as high-risk versus low-risk types) must be taken.

Persistent cervical infections with HPV have been shown to increase the risk of progression of cervical dysplasia (Remmink *et al*., 1995). As there is currently no reliable marker of persistent HPV infection, case–control studies based on a cross-sectional measurement of HPV-DNA by polymerase chain reaction assays cannot distinguish between transient and persistent infections (Franco *et al*., 1999). To improve the likelihood that the effect being examined is that of smoking among persistent HPV carriers, analyses by some investigators were limited to women who were HPV-DNA-positive for high-risk HPV types that are more likely to represent persistent infections than non-oncogenic types (Franco *et al*., 2001). Increased rate ratios for smoking were observed in one study that conducted these analyses (Hildesheim *et al*., 2001).

Table 2.1.10.1. Case–control studies on tobacco smoking and cervical cancer: main characteristics of study design

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Tokuhata (1967) USA Not specified	266 cases and 1463 controls	Population-based study Cases and controls selected from county death registry among women ever married and having died after 1950 Controls: breast cancer, heart and other non-cancerous diseases City and county directories used to identify next-of-kin Response rates ≥ 95% for both cases and controls
Thomas (1972) USA 1965–69	324 cases, aged 15–50 years, and 302 controls	Hospital-based study Cases histologically confirmed Controls: 1:30 probability sample of the 15–50-year-old white female residents of the county having at least one smear on record from 1965–69
Williams & Horm (1977); Williams *et al.* (1977) USA, Not specified	266 cases and 3198 controls	Cases and controls from the Third National Cancer Survey (57% of those selected for interview). Controls included all cases of cancer of other sites except lung, larynx, oral cavity, oesophagus and bladder [no matching].
Harris *et al.* (1980) UK 1974–79	237 cases and 422 controls	Hospital-based study at two Oxford hospitals Controls attended gynaecological clinics during a similar period to the cases; a few additional controls had received an initial cervical smear at the Abingdon Health Centre; excluding controls who had had hysterectomy or with history of cancer or severe mental illness
Stellman *et al.* (1980) USA 1974–77	332 cases and 1725 controls, aged 20–89 years	Hospital-based study Cases histologically confirmed Controls hospitalized for non-neoplastic diseases Analysis restricted to ever-married women, excluding former smokers
Wigle *et al.* (1980) Canada 1971–73	676 cases (168 ICC and 508 CIS) and 3644 controls, aged 20–64 years	Hospital-based study Cases histologically confirmed Controls comprised women with primary cancers unrelated to smoking and with benign breast neoplasms.

Table 2.1.10.1 (contd)

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Buckley *et al.* (1981) UK 1974–79	237 cases and 422 controls, aged 32–70 years	Hospital-based study Cases histologically confirmed Controls were women attending gynaecological care units for cervical smears, excluding those who had had hysterectomy or abnormal smear.
Clarke *et al.* (1982) Canada 1973–76	178 cases, aged 20–69 years, and 865 controls matched on age	Population-based study among residents of York County, Toronto Cases histologically confirmed Controls selected from the same neighbourhood as the cases
Berggren & Sjöstedt (1983) Sweden 1974–78	609 cases and 6090 controls, aged 15–65 years	Population-based study Cases histologically confirmed Controls were residents of the same geographical area as the cases, born on the same day as the cases or soon thereafter, excluding women with previous history of cervical cancer or abnormal smear.
Lyon *et al.* (1983) USA 1975–77	217 cases and 243 controls	Population-based study among residents of the metropolitan area of Utah Cases histologically confirmed Controls selected by random-digit dialling to give an age- and geographically stratified sample of the same population
Marshall *et al.* (1983) USA 1957–65	513 cases and 490 controls matched on age	Hospital-based study Cases histologically confirmed Controls selected from a pool of patients with non-neoplastic diseases of sites other than the genitourinary and gastrointestinal tracts
Trevathan *et al.* (1983) USA 1980–81	374 (194 mild/moderate dysplasia, 81 severe dysplasia, 99 *in situ*) cases, aged 17–55 years, and 288 controls	Hospital-based study Cases histologically confirmed Controls with negative Pap smears and no prior cervical biopsy selected from women attending the Family Planning Clinic
Martin & Hill (1984) South Africa 1950–74	257 case–control pairs, matched on age, number of children and home area (age range, 22–89 years)	Hospital- and population-based study [% of histologically confirmed cases not indicated Controls free of cancer (no information on selection of controls)]

Table 2.1.10.1 (contd)

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Clarke *et al.* (1985) Canada 1979–81	250 cases aged 20–59 years, and 500 controls matched on age, neighbourhood and type of dwelling	Population-based study among residents of the Toronto area Cases histologically confirmed Controls with intact uterus and no history of cancer identified from municipal records
Mayberry (1985) USA Not specified	210 cases and 317 controls (data from previous study on HSV-2 and *Chlamydiae trachomatis* and cervical cancer)	Hospital-based study Cases histologically confirmed Controls free of cervical abnormalities who attended gynaecological and birth control clinics at the University of California Medical Center in San Francisco
Baron *et al.* (1986) USA 1957–75	1174 cases aged 40–89 years, and 2128 controls	Hospital-based study Controls in the same age range, admitted during the same time period, with no diagnosis of cancer during hospitalization and no smoking-associated respiratory or circulatory diseases
Brinton *et al.* (1986) USA 1982–84	480 cases (incl. 63 adenocarcinoma or adenosquamous carcinoma), aged 20–74 years, and 797 controls, matched on telephone exchange, race and age	Population-based study in five cities reporting to the Comprehensive Cancer Patient Data System – Birmingham (AL), Chicago, Denver, Miami and Philadelphia Controls obtained by random-digit dialling
La Vecchia *et al.* (1986) Italy 1981–84	155 ICC (aged 22–74 years) and 169 controls 89 CIN (aged 19–71 years) and 118 controls Cases and controls matched on age	Hospital-based study in six wards of three major university hospitals in Milan Cases histologically confirmed Controls for ICC admitted for acute conditions other than malignant, hormonal or gynaecological disorders; controls for CIN were women with normal cervical smear from the same screening clinics
Peters *et al.* (1986) USA 1980–81	200 cases and 200 controls, matched on race, date of birth and language of interview	Population-based study Cases histologically confirmed Controls identified by an algorithm defining a sequence of houses in the neighbourhood where the case lived at diagnosis

Table 2.1.10.1 (contd)

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Celentano *et al.* (1987) USA 1982–85	153 cases and 153 controls, matched on age, race, residence within neighbourhood, intact uterus	Population-based study among Maryland residents referred to the Division of Gynecologic Oncology at John's Hopkins Hospital, MD Cases histologically confirmed Controls without history of cervical cancer obtained by case nomination (97), canvassing neighbourhood (49) and from senior citizen centres (7)
Ebeling *et al.* (1987) Germany 1983–85	129 cases and 275 controls	Hospital-based study Cases histologically confirmed Controls identified at the Skin Disease Hospital and at the Orthopaedic University Hospital, which drew patients from the same area as the gynaecological hospitals; women with venereal diseases, prior CIN and prior hysterectomy excluded
Nischan *et al.* (1988) Germany 1983–85	225 cases, aged 64 years or younger, and 435 controls, matched on age	Hospital-based study in four hospitals in Leipzig Cases histologically confirmed Controls, excluding women with venereal diseases, prior CIN and prior hysterectomy, identified at the Skin Disease Hospital and at the Orthopaedic University Hospital
Brock *et al.* (1989) Australia 1980–83	116 cases, aged 18–65 years, and 193 controls, matched on age	Population-based study within the Sydney metropolitan area Cases histologically confirmed Controls selected from the files of the family doctor or from a university-affiliated general practitioner from the same residential area
Herrero *et al.* (1989) Colombia, Costa Rica, Mexico, Panama 1986–87	667 cases, aged less than 70 years, and 1430 controls	Hospital- and community-based study Cases histologically confirmed Hospital controls selected from primary referral hospitals (Costa Rica and Panama); from eight tertiary level government hospitals (Bogota); and from three Social Security hospitals (Mexico City); all hospitals located in the area of residence of the cases Community controls randomly selected from current census listings of the corresponding case's county of residence
Slattery *et al.* (1989) USA 1984–87	266 cases, aged 20–59 years, and 408 controls, matched on age and residence	Population-based study in the urban areas of Utah Cases histologically confirmed Controls selected using random-digit dialling; women who had had a hysterectomy before 1984 excluded

Table 2.1.10.1 (contd)

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Licciardone *et al.* (1989) USA 1984–86	331 cases and 993 controls matched on age	Cancer registry-based study Cases histologically confirmed Controls randomly selected from other patients reported to the Missouri Cancer Registry during the same time period after exclusion of cancers at smoking- or alcohol-related sites
Cuzick *et al.* (1990) UK 1984–88	497 cases (110 CIN I, 103 CIN II, 284 CIN III), aged 18–39 years, and 833 controls	Population-based study in the London area Cases histologically confirmed Controls: randomly selected patients of local general practitioners or family planning clinics in the catchment area from which cases were drawn
Jones *et al.* (1990) USA 1982–84	293 cases, aged 20–74 years, and 801 controls, matched on race and age	Population-based study in Birmingham, Chicago, Denver, Miami and Philadelphia Controls ascertained using random-digit dialling
Peng *et al.* (1991) China 1987–88	101 cases, and 146 controls selected to provide a similar distribution of age and occupation	Hospital-based study in Chengdu, Sichuan Cases histologically confirmed Controls: patients admitted to the gynaecological ward/clinic, excluding women with abnormal cervical cytology, prior hysterectomy, or vulvar cancer
Bosch *et al.* (1992, 1993); Muñoz *et al.* (1992, 1993) Spain, 1985–87 Colombia, 1985–88	525 cases, aged less than 70 years, and 512 controls, matched on age, place of recruitment and date of cytology	Population-based study in nine provinces in Spain and in one city in Colombia (Cali) Cases histologically confirmed Controls with normal cytology or with inflammation only (Pap smear grades I and II) randomly selected from the population that generated the cases; included only those women who had not had previous treatment for cervical cancer or a hysterectomy.
Coker *et al.* (1992) USA 1987–88	103 cases (40 CIN II and 63 CIN III), aged 18–45 years, and 268 controls	Hospital-based study in North Carolina Cases histologically confirmed Controls: University of North Carolina Hospital Family Practice Center patients receiving routine Pap smear and having normal cervical cytology
Parazzini *et al.* (1992) Italy 1981–90	366 cases (58 CIN I, 70 CIN II, 238 CIN III), aged 18–59 years, and 323 controls with comparable age distribution	Hospital-based study in Milan Cases histologically confirmed Controls: women with normal cervical smears interviewed at the same screening clinic where cases were identified

Table 2.1.10.1 (contd)

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Becker *et al.* (1994) USA 1989–92	201 cases, aged 18–40 years, and 307 controls	Hospital-based study in the Albuquerque metropolitan area Cases histologically confirmed Frequency-matched controls, with normal cervical cytology, selected from the same clinics to which cases were referred for colposcopic examination
Eluf-Neto *et al.* (1994) Brazil 1990–91	199 cases, aged 25–79 years, and 225 controls, matched on age	Hospital-based study in seven hospitals in São Paulo City Cases histologically confirmed Controls selected from the same hospitals, excluding women with known risk factors for cervical neoplasia, treated for gynaecological conditions, or having had hysterectomy or conization
de Vet *et al.* (1994) Netherlands Not specified	257 cases, aged 20–65 years, and 705 controls, matched on age	Multicentre randomized clinical trial Cases histologically confirmed Controls: random sample of the female population of three cities and one neighbouring village for each city; subjects with recent pregnancy, diabetes mellitus or severe bowel or liver dysfunction excluded
Lazcano-Ponce *et al.* (1995) Mexico 1990–92	397 ICC, 233 CIN III and 1005 controls	Population-based study Cases histologically confirmed Controls: random sample from houses in the Mexico City metropolitan area
Stone *et al.* (1995) Costa Rica 1982–85	564 cases (415 carcinoma *in situ*, 149 invasive cancer), aged 25–59 years, and 764 controls, matched on age	Population-based study Cases histologically confirmed, identified through the Costa Rican National Tumor Registry Controls selected from a national multistage probability household survey
Cuzick *et al.* (1996) UK 1985–91	121 cases, aged 40 years or younger, and 241 controls, matched on age	Population-based study Cases histologically confirmed Controls drawn from the same general practitioner as the cases
Daling *et al.* (1996) USA 1986–92	314 cases, aged 18–74 years, and 672 controls, matched on age	Population-based study Cases histologically confirmed Controls identified using random-digit dialling

Table 2.1.10.1 (contd)

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Hirose *et al.* (1996) Japan 1988–93	556 cases, aged 18 years or older, and 26 751 controls	Hospital-based study Cases histologically confirmed Controls: first-visit outpatients with no prior diagnosis of cancer
Kjaer *et al.* (1996) Denmark 1987–88	645 cases (586 carcinoma *in situ*, 59 invasive cancer), aged 20–49 years, and 614 controls, matched on age	Population-based study among women living in greater Copenhagen Cases histologically confirmed Controls identified by random sampling using the computerized Danish Central Population Register
Ursin *et al.* (1996) USA 1977–91	195 cases and 386 controls, matched on age, race and neighbourhood	Population-based study in Los Angeles County, CA Cases histologically confirmed Controls identified by visiting houses in the cases' neighbourhood according to a predetermined algorithm
Chaouki *et al.* (1998) Morocco 1991–93	214 cases, aged 18–80 years, and 203 controls, matched on age	Hospital-based study in Rabat Cases histologically confirmed Controls from the same cancer hospital and a nearby general hospital, excluding women with a history of hysterectomy or conization, and conditions related to risk factors for cervical neoplasm (other anogenital cancers, cancers of the breast, oral cavity, oesophagus, lung, bladder and liver, cardiovascular diseases, chronic bronchitis, emphysema and sexually transmitted diseases)
Chichareon *et al.* (1998) Thailand 1990–93	338 cases (including 39 with adenocarcinoma/adenosquamous carcinoma) and 261 controls	Hospital-based study in Hat-Yai Cases histologically confirmed Age-stratified controls without anogenital tract cancers, cancers of the breast, endometrium, ovary, colon, benign genital tumours, tobacco-related diseases or history of conization or hysterectomy, selected from the same hospital
Ho *et al.* (1998) USA 1992–94	258 women with HPV infection (163 CIN I, 51 CIN II and 44 CIN III)	Hospital-based study in New York Cases histologically confirmed Reference population constituted of women with CIN I. Eligibility criteria included having had cervical biopsy and/or endocervical curettage on the day of recruitment, not being pregnant, no history of cancer and having an intact cervix

Table 2.1.10.1 (contd)

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Kanetsky *et al.* (1998) USA 1993–95	32 cases (12 CIN I, 10 CIN II, 9 CIN III/CIS, 1 ungradable CIN), aged 18 years and above, and 113 controls	Hospital-based study at the Harlem Hospital Center Cases histologically confirmed Controls: HIV-negative, black, non-Hispanic women with normal cervical cytology recruited from the gynaecology and family planning clinics
Ngelangel *et al.* (1998) The Philippines 1991–93	356 cases (including 33 with adenocarcinoma/adenosquamous carcinoma) and 381 controls matched on age	Hospital-based study in Manila Cases histologically confirmed Controls without diseases associated with known risk factors for cervical neoplasia and no history of conization or hysterectomy, selected from the same hospital
Olsen *et al.* (1998) Norway 1991–92	90 cases (10 CIN II, 80 CIN III), aged 20–44 years, and 216 controls	Population-based study in Oslo Cases histologically confirmed Controls without cervical dysplasia enrolled from an age-stratified random sample of women obtained through the Norwegian Central Population Register
Parazzini *et al.* (1998) Italy 1981–93	261 cases, aged less than 45 years, and 257 controls	Hospital-based study Cases histologically confirmed Controls aged less than 45 years, admitted to the same network of hospitals for acute conditions unrelated to cervical cancer risk factors, and belonging to the same catchment areas as cases
Hsieh *et al.* (1999) China, Province of Taiwan Not specified	183 cases and 293 controls, matched on age, marital status and residential area	Population-based study in Taipei Cases histologically confirmed Controls randomly selected from local household registration offices
Yoshikawa *et al.* (1999) Japan 1995–96	167 cases (94 CIN I, 40 CIN II, 33 CIN III), aged 55 years or younger, and 167 controls, matched on age and hospital	Hospital-based study in nine hospitals Cases histologically confirmed Controls selected from subjects with normal cervical cytology
Kjellberg *et al.* (2000) Sweden 1993–95	122 cases, aged 25–59 years, and 346 controls	Population-based study in northern Sweden Cases histologically confirmed

Table 2.1.10.1 (contd)

Reference[a] Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Rolon *et al.* (2000) Paraguay 1988–90	113 cases, aged 18–85 years, and 91 controls, matched on age	Hospital-based study in Asunción Cases histologically confirmed Controls without cervical cancer and with no history of conization or hysterectomy selected from outpatient clinics at the same hospitals; exclusion criteria included diseases associated with cervical cancer risk factors (anogenital tract cancers, tobacco-related diseases and cancer of the breast, endometrium, ovary or colon)
Lacey *et al.* (2001) USA 1992–96	263 cases (124 adenocarcinoma, 139 squamous-cell carcinoma), aged 18–69 years, and 307 controls, matched on age, race and geographical region	Multicentre population-based study Cases histologically confirmed Controls identified through random-digit dialling, excluding women with hysterectomy
Madeleine *et al.* (2001) USA 1990–96	150 cases, aged 18–70 years, and 651 controls, matched on age	Population-based study Cases histologically confirmed, identified through the SEER Cancer Surveillance System Controls identified using random-digit dialling among residents at reference date of the 13-county area in western Washington state; women with an intact uterus, who spoke English
Santos *et al.* (2001) Peru 1996–97	198 cases (173 squamous-cell carcinomas and 25 adenocarcinoma/adenosquamous carcinomas) and 196 controls, matched on age	Hospital-based study in two hospitals in Lima Cases histologically confirmed Controls selected from women without cervical cancer or history of conization or hysterectomy, attending the same hospitals; exclusion criteria included diseases associated with known risk factors for cervical cancer (cancers of the anogenital tract, tobacco-related cancers and cancer of the breast, endometrium, ovary or colon)

[a] Studies published after 1986, or before 1986 but not included in Volume 38 of the *IARC Monographs*
ICC, invasive cervical cancer; CIS, carcinoma *in situ*; CIN, cervical intraepithelial neoplasia

Table 2.1.10.2. Description of additional cohort studies on tobacco smoking and cervical cancer, cervical intraepithelial neoplasia (CIN) and carcinoma *in situ* (CIS) (with or without control for human papilloma virus (HPV) status)

Reference Country and years of study	Name of study	Cohort sample	Cases/deaths identification	Comments
Wright *et al.* (1978); Zondervan *et al.* (1996) UK 1968–77	Oxford Family Planning Association Study	17 032 women recruited in 17 large family planning clinics in England and Scotland, aged 25–39 years	Cases ascertained by follow-up in clinics	
Beral *et al.* (1988) UK 1968–87	Royal College of General Practitioners' Oral Contraception Study	47 000 women aged ≥ 15 years, half of whom were using oral contraceptives at recruitment	Cases ascertained by general practitioners	Study designed primarily to investigate oral contraceptive use and female genital cancer
Gram *et al.* (1992) Norway 1979–89	Tromsö Study	8143 women aged 20–49 years living in Tromsö with at least one negative test for CIN between 1977 and 1980	Cases ascertained by linkage to the Pathology Registry of the University Hospital	Participants were followed for development of CIN III or cervical cancer
Schiffman *et al.* (1993) USA 1989–90		21 146 women presenting for routine Pap smear screening	Cases diagnosed at the Kaiser Permanente clinic	Nested case–control study without matching; HPV-positive: 81% cases, 18% controls
Ylitalo *et al.* (1999) Sweden 1969–95		146 889 women born in Sweden and resident in Uppsala between 1969 and 1995, aged ≤ 50 years, and having had at least one smear test	Cases identified through National Cancer Registry	Nested case–control study; controls randomly selected among cohort, matched by date of entry into cohort (± 90 days), year of birth; with intact uterus and without history of prior in situ or invasive cervical carcinoma
Moscicki *et al.* (2001) USA 1990–2000		496 women examined at 2 family clinics with normal cytological findings at baseline and first follow-up excluding those testing HPV-negative at any time during follow-up	Cases ascertained at the clinics	Study designed primarily to investigate development of low-grade squamous intraepithelial lesions in HPV-infected women

Table 2.1.10.3. Case–control studies on tobacco smoking and invasive cervical cancer (ICC) (without control for human papillomavirus (HPV) status)

Reference Country and years of study	Relative risk (95% CI)					Adjustment factors	Comments
	Ever	Current	Former	By quantity/duration			
Tokuhata (1967) USA Not specified	1.2						Similar in white and black women
Williams & Horm (1977) USA Not specified				*Pack–years* ≥ 20 21–39 ≥ 40	**Invasive** 1.2 1.6 1.8	After adjustment for race, no. of children, socioeconomic indicators, a 'mild' positive association remained.	266 cases
Stellman *et al*. (1980) USA 1974–77				Risk ratios for > 10 cigarettes/day ranged from 1.4 to 1.6 before adjustments and from 1.2 to 1.3 after adjustment for age and socioeconomic status, the value depending on the amount smoked. Smokers of < 10 cigarettes/day have a relative risk of < 1.			Socioeconomic status has little confounding effect; the reduction of relative risks after adjustment is due mainly to age.
Wigle *et al*. (1980) Canada 1971–73		Invasive, 2.0 CIS, 3.8	Invasive, 1.0 CIS, 1.3	*Pack–years* < 10 11–20 21–30 ≥ 31	**Invasive** 1.2 1.7 2.1 2.7	No adjustment made for social or sexual variables	
Buckley *et al*. (1981) UK 1974–79		Combined risk (dysplasia, CIS, ICC) 7.0 7.8 3.2	 2.8 3.7 2.7			 No adjustment No. of sexual partners of husband Smoking of husband	Relative risk 35 among small series of multiple-partner women with husbands who smoked versus those with nonsmoking or formerly smoking husbands

2.1.11 *Endometrial cancer*

A total of 27 case–control studies have examined the association between cigarette smoking and endometrial cancer. The principal design characteristics and results of these studies are summarized in Tables 2.1.11.1 and 2.1.11.2, respectively.

All but two case–control studies (Shu *et al*., 1991; Weir *et al*., 1994) reported an inverse association of cigarette smoking with endometrial cancer, and in the majority of these studies the decrease in risk was statistically significant (Weiss *et al*., 1980; Lesko *et al*., 1985; Baron *et al*., 1986; Franks *et al*., 1987; Levi *et al*., 1987; Stockwell & Lyman, 1987; Kato *et al*., 1989; Koumantaki *et al*., 1989; Elliott *et al*., 1990; Rubin *et al*., 1990; Brinton *et al*., 1993; Parazzini *et al*., 1995; McCann *et al*., 2000; Weiderpass & Baron, 2001). Quantitative measures of smoking in relation to endometrial cancer have been examined in 13 studies. Most studies showed a negative trend with increasing intensity (Lesko *et al*., 1985; Levi *et al*., 1987; Stockwell & Lyman, 1987; Parazzini *et al*., 1995; Weiderpass & Baron, 2001), duration (Brinton *et al*., 1993; Parazzini *et al*., 1995) or pack–years (Williams & Horm, 1977; Baron *et al*., 1986; Lawrence *et al*., 1987). Only one study found a significantly elevated risk for endometrial cancer related to smoking. This was in premenopausal women who smoked 10–20 cigarettes/day, and no dose–response relationship was observed (Weir *et al*., 1994). Also, one study found a significant positive trend between risk for endometrial cancer and amount smoked daily, but the effects of duration were not statistically significant (Shu *et al*., 1991).

In studies that investigated the risk associated with smoking cessation, the effect was greater among current smokers than among former smokers (Lesko *et al*., 1985; Levi *et al*., 1987; Lawrence *et al*., 1987, 1989; Rubin *et al*., 1990; Austin *et al*., 1993; Weiderpass & Baron, 2001) or was confined to current smokers (Tyler *et al*., 1985; Elliott *et al*., 1990; Brinton *et al*., 1993), and the association weakened with time since smoking cessation (Weir *et al*., 1994; Parazzini *et al*., 1995).

Three studies (Lesko *et al*., 1985; Brinton *et al*., 1993; Weir *et al*., 1994) examined results by menopausal status and showed that the reduced risk among smokers was restricted to women diagnosed with endometrial cancer after menopause.

Prospective cohort studies of smoking and endometrial cancer risk in which the problems of unbiased selection of study subjects and recall are minimized are scarce. The limited evidence that is available from prospective studies does not refute the existence of an inverse association between smoking and risk for endometrial cancer (Table 2.1.11.3).

Factors suggested as potential confounders in the evaluation of the association of endometrial cancer with exposure to cigarette smoke include estrogen replacement therapy, obesity, lack of physical activity and age at menopause. Several investigators have assessed whether the presence of selected risk factors could modify the relationship between smoking and risk for endometrial cancer. Some studies have noted a greater reduction in smoking-associated risk among obese women (Brinton *et al*., 1993; Parazzini *et al*., 1995). Others have reported a greater reduction in smoking–associated risk among

women taking estrogen replacement therapy (Weiss *et al*., 1980), but not all studies support the existence of such an effect (Brinton *et al*., 1993).

The biological mechanisms that might underlie the reduced risk for endometrial cancer among smokers remain unclear. In the previous *IARC Monograph* on tobacco smoking (IARC, 1986), the Working Group noted that there was consistent evidence that menopause occurs 1–2 years earlier among cigarette smokers than in nonsmokers, indicating that smoking affects hormonal status, a factor known to be related to endometrial cancer. However, no conclusion was drawn regarding the observed reduction in endometrial cancer associated with tobacco exposure due to methodological problems with the interpretation of mortality studies.

Some researchers have suggested that exposure to tobacco may reduce estrogen production, a hypothesis that has received some support from findings that estriol excretion is reduced among postmenopausal smokers. Another theory is that smoking affects the metabolism, absorption or distribution of hormones. Recent studies have proposed a reduction in relative body weight and consequent decrease in levels of circulating estrogen and an earlier age at menopause as a possible mechanism (Terry *et al*., 2002b).

Table 2.1.11.1 Case–control studies on smoking and endometrial cancer: main characteristics of study design

Reference Country and years of study	Cases and controls	Criteria for eligibility
Williams & Horm (1977) USA Early 1960s	358 cases and 3188 controls	Hospital-based study Cases and controls from the Third National Cancer Survey Controls with tobacco-related cancers (lung, larynx, mouth, oesophagus and bladder) excluded
Weiss *et al.* (1980) USA 1975–76	322 cases and 289 controls	Population-based study in western Washington Cases aged 50–74 years; 85% response rate Controls randomly selected from general population; aged 50–74 years; controls who had a hysterectomy > 1 year before interview and non-Caucasians excluded
Kelsey *et al.* (1982) USA 1977–79	167 cases and 903 controls	Hospital-based study in Connecticut Cases confirmed histologically; aged 45–74 years; 67% response rate Controls in same age group admitted to surgical departments; large variety of diagnoses, none of which accounted for more than 4%; hysterectomy excluded; 72% response rate
Smith *et al.* (1984) USA 1980–82	70 cases and 612 controls	Population-based study Cases identified through Cancer Registry of Iowa; stage of cancer reviewed; aged 20–54 years Controls frequency-matched for age; controls with previous cancer of reproductive organs excluded 95% response rate for cases and controls
Lesko *et al.* (1985) USA 1976–83	510 cases and 727 controls	Hospital-based study in the north-east of USA, conducted using interviews Cases histologically confirmed; median age, 59 years; 95% response rate; history of previous or concurrent malignant disease and bilateral oophorectomy excluded Controls with specific, non-tobacco-related cancers: colorectal cancer (40%), melanoma (38%), lymphoreticular neoplasia or cancer of thyroid or adrenal glands (22%); history of previous or concurrent malignant disease and bilateral oophorectomy excluded; median age, 52 years
Tyler *et al.* (1985) USA 1980–82	437 cases and 3200 controls	Population-based cancer and steroid hormone study conducted using interviews Cases confirmed histologically; 72% of cases interviewed; aged 20–54 years Controls selected by random-digit dialling; aged 20–54 years; frequency-matched on age (5-year groups); 83% response rate

Table 2.1.11.1 (contd)

Reference Country and years of study	Cases and controls	Criteria for eligibility
Baron *et al.* (1986) USA 1957–65	476 cases and 2128 controls	Hospital-based study in Buffalo, NY Cases aged 40–89 years Controls with benign conditions of the uterus, breast, gastrointestinal tract and skin; cancers and diseases of the respiratory or circulatory systems excluded; aged 40–89 years
Franks *et al.* (1987) USA 1980–82	79 cases and 416 controls	Population-based study in 6 areas Cases confirmed histologically; postmenopausal women aged 40–55 years; perimenopausal women excluded Controls selected through random-digit dialling in same areas as cases; aged 40–55 years
Lawrence *et al.* (1987) USA 1979–81	200 cases and 200 controls	Population-based study in New York conducted using interviews Cases confirmed histologically as stage IA (83) or IB (117); aged 40–69 years; 65% of eligible cases participated. Controls randomly selected through driver's licence files; individually matched by county of residence and year of birth; 71% of first selected controls participated.
Levi *et al.* (1987) Italy 1983–85	357 cases and 1122 controls	Hospital-based study in Milan conducted using interviews Cases histologically confirmed; aged 31–74 years Controls with traumatic conditions (32%), non-traumatic orthopaedic disorders (25%), surgical conditions (15%) and eye, nose, throat and dental disorders (28%); aged 25–74 years; malignant, hormonal, gynaecological and tobacco-related diseases and hysterectomy excluded 98% of eligible cases and controls participated.
Stockwell & Lyman (1987) USA 1981	1374 cases and 3921 controls	Population-based study Study population identified through Florida Cancer Data System; 28% with unknown smoking status Controls with non-tobacco-related cancers: colon cancer (62%) or rectal cancer (23%), melanoma (11%), or endocrine neoplasms (4%) (tobacco-related cancer sites excluded) Controls older than cases
Kato *et al.* (1989) Japan 1980–86	239 cases and 8920 controls	Hospital-based study at Aichi Cancer Centre Cases aged ≥ 20 years Controls with cancer of stomach (31%), large intestine (19%), uterus other than corpus (17%), lung (7%) and other sites; alcohol-related cancer and cancer of ill-defined sites excluded

Table 2.1.11.1 (contd)

Reference Country and years of study	Cases and controls	Criteria for eligibility
Koumantaki *et al.* (1989) Greece 1984	83 cases and 164 controls	Hospital-based study among Greek Caucasians conducted using interviews Cases confirmed by biopsy; aged 40–79 years; 80% of eligible cases participated. Controls with traumatic fractures (58%), other traumatic conditions (6%), rheumatoid arthritis (46%) and other orthopaedic conditions (10%); hysterectomy excluded; aged 40–79 years; 95% participation rate
Lawrence *et al.* (1989) USA 1979–81	84 cases and 168 controls	Population-based study conducted using interviews Cases histologically confirmed stage 2–4; aged 40–69 years; 84% of eligible cases participated. Controls randomly selected through driver's license registry, individually matched (2:1) for county of residence and year of birth; 69% response rate
Elliott *et al.* (1990) USA 1985–87	46 cases and 140 controls	Population-based study in Baltimore conducted using interviews Cases confirmed histologically; mean age, 62.2 years Controls selected through random digit dialling after frequency-matching for prefix of telephone number (as proxy for area of residence); hysterectomy excluded; mean age, 54.3 years; 58% participation rate
Rubin *et al.* (1990) USA 1980–82	196 cases and 986 controls	Population-based study in 8 geographical areas conducted using interviews Cases from cancer and steroid hormone study, histologically confirmed; aged 40–54 years; 73% participation rate Controls selected by random digit dialling, frequency-matched on age (5-year groups); hysterectomy excluded; 84% participation rate
Shu *et al.* (1991) China 1988–90	268 cases and 268 controls	Population-based study in Shanghai conducted using interviews Cases histologically confirmed; aged 18–74 years; 91% of eligible cases participated. Controls randomly selected from Shanghai population registry, individually matched for age (± 2 years); hysterectomy excluded; 96% participation rate
Austin *et al.* (1993) USA 1984–88	168 cases and 334 controls	Hospital-based study in Alabama conducted using interviews Cases confirmed histologically; aged 40–82 years; 93% participation rate Controls from university optometry clinic, frequency-matched by age and race; hysterectomy excluded; 77% participation rate

Table 2.1.11.1 (contd)

Reference Country and years of study	Cases and controls	Criteria for eligibility
Brinton *et al.* (1993) USA 1987–90	405 cases and 297 controls	Population-based study in 5 areas conducted using interviews Cases confirmed histologically; aged 20–74 years; 87% of eligible cases participated. Controls < 65 years selected through random digit dialling and controls ≥ 65 years through Health Care Financing Administration files; individually matched on age (5-year group), race and area of residence; 66% of eligible controls participated
Weir *et al.* (1994) Canada 1977–78	88 cases and 551 controls	Population-based study conducted using interviews Cases confirmed histologically; aged 40–74 years Controls individually matched by age (± 5 years), neighbourhood and type of dwelling; hysterectomy and history of cancer excluded
Parazzini *et al.* (1995) Italy 1983–92	726 cases and 1452 controls	Hospital-based study in Milan conducted using interviews Cases confirmed histologically; aged 31–74 years Controls with traumatic conditions (34%), non traumatic orthopaedic conditions (26%), surgical conditions (15%) and other illnesses (25%) 98% participation rate for cases and controls
Hirose *et al.* (1996) Japan 1988–93	145 cases and 26 751 controls	Hospital-based study at Aichi Cancer Centre conducted using a questionnaire; 98% participation rate Cases confirmed histologically; aged ≥ 18 years Controls aged ≥ 20 years; cancer diagnosis excluded
Goodman *et al.* (1997) Hawaii, USA, 1985–93	332 cases and 511 controls	Population-based study conducted using interviews Cases confirmed histologically; aged 18–84 years; 66% of eligible cases participated. Controls randomly selected from population rosters, individually matched 2:1 or 3:1 for ethnicity and age (± 2.5 years); hysterectomy excluded; 73% participation rate
Jain *et al.* (2000) Canada 1994–98	552 cases and 562 controls	Population-based study in Toronto, Peel, Halton and York conducted using interviews Cases identified through Ontario Cancer Registry, histologically confirmed; aged 30–79 years Controls randomly selected from property assessment lists, frequency-matched by age (5-year group) and geographical area; hysterectomy excluded; low participation rate

Table 2.1.11.1 (contd)

Reference Country and years of study	Cases and controls	Criteria for eligibility
McCann *et al.* (2000) USA 1986–91	232 cases and 639 controls	Population-based study conducted using interviews Cases confirmed histologically; aged 40–85 years; 51% response rate Controls < 65 years randomly selected from driver's licence lists and for controls ≥ 65 years from Health Care Financing Administration lists, frequency-matched on age and county of residence; hysterectomy excluded; 51% of eligible controls participated.
Parslov *et al.* (2000) Denmark 1987–94	237 cases and 538 controls	Population-based study; questionnaire Cases histologically confirmed; aged 25–49 years; 93% participation rate Controls randomly selected from Danish Central Person Registry, individually matched by age and geographical region; 91% participation rate
Weiderpass & Baron (2001) Sweden 1994–95	789 cases and 3368 controls	Population-based study among postmenopausal Swedish women residents with intact uterus Cases confirmed histologically; aged 50–74 years; 75% participation rate Controls randomly selected from Swedish population registry; aged 50–74 years; 80% participation rate

Table 2.1.11.2. Case–control studies on smoking and endometrial cancer

Reference Country and years of study	Exposure estimates	Relative risk (95% CI)		Comments

2.1.12 *Prostate cancer*

In a review of prostate cancer and its relationship to smoking, Hickey *et al*. (2001) found that the relationship in cohort studies that examined only causes of death was stronger than that in studies in which the incidence of cancer was determined during the individuals' lives, which suggested to the reviewers that smoking might convert a relatively benign cancer into a more aggressive one. Alternatively, the small excesses observed in the mortality studies may have been caused by the diagnostic bias referred to as one of the problems with cohort studies in the General Remarks: namely, the effect of death in the course of a slowly progressive major disease, as prostate cancer may be, is attributed to the chronic disease when it actually occurred as a result of an acute disease related to smoking, such as bronchopneumonia or myocardial infarction. It is certain, from the many studies that have been reported, that any association with smoking is at most weak and the cohort studies in this review are consequently limited to those that reported cancer incidence rates. Their design is described in Tables 2.1 and 2.1.12.1. The results of 18 studies, including separately the two series reported by Hakulinen *et al*. (1997) are summarized in Table 2.1.12.2. One study included in the review of Hickey *et al*. (2001), namely that by Whittemore *et al*. (1984), has been omitted as 44% of the 243 cases were diagnosed only at death, thus causing it to share the potential bias of a mortality study.

Several of the incidence studies provide only rudimentary details about smoking behaviour as they were focused primarily on other factors. Of the 17 studies, two provided evidence of statistically significantly increased risks associated with smoking. Firstly, Adami *et al*. (1996) found some evidence of a dose–response relationship, with the risk increasing with the number of cigarettes smoked per day ($p = 0.04$), although the small number of heavy smokers (38) showed no excess incidence. Secondly, Cerhan *et al*. (1997) found a significantly increased risk of 2.7 (95% CI, 1.2–6.0) for the nine cigarette smokers in their series who smoked 20 or more cigarettes a day. Seven studies, however, found lower risks for current smokers than for nonsmokers, which was almost as many as the nine studies that found increased risks.

The results of 30 case–control studies have been reviewed by Levi and La Vecchia (2001). Two of the studies found some evidence of a positive relationship (Honda *et al*., 1988; based on 216 cases; Schuman *et al*., 1977; based on 48 cases) and a third found a significantly positive relationship with ever smoking, but no relationship with either dose or duration (van der Bulden *et al*., 1994; based on 345 cases). In contrast, the larger study by Villeneuve *et al*. (1999; based on 1623 cases) found a non-significant inverse relationship. The rest found no association worth noting.

Table 2.1.12.1. Description of additional cohort studies on smoking and prostate cancer

Reference Country and years of study	Name of study Cohort sample	Cases/deaths	Comments
Le Marchand *et al.* (1994) Hawai, USA 1975–89	Random sample among 20 316 men from the 5 main ethnic groups in Hawaii: Japanese, Caucasians, Filipino, Hawaiian/Part-Hawaiian, Chinese; aged ≥ 45 years	Cases identified by the Hawaiian Tumor Registry	Study investigating primarily animal fat intake and prostate cancer
Parker *et al.* (1999) USA 1986–95	1177 Iowa men aged 40–86 years	Cases ascertained by Iowa Cancer Registry	Cohort based on controls of a case–control study conducted in 1986–89; study investigating primarily farming activities and risk of prostate cancer
Cerhan *et al.*, 1997 USA 1982–93	Iowa 65+ Rural Health Study 1050 non-institutionalized residents of rural counties in Iowa, aged 65–101 years	Cases ascertained by State Health Registry of Iowa's cancer database	Study investigating primarily body mass and physical activity as risks for prostate cancer
Thompson *et al.* (1989) USA 1972–87	Adult residents of an upper-middle-class community in southern California, aged 50–84 years	1) Incident cases and 2) cases diagnosed before entering cohort or listed on death certificate without prior reporting	[Results based on total cases cannot be considered prospective.]

Table 2.1.12.2. Cohort studies on smoking and prostate cancer

Reference Country and years of study	Name of study No. of men	No. of cases	Exposure related to nonsmokers	Relative risk (95% CI)
Mills *et al*. (1989) USA 1976–82	Adventists' Health Study approximately 14 000 men	172	Former smoker Current smoker	1.2 (0.9–1.7) 0.5 (0.2–1.6)

2.1.13 *Leukaemia*

The study of the effects of smoking on leukaemia presents a problem, because leukaemia is not one disease with a specific etiology, but a combination of several diseases that have a pathological characteristic in common (namely, an abnormal number of white cells in the blood) and which may have — and in some respects certainly do have — different causes. In principle, it would be desirable to consider separately at least four diseases: namely, the acute myeloid, chronic myeloid, acute lymphoid and chronic lymphoid leukaemias of adults. For therapeutic purposes, the myeloid leukaemias may be subdivided further, but the number of cases in most of the categories would be small and they have not generally been considered separately in etiological studies. Indeed even the acute and chronic forms have seldom been studied separately (although chronic lymphoid leukaemia is sometimes distinguished and may be classed with lymphomas) and the data available in relation to smoking permit only the examination of leukaemia as a whole and of the myeloid and lymphoid categories separately.

It is clear, from the many studies that have been reported, that any association of leukaemia with smoking is weak, so that the most valid evidence is likely to be obtained from cohort studies rather than from case–control studies. Two types of leukaemia (acute myeloid and acute lymphoid leukaemia) are usually rapidly fatal and there is little likelihood that cause of death would be attributed incorrectly to these leukaemias rather than to independent concurrent disease. It is also usually clear whether death during the course of chronic myeloid leukaemia is attributable to the disease itself. Only in the case of chronic lymphoid leukaemia is there any appreciable risk of death being attributed to the disease when it was actually due to an independent smoking-related condition. Table 2.1.13.1 therefore summarizes the results of both incidence and mortality studies. Many of these are studies of leukaemia only. In others, however, leukaemia was only one of many cancers examined and the results of these need to be interpreted with caution when the numbers are small, as they may have been singled out for report because they appeared to be of interest. Two such small mortality studies have been excluded, because cigarette smokers were compared with non-cigarette smokers (including men who smoked only pipes and/or cigars) rather than with lifelong nonsmokers (Tverdal *et al*., 1993; Weir & Dunn, 1970).

The results provide some weak evidence of an association of smoking with leukaemia. The incidence data are conflicting. The largest study, based on 400 cases, provided no evidence of an increased risk (Adami *et al*., 1998), but most of the others did, including two that reported statistically significant excesses for the heaviest cigarette smokers, but were based on very small numbers (Mills *et al*., 1990; Tulinius *et al*., 1997). The mortality data, in contrast, mostly showed small and statistically significant excesses of the order of 30–50% among current smokers, including the data from the US Veterans' study (McLaughlin *et al*., 1989) and the data in men from the two studies carried out by the American Cancer Society (Garfinkel & Boffeta, 1990). Three of the four studies of men, moreover, showed positive dose–response relationships. The only one of the six sets of data

not to show any excess risk in cigarette smokers was that for women in the first of the American Cancer Society's studies, which described the observations made between 1959 and 1965 when few women had been smoking for very many years.

Eight studies gave separate data for myeloid leukaemias; six of these also gave data for lymphoid leukaemias, including three that did not provide any data for all leukaemias combined (Paffenbarger *et al*., 1978; Friedman, 1993; Doll *et al*., 1994). Separate data for myeloid and lymphoid leukaemia are summarized in Table 2.1.13.2, but descriptions of the studies are not included in this table, as most of them are described in Table 2.1.13.1 (McLaughlin *et al*., 1989; Garfinkel & Boffeta, 1990; Mills *et al*., 1990; Linet *et al*., 1991; Adami *et al*., 1998). Three, however, are not listed in Table 2.1.13.1 and are described below. Doll *et al.* (1994) followed 34 000 male physicians in the United Kingdom, who had been sent questionnaires about their smoking habits at the end of October 1951 and subsequently in 1957, 1966, 1972, 1978 and 1990, and determined the causes of death of those who died before November 1991. Paffenbarger *et al*. (1978) followed 50 000 former students (all males) at Harvard and Pennsylvania State Universities, who had been given questionnaires on entry in 1916–50 and 1931–40, respectively, and determined the causes of death of those who had died by 1975. In a case–control study nested in this cohort, each person who had died was matched with four controls from the same area, born in the same year, and alive at the time the affected person had died. Friedman (1993) followed 61 704 men and 81 287 women with known smoking habits, who had attended two Kaiser Permanente Medical Centers in the USA, for a regular health appraisal, from the time of first attendance in 1964–72 to the end of 1988, death, or cessation of requested follow-up and determined the incidence of leukaemia from their clinical records. The incidence of leukaemia among nonsmokers and former smokers did not take into account data for smokers of cigars or pipe, but the data for current smokers did so. The results of all the studies were adjusted for age and (where necessary) for sex and, in some instances, also for additional characteristics, i.e. for calendar year of observation by Doll *et al*. (1994) and for area of residence by Nordlund *et al*. (1997).

There is strong evidence for an association of cigarette smoking with myeloid leukaemia. Six out of eight sets of data for men, or for men and women treated as a single group, showed excess relative risks for current cigarette smokers. All of the excess risks were more than 60% and all were associated with dose–response relationships. The exceptions were the data set of Adami *et al*. (1998) in Sweden and a small data set for white insurance policy-holders in the USA reported by Linet *et al*. (1991). Of the two data sets for women, one (the first obtained by the American Cancer Society) showed no association with smoking whereas the other (the second obtained by the American Cancer Society) suggested a weak association that was not statistically significant (Garfinkel & Boffetta, 1990).

The data for lymphoid leukaemia are very different. Only two of eight studies provide any evidence of an increased risk associated with smoking (Paffenbarger *et al*., 1978; Linet *et al*., 1991) and in neither case was the excess risk statistically significant.

Although the strongest evidence comes from cohort studies, some data are also available from case–control studies, details of which are not included in this review. It is worth noting, however, that when Brownson *et al*. (1993) undertook an overview of the published studies of cigarette smoking and adult leukaemia, they found that a pooled analysis of eight case–control series (including the study by Paffenbarger *et al*. (1978) as a case–control study) gave relative risks of 1.1 (95% CI, 1.0–1.2) for all leukaemias, 0.9 (95% CI, 0.8–1.1) for chronic lymphoid leukaemia, 1.2 (95% CI, 0.9–1.5) for chronic myelocytic leukaemia and 1.3 (95% CI, 1.1–1.5) for acute non-lymphoid leukaemia (equivalent to acute myeloid leukaemia in most studies).

Five subsequent studies provided inconsistent, but generally similar results when smokers were compared with nonsmokers. Mele *et al.* (1994) reported on 118 cases of acute myeloid leukaemia and 28 cases of acute lymphoid leukaemia in three Italian cities from 1987 to 1990. The relative risks obtained were 1.6 (95% CI 0.9–2.8) for acute myeloid leukaemia in current smokers [smokers with a history of consumption of more than 10 pack–years are at greater risk] and 0.6 (95% CI, 0.2–2.0) for acute lymphoid leukaemia in current smokers. Wakabayashi *et al*. (1994) reported on 75 cases of acute non-lymphoid leukaemia seen at the Hyogo College of Medicine in Japan from 1981 to 1990; a relative risk of 1.76 (95% CI, 0.96–3.23) was found for smokers. Kane *et al*. (1999) reported on 695 cases of acute myeloid leukaemia and 99 cases of acute lymphoid leukaemia seen in five areas of England from 1991 to 1996; the odds ratios for current smokers were 1.4 (95% CI, 1.1–1.8) for acute myeloid leukaemia and 1.3 (95% CI, 0.7–2.3) for acute lymphoid leukaemia. Bjork *et al* (2001) reported on 372 cases of acute myeloid leukaemia seen in southern Sweden; the relative risks obtained were greater than 1.0 when smoking had continued for more than 20 years for both light smokers (1–10 cigarettes per day: odds ratio, 1.1; 95% CI, 0.65–1.9) and moderate or heavy smokers (>10 cigarettes per day: odds ratio, 1.6; 95% CI, 1.0–2.4) but were less than 1.0 when smoking had continued for 20 years or less. However, Stagnaro *et al*. (2001) reported on 646 cases of leukaemia in 12 areas of Italy and found odds ratios of less than 1.0 for current smokers both for all leukaemia (0.88; 95% CI, 0.69–1.1) and acute myeloid leukaemia (0.93; 95% CI, 0.81–1.4) and an increased odds ratio for current smokers only for acute lymphoid leukaemia (1.2; 95% CI, 0.54–2.5).

For the most part, case–control studies and cohort studies show a difference in risk between myeloid and lymphoid leukaemias.

Characteristics of tobacco-related cases

In general, it has not been possible to link individual malignant neoplasms with specific causes. In the case of leukaemia, some evidence may be obtained from knowledge of the chemicals in tobacco smoke and their relationship to specific cytogenetic changes. For example, benzene, a well-known leukaemogen is known to be present in significant concentrations in tobacco smoke.

According to Korte *et al*. (2000), linear extrapolation from the known effects of high doses suggests that benzene may be responsible for 8–48% of smoking-induced cancer and

a somewhat higher proportion (12–58%) of smoking-induced acute myeloid leukaemia. Specific increases in the frequency of partial loss of chromosomes 5 and 7 and translocations involving chromosomes 8 and 21 have been found in the lymphocytes of healthy Chinese workers occupationally exposed to benzene (Smith *et al*., 1998; Zhang *et al*., 1998) and similar chromosomal abnormalities have been noted in smokers in 5–10% of cases of adult acute myeloid leukaemia (Walker *et al*., 1994; Grimwade *et al*., 1998).

There have as yet been few detailed studies on the cytogenetics of acute myeloid leukaemia subdivided by the individuals' smoking habits, but some of them offer support for the concept of a specific effect of benzene in the smoker. Lebailly *et al*. (2002) divided 472 cases of acute myeloid leukaemia into six cytogenetic groups and found higher odds ratios among smokers than in nonsmokers in 32 cases with 8:21 translocations (ever-smokers, 4.77; 95% CI, 1.77–12.85; current smokers, 7.07; 95% CI, 2.64–18.95) and diminished odds ratios in 54 cases with 15:17 translocations (ever-smokers, 0.57; 95% CI, 0.32–1.00; current smokers, 0.41; 95% CI, 0.23–0.96), bearing out the earlier findings reported by Sandler *et al*. (1993) and Davico *et al*. (1998) from studies with smaller numbers. Among 155 cases of acute myeloid leukaemia with recognizable chromosomal aberrations, Sandler *et al*. (1993) found 19 8:21 translocations, giving an odds ratio for ever-smokers of 1.7 (95% CI, 0.60–5.13) and 26 with 15:17 translocations, giving an odds ratio of 0.42 (95% CI, 0.17–1.01), whereas among 26 cases of acute non-lymphoid leukaemia with recognizable chromosomal aberrations, Davico *et al*. (1998) found nine with aberrations of chromosome 8 (six 8+, two 8– and one 8:21 translocation), giving odds ratios of 4.1 (95% CI, 0.5–35.5) relative to patients with normal karyotypes for smokers of ≤ 10 cigarettes/day and 14.2 (95% CI, 1.4–142.3) for heavier smokers.

Only Bjork *et al*. (2001) failed to obtain similar results. Among 73 cases of acute myeloid leukaemia with recognizable chromosomal aberrations, 12 had 8+ aberrations, giving an odds ratio for ever versus never-smokers of 0.91 (95% CI, 0.25–3.30). Smoking, however, was light in this study, with a medium number of pack–years of 21 for all aberrations and 14 for 8+ aberrations.

2.1.14 *Other organs*

The cancers reviewed in this section generally have low incidence and mortality rates and are not considered to be strongly associated with cigarette smoking. This raises the possibility of preferential reporting of positive associations in cohort studies.

(*a*) *Cancer of the salivary gland*

A population-based case–control study on salivary gland cancer (based on 25 cases) from Puerto Rico (Hayes *et al*., 1999) reported relative risks of 9.0 for men and 4.2 for women. Increasing number of cigarettes smoked per day showed a statistically significant trend for men ($p = 0.02$) and a statistically non-significant trend for women ($p = 0.07$). Two other case–control studies (Spitz *et al*., 1990; Swanson & Burns, 1997), however, found no increase in risk for cancer of the salivary gland among cigarette smokers, or only for the highest category of smoking intensity (≥ 80 pack–years).

(*b*) *Cancer of the small intestine*

Results are available from three case–control studies on the association between smoking and cancer of the small intestine; two found a two- to fourfold increase in risk among smokers (Chen *et al*., 1994; Wu *et al*., 1997), and the third indicated a 90% increase in risk (Kaerlev *et al*., 2002). In contrast, two other case–control studies, one conducted in the USA and the other in Italy, found no evidence for an effect of smoking on cancer of the small intestine (Chow *et al*., 1993; Negri *et al*., 1999).

(*c*) *Cancers of the gallbladder and extra-hepatic bile ducts*

Cancers of the gallbladder and extra-hepatic bile ducts were considered in the previous *IARC Monograph* on tobacco smoking (IARC, 1986), but many more studies have been published since then. The results of the relevant cohort and case–control studies are summarized in Table 2.1.14.1.

In the US Veterans' Study, Chow *et al.* (1995) found marginally elevated relative risks in former smokers and significantly elevated risks in current smokers. Subjects who reported smoking more than 20 cigarettes per day also had significantly elevated relative risks. Starting smoking at a younger age (< 20 years) increased relative risks relative to subjects who had started smoking at a later age (> 20 years). Elevated, but non-significant risks were found in relation to duration of smoking.

Chow *et al*. (1994) studied 34 men and 30 women from Los Angeles county, CA, USA, with bile duct cancers, and 15 men and 26 women with cancer of the ampulla of Vater. These cases were compared with 97 men and 158 women chosen by random-digit dialling or from the Health Care Financing Administration files if over 65 years of age. All cases were histologically verified. Elevated, but non-significant risks were found in former smokers in all groups except for women with cancer of the ampulla of Vater.

Moerman *et al*. (1994) compared 114 cases of bile duct cancer with 487 population controls. After adjustment for age, sex and respondent status, former smokers were at a

lower risk (0.7; 95% CI, 0.4–1.2) than current smokers (1.3; 95% CI, 0.8–2.2) and a non-significant trend in relative risks was observed in relation to the duration of smoking: 1.5 for current smokers at interview and 1.4, 1.1 and 1.2 in those who smoked for 2, 5 and 10 years, respectively, before the interview.

Yen *et al*. (1987) recruited 67 patients with bile duct cancer from 11 hospitals in Massachussets, USA, and 273 controls admitted with cancers unrelated to tobacco or alcohol consumption. After adjustment for age and sex, a negative association was found in relation to former smoking (odds ratio, 0.5), and in relation to current smoking (odds ratio, 0.4; $p < 0.05$).

Zatonski *et al*. (1992) compared 73 cases of gallbladder cancer with 186 controls in Opole, Poland. No significant association was found in relation to lifetime number of cigarettes smoked (odds ratio, 0.6 for < 197 100 cigarettes in lifetime; 1.1 for more).

Scott *et al*. (1999) compared the medical records of 68 cases of gallbadder cancer, all histologically verified, from six hospitals in Massachussets, USA, with 272 controls with gallstones or who underwent cholecystectomy. No significant associations between gallbladder cancer and any smoking category (ever, current, former, years smoked or years since quitting) were found. A statistically non-significant fivefold increase in risk was found in relation to smoking after adjustment for age, sex, the presence/absence of gallstones and history of gallstones.

[The Working Group noted that medical records are not necessarily a reliable source of information on tobacco smoking.]

Chalasani *et al*. (2000) compared 26 cases of cholangiocarcinoma to 87 controls from eight hospitals in the USA. After adjustment for age and duration of primary sclerosing cholangitis, no significant association was found in relation to former or current smoking.

Confounding

In considering cancer of the gallbladder and extra-hepatic bile ducts, particular attention has to be paid to potential confounders, namely body-mass index and gallbladder disease.

Chow *et al.* (1994) noted an increased risk for extrahepatic bile duct cancer in relation to body-mass index in both men (odds ratio, 4.0; 95% CI, 1.1–14.2) and women (odds ratio, 2.7; 95% CI, 0.8–9.4) in the highest body-mass index quartile. In addition, a history of gallbladder disease, gallstones and gallbladder inflammation was found to be an important risk factor for the development of gallbladder cancer. Gallbladder disease was also found to be an important risk factor in the study by Scott *et al*. (1999) (odds ratio, 17.2; 95% CI, 1.5–190), by Zatonski *et al*. (1992) and in a recent SEARCH case–control study on 196 cases and 1515 controls (odds ratio, 4.4 for gallbladder disease) (Zatonski *et al.*, 1997). The only study reviewed that was stratified by smoking and gallbladder disease and body-mass index was that of Zatonski *et al*. (1992) that did not find an association with tobacco smoking.

(*d*) *Soft-tissue sarcoma*

One cohort study found an association between cigarette smoking and mortality from soft-tissue sarcoma after 26 years of follow-up, but no dose–response relationship was found with the number of cigarettes smoked per day, duration of smoking or number of pack–years (US Veterans' Study: Zahm *et al*., 1992). No effect of cigarette smoking was detected in an Italian hospital-based case–control study (Franceschi & Serraino, 1992).

(*e*) *Skin cancer*

(i) *Melanoma*

A number of case–control studies have found no difference in the prevalence of tobacco smoking between patients with malignant melanoma and controls (Østerlind *et al*., 1988; Siemiatycki *et al*., 1995; Westerdahl *et al*., 1996; Lear *et al*., 1998; de Hertog *et al*., 2001). An inverse association was found in one study (Green *et al*., 1999).

(ii) *Non-melanoma skin cancer*

Tobacco smoking has been linked to the incidence of squamous-cell carcinoma in a prospective follow-up study of patients with prior skin cancer (Karagas *et al*., 1992) and in the Nurses' Health Study (Grodstein *et al*., 1995), as well as in several case–control studies (Aubry & MacGibbon, 1985; Lear *et al*., 1998; de Hertog *et al*., 2001). In contrast, neither cohort studies (Nurses' Health Study: Hunter *et al*., 1990; Skin Cancer Prevention Study: Karagas *et al*., 1992; Health Professionals' Follow-up Study: van Dam *et al*., 1999) nor case–control studies (Sahl *et al*., 1995; Lear *et al*., 1998; de Hertog *et al*., 2001) found an effect of smoking on the incidence of basal-cell carcinoma.

(*f*) *Ovarian cancer*

Two studies have shown an association of smoking with ovarian cancer (British Doctors' Study: Doll *et al*., 1980; Green *et al*., 2001), but most studies were null (Smith *et al*., 1984; Stockwell & Lyman, 1987; Whittemore *et al*., 1988; Polychronopoulou *et al*., 1993; Norwegian Cohort Study: Engeland *et al*., 1996; Kuper *et al*., 2000). Recent interest in separating histological types of ovarian cancer has prompted researchers to report associations separately. Two studies have reported that smokers were at excess risk for mucinous epithelial ovarian cancer (Marchbanks *et al*., 2000; Green *et al*., 2001), but not for other histological types (Marchbanks *et al*., 2000), but a third study did not support these findings (Kuper *et al*., 2000).

(*g*) *Testicular cancer*

No association has been found between cigarette smoking and risk for testicular cancer (Henderson *et al*., 1979; Coldman *et al*., 1982; UK Testicular Cancer Study Group, 1994; Siemiatycki *et al*., 1995). One study found an increased risk, but positive dose–response relationships for duration and intensity of smoking were seen only in patients from one of three hospitals (Brown *et al*., 1987).

(*h*) *Cancer of the central nervous system*

The incidence of gliomas has been associated with smoking in men (Hurley *et al*., 1996; Lee *et al*., 1997), but not in women (Hurley *et al*., 1996; Blowers *et al*., 1997; Lee *et al*., 1997) or in both sexes combined (Ryan *et al*., 1992). One study reported increased risks for meningiomas associated with smoking (Ryan *et al*., 1992). Another study found an association of brain tumours with smoking untipped cigarettes, but not with smoking filter-tipped cigarettes (Burch *et al*., 1987). Other studies have shown a lack of association of tobacco use with tumours of the central nervous system (Hochberg *et al*., 1990; US Veterans' Study: McLaughlin *et al*., 1995).

(*i*) *Thyroid cancer*

Three studies have reported an inverse association of smoking with risk for thyroid cancer (Galanti *et al*., 1996; Kreiger & Parkes, 2000; Rossing *et al*., 2000). Two studies have reported no association (Ron *et al*., 1987; Kaiser Permanente Medical Care Program Study: Iribarren *et al*., 2001) and two a positive association with smoking (Sokic *et al*., 1994; Memon *et al*., 2002).

(*j*) *Cancer of the adrenal gland*

There are few data on risk factors for adrenal carcinoma. The US Veterans' Study reported a fivefold increase in risk among current cigarette smokers during 26 years of follow-up, with risk being particularly high among those who smoked most intensely (Chow *et al*., 1996). Other forms of tobacco use were associated with a statistically non-significant increase in risk. A case–control study in the USA found a twofold increase in risk for adrenal cancer among heavy smokers in men, but not in women (Hsing *et al*., 1996).

(*k*) *Lymphoma*

(i) *Non-Hodgkin lymphoma*

Six cohort studies have examined the association between non-Hodgkin lymphoma and smoking. In five of these, no increased risk among smokers was evident (British Doctors' Study: Doll *et al*., 1994; US Veterans' Study: McLaughlin *et al*., 1995; Swedish Construction Workers' Cohort: Adami *et al*., 1998; Kaiser Permanente Medical Care Program Study: Herrinton & Friedman, 1998; Iowa Women's Health Study: Parker *et al*., 2000). However, in one prospective study, men who had ever smoked cigarettes had a twofold increase in risk for non-Hodgkin lymphoma, and the risk was still higher among the heaviest smokers (Lutheran Brotherhood Insurance Study: Linet *et al*., 1992). In general, data from case–control studies also fail to support a large effect of smoking on the incidence of non-Hodgkin lymphoma (reviewed by Peach & Barnett, 2001; Stagnaro *et al*., 2001).

Only three studies have examined histological subtypes of non-Hodgkin lymphoma. In the Iowa Women's Health Study (37 336 women followed for 11 years), smoking was

associated with increased risk for follicular non-Hodgkin lymphoma (Parker *et al*., 2000). Similarly, two other studies reported a weak positive association between smoking and risk for follicular lymphoma, but no effect for other histological types (Herrinton & Friedman, 1998; Stagnaro *et al*., 2001).

(ii) *Hodgkin lymphoma*

Three studies provided no support for the hypothesis that smoking increases risk for Hodgkin disease (Abramson *et al*., 1978; Bernard *et al*., 1987; Stagnaro *et al*., 2001) and four studies found weak associations (Harvard Alumni Study: Paffenbarger *et al*., 1977; US Veterans' Study: McLaughlin *et al*., 1995; Siemiatycki *et al*., 1995; Swedish Construction Workers Cohort: Adami *et al*., 1998).

(*l*) *Multiple myeloma*

Nine studies suggested no association between smoking and risk of multiple myeloma. Support for this conclusion comes from a number of cohort studies (US Veterans' Study: Heineman *et al*., 1992; Lutheran Brotherhood Insurance Study: Linet *et al*., 1992; Kaiser Permanente Medical Care Program Study: Friedman, 1993; British Doctors' Study: Doll *et al*., 1994; US Veterans' Study: McLaughlin *et al*., 1995; Swedish Construction Workers' Cohort: Adami *et al*., 1998) and case–control studies (Linet *et al*., 1987; Brown *et al*., 1992; Stagnaro *et al*., 2001). Only the relatively small Adventists' Health Study reported an increased incidence of multiple myeloma among former and current smokers and statistically significant trends by number of cigarettes and duration of smoking (Mills *et al*., 1990).

Table 2.1.14.1. Studies on tobacco smoking and cancers of the biliary tract and gallbladder

Reference Country and years of study	Subjects (cases and controls)	Smoking category	Relative risk (95% CI) (relative to never-smokers)				Comments
Cohort study							
Chow *et al.* (1995) USA 1954–80	US Veterans' Study 250 000 men; 303 biliary tract cancers	Former smoker	1.2 (0.8–1.8)				Adjusted for age and calendar time period; age at starting smoking and number of years of smoking also adjusted for cigarettes/day
		Current smoker	1.5 (1.1–2.0)				
		Cigarettes/day					
		< 10	1.6 (1.0–2.6)				
		10–20	1.2 (0.8–1.8)				
		≥ 21	1.8 (1.2–2.7)				
		Age at starting smoking (years)					
		< 20	1.8 (1.1–3.1)				
		20–24	1.6 (0.9–2.9)				
		> 24	1.4 (0.8–2.7)				
		Duration (years)					
		< 30	1.6 (0.8–3.3)				
		30–39	1.7 (0.9–2.9)				
		≥ 40	1.7 (1.0–2.9)				
Case–control studies							
Yen *et al.* (1987) USA 1975–79	67 extrahepatic bile duct cancers, 273 controls with other cancers	Former smoker	0.5 (0.3–1.0)				Adjusted for age and sex
		Current smoker	0.4 (0.2–0.9)				
		Packs/day					
		1	0.3 (1.0–0.9)				
		> 1	0.5 (0.2–1.2)

2.2 Pipe, cigar, bidi and other tobacco smoking

2.2.1 *Pipe and cigar smoking*

(*a*) *Introduction*

Although cigar and pipe smoking are less common than cigarette smoking throughout much of the world, these products are used extensively in certain countries and subcultures. Furthermore, the resurgence in the use of premium cigars in the USA between 1993 and 1997 illustrates how aggressive marketing of a specific tobacco product can rapidly increase its usage, even in cultures where it appears to be no longer fashionable.

The data on cancer risk in relation to cigar and pipe smoking are more limited than those available from studies of cigarette smoking. Fewer people have exclusively smoked cigars and/or pipes than have exclusively smoked cigarettes. The published studies are generally based on men, even though women in certain countries smoke cigars and/or pipes. Most studies of smoking cessation have greater statistical power to examine cigarette smoking than smoking of cigars or pipes. The smaller number of exclusive cigar and/or pipe smokers limits the opportunity to examine cancer risk in relation to the amount and duration of smoking, or to assess interactions with alcohol consumption. Persons who smoke cigarettes in combination with cigars and/or pipes typically have a risk for tobacco-attributable cancers that is intermediate between those who smoke cigarettes only and those who exclusively smoke cigars or pipes. The analyses presented here pertain only to exclusive cigar and/or pipe smokers, excluding smokers who also smoked cigarettes. While the main characteristics of the case–control studies are presented together with the results of the studies, the reader is referred to the beginning of Section 2 for a description of the cohort studies presented.

The tables are subdivided between (a) studies on smokers of pipes only and cigars only and (b) studies on smokers of both pipes and cigars, and studies that combined pipe and/or cigar smokers in one category.

(*b*) *Cancer of the lip, oral cavity and pharynx*

(i) *Cancer of the lip*

Clinical reports as early as 1795 linked pipe smoking with carcinoma of the lip (ICD-9: 140) and tongue (ICD-9: 141) (Sömmering, 1795; Clemmesen, 1965) as noted by Doll (1998). These reports were not taken very seriously, however, and these carcinomas were generally attributed to the heat of the clay pipe stem rather than to any intrinsic carcinogenicity of tobacco (Doll, 1998). Several case series and case reports published since the 1920s have noted the association of lip cancer with various combinations of pipe smoking, sunlight, ionizing radiation, and/or alcohol consumption (Broders, 1920; Ahlbom, 1937; Ebenius, 1943; Bernier & Clark, 1951; Hämäläinen, 1955; Wynder *et al*., 1957).

Two large case–control studies of lip cancer provide information on the relationship of lip cancer with pipe and cigar smoking. Keller (1970) studied 314 male cases, representing a 20% sample of patients discharged from all Veterans Administration hospitals in

the USA from 1958 until 1962. Two control groups were identified by sampling — one of patients with cancers of the mucous membrane of the mouth and pharynx, the other of patients discharged during the same period with no oral or pharyngeal cancer. Smoking of pipes, cigars and cigarettes was significantly associated with lip cancer. [The Working Group noted that the data did not include the amount smoked or duration of smoking and that only frequencies of exposure were compared.]

Spitzer *et al*. (1975) studied all male cases of squamous-cell carcinoma of the lip occurring in Newfoundland, Canada, over an 11-year period (1961–71; 366 cases). Three control groups were selected: 132 patients with oral cavity cancer, 81 patients with squamous-cell carcinoma of the skin of the head and neck and 210 randomly selected population controls. In comparison with the population controls, the relative risk for lip cancer associated with pipe smoking, adjusted for age, was 1.5 ($p < 0.05$). [The Working Group noted that the study focused on risk for lip cancer related to the occupation of fishing and gave no other information on tobacco use.]

Subsequent case–control and prospective studies of oropharyngeal cancer have not been sufficiently large to examine lip cancer separately in relation to exclusive use of pipes and/or cigars.

(ii) *Oral and pharyngeal cancer*

Cohort studies

Table 2.2.1 presents the results from seven cohort studies that looked at cancers of the oral cavity and pharynx (ICD-9: 140–149) among men who smoked exclusively cigars and/or pipes (Hammond & Horn, 1958; Kahn, 1966; Doll & Peto, 1976; Carstensen *et al*., 1987; Shanks & Burns, 1998; Iribarren *et al*., 1999; Shapiro *et al*., 2000).

The largest study was based on 12 years of follow-up of the Cancer Prevention Study I (CPS-I) cohort (Shanks & Burns, 1998). Twenty-five deaths from cancers of the oral cavity and pharynx were identified between 1959 and 1972 among the 15 191 men who reported current and exclusive smoking of cigars at the time of enrolment in the study. The age-standardized relative risk for death from cancer of the oral cavity and pharynx was 7.9 (95% CI, 5.1–11.7) among all cigar smokers, relative to lifelong nonsmokers and increased with the number of cigars smoked per day to 15.9 (95% CI, 8.7–26.8) in men who smoked five or more cigars per day. The corresponding estimate for men who reported current smoking of cigarettes exclusively was 8.2 (95% CI, 7.2–9.4). Mortality results were not reported for the 9623 men who smoked exclusively pipes at the time of enrolment in the study, or for former smokers of either cigars or pipes.

Iribarren *et al*. (1999) reported a higher incidence of cancer of the oral cavity and pharynx among 1546 men who reported current smoking of cigars only and no past cigarette smoking at the time of enrolment in the Kaiser Permanente Medical Care Program between 1964 and 1973 than in nonsmokers. Follow-up from 1971 until 1996 identified eight subjects with oral and pharyngeal cancer among the cigar smokers. The relative risk among cigar smokers compared with that of 16 228 men who had never smoked cigarettes and did not smoke a pipe at enrolment was 2.6 (95% CI, 1.2–5.8). Among cigar smokers,

risk was higher among men who smoked five or more cigars per day (relative risk, 7.2; 95% CI, 2.4–21.2) than in those who smoked less than five cigars per day (relative risk, 1.3; 95% CI, 0.4–4.4). [The Working Group noted that the inclusion of former pipe smokers in the referent group in this analysis potentially underestimates the association between cigar smoking and cancer of the oral cavity and pharynx.]

Shapiro *et al*. (2000) examined death rates from cancers of the oral cavity and pharynx among 7888 current and 7868 former cigar smokers in the Cancer Prevention Study II (CPS-II), followed from 1982 to 1994. The relative risk was highest among men who reported smoking three or more cigars per day (relative risk, 7.6; 95% CI, 2.9–19.6) and those who had smoked cigars for ≥ 25 years (relative risk, 4.6; 95% CI, 1.6–13), relative to lifelong nonsmokers.

Case–control studies

The case–control studies published since 1986 have consistently shown an increased risk for cancer of the oral cavity and pharynx among men who exclusively smoke cigars or pipes (Table 2.2.2).

Zheng *et al*. (1990) identified 404 patients diagnosed with histologically confirmed oral cancer (ICD 141, 143–145) at participating hospitals in Beijing in 1988–89. An equal number of controls matched on age, sex and hospital were randomly selected from non-cancer patients attending hospital for minor surgery and other conditions judged to be of less than 1-year duration. Among pipe smokers, the odds ratio adjusted for alcohol consumption, years of education, sex and age was 5.7 (95% CI, 2.4–13.3) in men and 4.9 (95% CI, 1.5–16.0) in women. The corresponding estimates associated with cigarette smoking only were 1.6 (95% CI, 1.0–2.6) in men and 2.0 (95% CI, 0.9–4.4) in women.

La Vecchia *et al*. (1998) reported an association between exclusive cigar smoking and cancers of the upper aerodigestive tract from a hospital-based case–control study in Italy and Switzerland. The cases in this study included cancers of the oesophagus as well as tumours of the oral cavity and pharynx and overlap with those in an earlier study by Franceschi *et al*. (1990).

Four other case–control studies have combined cigar and pipe smokers to examine the relationship of tobacco and alcohol consumption with cancers of the oral cavity and pharynx (Blot *et al*., 1988; Franceschi *et al*., 1990, 1992; Fernandez Garrote *et al*., 2001). The largest of these studies is that by Blot *et al*. (1988), based on 762 cases of oropharyngeal cancer diagnosed in four population-based tumour registries in the USA and 837 controls. Trained interviewers collected the information on tobacco and alcohol consumption. The relative risk estimate for men who smoked 40 or more cigars per week was 16.7 (95% CI, 3.7–76.7) when compared with the risk in never-smokers. The corresponding estimate in men who smoked 40 or more pipes per week was 3.1 (95% CI, 1.1–8.7).

Franceschi *et al*. (1990, 1992) reported a strong association between ever smoking cigars or pipes and diagnosis of cancers of the oral cavity (all subsites combined) in a hospital-based case–control study in Italy (relative risk, 20.7; 95% CI, 5.6–76.3). The

association was stronger for cancer of the mouth (relative risk, 21.9; 95% CI, 3.8–125.6) than for cancer of the tongue (relative risk, 3.4; 95% CI, 0.3–39.1).

Fernandez Garrote *et al*. (2001) examined the relationship between cigar or pipe smoking and incident cancer of the oral cavity and pharynx in a hospital-based study in Cuba. The relative risk estimate among men who smoked four or more cigars or pipes per day was 20.5 (95% CI, 4.7–89.7).

Table 2.2.3 presents the results of two studies that have stratified the analysis of cancer of the oral cavity and pharynx in relation to cigar and/or pipe smoking by levels of alcohol consumption (Blot *et al*., 1988; Iribarren *et al*., 1999). Men who smoked cigars and/or pipes and consumed three or more alcoholic drinks per day (Iribarren *et al*., 1999) or 30 or more alcoholic drinks per week (Blot *et al*., 1988) had a substantially higher risk than men who drank alcohol but abstained from smoking, or smoked pipe and/or cigar but drank alcohol only occasionally.

(*c*) *Lung cancer*

In most published cohort studies (Table 2.2.4) and case–control studies (Table 2.2.5), men who exclusively smoke cigars and/or pipes have a consistently higher risk for cancer of the trachea, lung and bronchus (ICD-162) than men who have never smoked any tobacco product.

Lung cancer risk increased with the number of cigars smoked per day in both the CPS-I (Shanks & Burns, 1998) and CPS-II (Shapiro *et al*., 2000) cohorts and in the Kaiser Permanente Medical Care Program cohort (Iribarren *et al*., 1999)

Lung cancer risk increased with the amount and/or duration of smoking in two large European multi-centre, hospital-based case–control studies (Lubin *et al*., 1984; Boffetta *et al*., 1999) and in a case–control study in China (Lubin *et al.*, 1992).

In the case–control by Boffetta *et al.* (1999), lung cancer risk decreased with time since cessation of cigar or pipe smoking.

The relationship between depth of inhalation and lung cancer risk from cigar and/or pipe smoking has been examined in several studies (Lubin *et al*., 1984; Benhamou *et al*., 1986; Shanks & Burns, 1998; Boffetta *et al*., 1999; Shapiro *et al*., 2000). Lung cancer risk was generally highest in cigar smokers who report that they inhale the smoke, but cigar smokers who report no inhalation still have a lung cancer risk two to five times higher than that for lifelong nonsmokers (Boffetta *et al*., 1999; Shapiro *et al*., 2000). Men who had switched from cigarette smoking to pipes or cigars reported deeper inhalation of the smoke and had higher risks for lung cancer than men who had always smoked pipes or cigars (Wald & Watt, 1997).

There is some evidence that the risk for lung cancer from cigar smoking may have increased over time. The relative risk estimates in cohort studies from the 1950s and 1960s generally ranged from 1.5 to 2.0 for men who were current smokers of either pipes or cigars at the time of the study (Kahn, 1966). However, all of the cohort studies (Doll & Peto, 1976; Carstensen *et al*., 1987; Lange *et al*., 1992; Tverdal *et al*., 1993; Ben-Shlomo *et al*., 1994; Shanks & Burns, 1998; Iribarren *et al*., 1999; Shapiro *et al*., 2000) and

case–control studies (Lubin & Blot, 1984; Benhamou *et al*., 1986; Damber & Larsson, 1986; Boffetta *et al*., 1999) published after 1975 have reported relative risk estimates of > 2.0, many with point estimates above 4.0.

(*d*) *Laryngeal cancer*

(i) *Cohort studies*

Cigar and pipe smoking were found to be strongly associated with increased risk for cancer of the larynx (ICD-9: 161) among men in three cohort studies (Table 2.2.6) (Kahn, 1966; Shanks & Burns, 1998; Shapiro *et al*., 2000).

Kahn (1966) identified six deaths from laryngeal cancer among male US veterans who smoked exclusively cigars at the time of enrolment in the US Veterans' Study and were followed from 1954 until 1962. The age-adjusted relative risk estimate associated with current cigar smoking was 10.3 (95% CI, 2.6–41.3).

Death from laryngeal cancer was associated with cigar smoking in analyses based on a 12-year follow-up of men in the CPS-I cohort (Shanks & Burns, 1998). The age-adjusted relative risk associated with current cigar smoking was 10.0 (95% CI, 4.0–20.6), based on seven deaths from laryngeal cancer among cigar smokers. The relative risk estimate was increased to 26.0 (95% CI, 8.4–60.7) among men who smoked five or more cigars per day and to 53.3 (95% CI, 0.7–296) among those who reported moderate to deep inhalation. The increased risk for laryngeal cancer associated with current cigar smoking during the 12-year follow-up was similar to the increased risk associated with current cigarette smoking during the first four years of follow-up [relative risk, 10.0; 95% CI, 3.5–28.5] (US Department of Health and Human Services, 1989).

Seven deaths from laryngeal cancer were recorded in CPS-II during follow-up from 1982 until 1994 among men who exclusively smoked cigars (Shapiro *et al*., 2000). Current cigar smoking was associated with an increased death rate from laryngeal cancer compared with never-smokers (relative risk, 10.3; 95% CI, 2.6–41.0). The corresponding age-adjusted estimate associated with current cigarette smoking was 10.5 (95% CI, 3.6–30.4) among men in CPS-II during the first 4 years of follow-up (1982–86) (US Department of Health and Human Services, 1989). In dose–response analyses based on a small number of cases, the relative risk associated with cigar smoking was higher in current smokers than in former smokers, in those who smoked more cigars per day, who reported smoking for 25 or more years and who reported inhaling the cigar smoke.

(ii) *Case–control study*

In a hospital-based case–control study in northern Italy, Franceschi *et al*. (1990) identified 162 incident cases of men with laryngeal cancer and 1272 controls between June 1986 and June 1989 (Table 2.2.7). Only one case exclusively smoked cigars or pipes, whereas 94% of cases and 76% of controls smoked cigarettes.

Several of the studies that examined the relation of cigar and/or pipe smoking to laryngeal cancer are not considered here, either because they included persons who also

smoked cigarettes (Falk *et al*., 1989; Muscat & Wynder, 1992) or because cigarette smokers were included in the referent group (Freudenheim *et al*., 1992).

(*e*) *Oesophageal cancer*

(i) *Cohort studies*

Exclusive smoking of cigars and/or pipes has been associated with increased risk for cancer of the oesophagus (ICD-9: 150) in several cohort studies (Table 2.2.8) (Kahn, 1966; Carstensen *et al*., 1987; Shanks & Burns, 1998; Shapiro *et al*., 2000).

In the US Veterans' Study, 14 deaths from oesophageal cancer occurred between 1954 and 1962 among men who, at enrolment, reported currently or formerly smoking cigars exclusively (Kahn, 1966). Risk was higher among current cigar smokers (relative risk, 5.3; 95% CI, 2.4–12.1, based on 12 deaths), than in former cigar smokers (relative risk, 2.4; 95% CI, 0.5–10.9, based on two deaths). Few male veterans had smoked pipes exclusively. The association between current pipe smoking and oesophageal cancer was based on only three deaths (relative risk, 2.0; 95% CI, 0.6–7.1).

Pipe and cigar smoking were associated with similar increases in death rate from oesophageal cancer in a cohort of 25 129 Swedish men (Carstensen *et al*., 1987). The Swedish Census Study cohort is unusual in that 27% of the men smoked a pipe, whereas only 5% smoked exclusively cigars and 32% cigarettes. The relative risk estimate associated with current pipe smoking was 3.6 (95% CI, 1.1–11.8, based on six deaths), whereas the association with current cigar smoking was 6.5 (95% CI, 1.3–33.5, based on two deaths).

The largest study of the association of oesophageal cancer with cigar smoking was based on CPS-I, in which 30 deaths from oesophageal cancer were identified among 15 191 men who reported exclusive cigar smoking at the time of enrolment (Shanks & Burns, 1998). The overall relative risk associated with current cigar smoking was 3.6 (95% CI, 2.2–5.6) relative to lifelong nonsmokers. Risk increased with the number of cigars smoked per day and with the self-reported depth of inhalation.

Shapiro *et al*. (2000) identified 17 deaths from oesophageal cancer among 15 756 men participating in CPS-II who reported current or former cigar smoking at the time of enrolment and were followed from 1982 through 1994. The relative risk estimate was slightly higher in current cigar smokers (relative risk, 1.8; 95% CI, 0.9–3.7) than in former cigar smokers (relative risk, 1.3; 95% CI, 0.6–2.8). Dose–response analyses based on nine deaths among current cigar smokers showed an increase in the risk of oesophageal cancer with the duration of smoking, but not with the number of cigars smoked per day or with depth of inhalation.

(ii) *Case–control studies*

The case–control studies on smoking and oesophageal cancer are summarized in Table 2.2.9 (Franceschi *et al*., 1990; Kabat *et al*., 1993; La Vecchia *et al*., 1998).

Kabat *et al*. (1993) examined the relationship of pipe and/or cigar smoking to specific histological types of oesophageal cancer in a hospital-based case–control study of 431 male

cases and 4544 hospital controls in the USA. Eleven cases of squamous carcinoma of the oesophagus and nine cases of adenocarcinoma of the distal oesophagus or gastric cardia had smoked pipes and/or cigars only. The risk among pipe and/or cigar smokers was not significantly higher than that of lifelong nonsmokers for squamous carcinoma (relative risk, 1.8; 95% CI, 0.8–4.1) or adenocarcinoma (relative risk, 1.1; 95% CI, 0.5–2.3).

None of the studies of pipe and/or cigar smoking in relation to oesophageal cancer have been sufficiently large to assess the possible interactions between smoking and alcohol consumption.

(*f*) *Stomach cancer*

Pipe and/or cigar smoking were consistently associated with a small increase in incidence of stomach cancer (ICD-9: 151) in most cohort studies (Table 2.2.8) and case–control studies (Table 2.2.9), but the number of cases who smoked cigars and/or pipes exclusively was small and the 95% confidence intervals in these studies often included the null.

Chao *et al*. (2002) examined the relationship between tobacco smoking and death from stomach cancer among men who currently or formerly smoked cigars or pipes at the time of enrolment in CPS-II. Increased mortality from stomach cancer was associated with current cigar smoking (relative risk, 2.3; 95% CI, 1.5–3.5; 25 deaths) and pipe smoking (relative risk, 1.3; 95% CI, 0.8–2.2; 16 deaths). Relative risk estimates were highest in men who reported smoking five or more cigars per day (relative risk, 4.2; 95% CI, 2.3–7.6) and those who inhaled the smoke (relative risk, 3.9; 95% CI, 1.9–8.0).

(*g*) *Colorectal cancer*

Current pipe and/or cigar smoking were associated with an increased risk for cancer of the colon and/or rectum (ICD-9: 153–4) in several cohort studies (Table 2.2.10).

The largest analysis is based on follow-up of the US Veterans' Study from 1954 until 1980. Heineman *et al*. (1995) reported a higher death rate from both colon cancer (relative risk, 1.3; 95% CI, 1.1–1.4) and rectal cancer (relative risk, 1.4; 95% CI, 1.2–1.8) among men who exclusively smoked pipes and/or cigars compared with never-smokers. The relative risk for colon cancer increased significantly with the number of cigars smoked per day (p for trend = 0.004) and the relative risk for rectal cancer increased with the number of pipes smoked per day (p for trend = 0.007).

Current smoking of pipes and/or cigars was associated with an increased risk for colon or colorectal cancer in the British Doctors' Study (relative risk, 1.7; 95% CI not stated) (Doll & Peto, 1976), the Lutheran Brotherhood Insurance Study (relative risk, 1.6; 95% CI, 0.8–3.2) (Hsing *et al*., 1998) and the Finnish Mobile Clinic Health Examination Study (relative risk, 1.5; 95% CI, 0.8–2.6) (Knekt *et al*., 1998). Current cigar and/or pipe smoking was also significantly associated with increased mortality from colorectal cancer among men in the CPS-II who had smoked for 20 or more years (relative risk, 1.3; 95% CI, 1.1–1.6) (Chao *et al*., 2000).

The Working Group was aware of no published case–control studies of exclusive pipe and/or cigar smoking in relation to cancers of the colon and rectum.

(*h*) *Cancer of the liver and intrahepatic bile ducts*

Carstensen *et al.* (1987) reported an association between current cigar smoking and increased death rates from cancer of the liver and biliary passages (ICD-9: 155–156) among 25 129 Swedish men followed from 1963 to 1979 (relative risk, 7.2; 95% CI, 2.2–23.4, based on four deaths) (Table 2.2.11).

Hsing *et al.* (1990a) reported an increased risk for primary liver cancer among current pipe and/or cigar smokers participating in the US Veterans' Study (relative risk, 3.1; 95% CI, 2.0–4.8).

(*i*) *Cancer of the gallbladder and extrahepatic bile ducts*

Cancer of the extrahepatic bile ducts (ICD-O: 156.1) was also associated with cigar and/or pipe smoking in a population-based case–control study of 105 histologically confirmed cases and 255 controls in Los Angeles County, USA (Table 2.2.12) (Chow *et al*., 1994). Two cases of cancer of the extrahepatic bile duct occurred among men who had ever smoked cigars or pipes exclusively (relative risk, 1.6; 95% CI, 0.3–9.9), compared with lifelong nonsmokers. Two additional cases involved the ampulla of Vater (relative risk, 7.6; 95% CI, 0.6–100.4).

(*j*) *Cancer of the pancreas*

Pipe and/or cigar smoking were associated with an increased risk for pancreatic cancer (ICD-9: 157) in most of the cohort studies (Table 2.2.13) and case–control studies (Table 2.2.14).

(i) *Cohort studies*

The largest study encompassed a 12-year follow-up of men in CPS-I (Table 2.2.13) (Shanks & Burns, 1998). The age-adjusted relative risk for death from pancreatic cancer among current exclusive cigar smokers, compared with lifelong nonsmokers, was 1.6 (95% CI, 1.2–2.1), based on 56 deaths. The risk for pancreatic cancer increased with the number of cigars smoked per day and with the depth of inhalation of the cigar smoke.

Higher risks for pancreatic cancer in current cigar smokers than in nonsmokers were also reported among men in the US Veterans' Study (relative risk, 1.5; 95% CI, 0.99–2.3, 27 deaths) (Kahn, 1966), in the Kaiser Permanente Medical Care Program Study (relative risk, 1.2; 95% CI, 0.5–2.9, 6 cases) (Iribarren *et al*., 1999) and in CPS-II (relative risk, 1.3; 95% CI, 0.9–1.9, 28 deaths) (Shapiro *et al*., 2000).

Current pipe smoking was significantly associated with increased risk for pancreatic cancer in the Swedish Census Study (relative risk, 2.8; 95% CI, 1.5–5.2) (Carstensen *et al*., 1987).

(ii) *Case–control study*

In the hospital-based case–control study reported by Muscat *et al*. (1997), men who ever smoked cigars exclusively had an increased risk for pancreatic cancer (relative risk, 3.1; 95% CI, 1.4–6.9) (Table 2.2.14). For ever smoking a pipe, the odds ratio for pancreatic cancer incidence was 1.8 (95% CI, 0.9–5.3).

(*k*) *Cancer of the bladder and kidney*

Epidemiological studies of cigar and/or pipe smoking in relation to cancers of the urinary bladder (ICD-9: 188) and kidney (ICD-9: 189) are summarized in Table 2.2.15 (cohort studies) and Table 2.2.16 (case–control studies). Men who exclusively smoked pipes had a significantly increased risk for bladder cancer in the Swedish Census Study (relative risk, 4.0; 95% CI, 1.9–8.6), the largest prospective study to evaluate pipe smoking (Carstensen et al., 1987). Men who smoked more than three cigars daily had an increased risk for bladder cancer relative to that of lifelong nonsmokers in CPS-I (Shanks & Burns, 1998) and CPS-II (Shapiro et al., 2000).

Taken separately, none of the cohort or case–control studies included a sufficient number of cases who smoked pipes or cigars exclusively to evaluate dose–response relationships precisely. The largest study of bladder cancer was the pooled analysis of European case–control studies by Pitard *et al.* (2001). The risk for bladder cancer increased significantly with number of years of smoking for both pipes (p for trend = 0.006) and cigars (p for trend < 0.001).

The four studies on kidney cancer (Kahn, 1966; Jensen *et al.*, 1988; McLaughlin *et al.*, 1995; Iribarren *et al.*, 1999) had limited statistical power to assess associations between pipe or cigar smoking and cancers of the renal pelvis or parenchyma.

(*l*) *Prostate cancer*

Men who exclusively smoked pipes or cigars had higher death rates from prostate cancer (ICD-9: 185) than lifelong nonsmokers during the first 8.5 years of follow-up of the US Veterans' Study (Kahn, 1966). Compared with lifelong nonsmokers, the relative risk estimate was 1.5 (95% CI, 0.98–2.4) for men who currently smoked pipes, and 1.5 (95% CI, 1.03–2.2) for current cigar smokers. Little association was seen between prostate cancer mortality and pipe and/or cigar smoking in the 26-year follow-up of the same cohort (Hsing *et al*., 1991). [The Working Group noted that the information on smoking was not updated during either follow-up, so that misclassification of exposure could have attenuated the findings in the longer follow-up.]

Hsing *et al*. (1990b) also studied the much smaller Lutheran Brotherhood Insurance Study cohort (Table 2.2.17). Mortality from prostate cancer was higher among men who ever smoked pipes or cigars than in lifelong nonsmokers (relative risk, 1.6; 95% CI, 0.7–3.5), although the association was based on only nine deaths. No increase in risk for prostate cancer was seen among men who currently smoked pipes in the Norwegian Screening Study (Tverdal *et al*., 1993) or among men who ever smoked pipes or cigars in

a population based case–control study in Montreal, Canada (Table 2.2.18; Sharpe & Siemiatycki, 2001).

(*m*) *Cancer of the haematopoietic system*

The cohort studies (Table 2.2.19) and case–control studies (Table 2.2.20) that have related cigar and/or pipe smoking to haematopoietic cancers are generally too small to be informative.

(*n*) *Cancer of other organs*

The Norwegian Screening Study examined the relationship between pipe and/or cigar smoking and the risk for brain cancer (Tverdal *et al.*, 1993). The number of cases was too small to be informative (Table 2.2.21).

2.2.2 *Bidi and other tobacco smoking*

(*a*) *Introduction*

This section covers smoking in forms practiced mainly in South Asia and in Africa. Most of the available studies have been conducted in India on the association of cancer with bidi smoking as well as, depending on the region studied, smoking of chillum (clay pipe), cheroot and chutta, including reverse chutta smoking. Other studies have reported on *khii yoo* smoking in Northern Thailand, kiraiku smoking in Kenya and reverse cigarette smoking.

Bidi smoking is the most common form of tobacco smoking in India. The bidi is an indigenous smoking stick 4–8 cm long, usually containing 0.15–0.25 g coarse tobacco flakes rolled in a rectangular piece of dried *temburni* leaf (*Diospyros melanoxylon*). The number of bidis produced and consumed in India is 7–8 times higher than the number of cigarettes, thus most studies on health risks to smokers in India have concentrated on bidi smoking. Moreover, cigarette smoking is common generally only in higher socioeconomic groups. Besides bidis and cigarettes, other smoking habits include various indigenous forms of pipe and cheroot smoking. Cheroots are small cigars made of heavy-bodied cured tobacco rolled in a dried tobacco leaf and tied with a thread. Chuttas are coarsely prepared cheroots. The length of chuttas varies from 5 to 12 cm. Chutta smoking is widespread in coastal areas of Andhra Pradesh, Tamil Nadu and Orissa. The hookah, or hooka, is a pipe that allows the tobacco smoke to pass through water before the smoker inhales it (water pipe). The chillum is a straight, conical clay pipe used for tobacco smoking.

When assessing the carcinogenic effects of smoking, it is necessary to consider several potentially confounding common habits such as chewing of betel quid with tobacco, chewing tobacco with or without lime, and drinking alcoholic beverages. Betel-quid chewing is the chewing of a quid made up of fresh betel leaves (*Piper betle*), areca nut (*Areca catechu*), slaked lime (calcium hydroxide) and almost always, tobacco. Various

condiments are often added in small quantities. Other forms of smokeless tobacco include a powder or paste used to clean the teeth and snuff.

(*b*) *Cancer of the oral cavity and pharynx*

Results of case–control studies on bidi and other tobacco smoking and cancer of the oral cavity and pharynx are presented in Table 2.2.22.

(i) *Cancer of the oral cavity*

Three hospital-based case–control studies on cancers of subsites of the oral cavity (gingiva, tongue and floor of the mouth, buccal and labial mucosa) were conducted at the Regional Cancer Centre in Trivandrum, Kerala, a state in southern India, during 1983–84. Control patients, matched for age (within 5 years), sex and religion, were selected among outpatients who came for treatment to the Medical College in Trivandrum, with respiratory, intestinal and genitourinary infections or who came for a cancer check-up for sites other than the head and neck. Both cases and controls were interviewed by trained social workers to elicit sociodemographic information, history of habits and clinical details. All cancer cases were confirmed by biopsy. Chewing of betel quid with or without tobacco, bidi smoking, cigarette smoking, alcohol use and nasal snuff inhalation were the main habits practiced by the study population. These studies analysed only men for smoking and alcohol habits because few women practiced these habits.

The case–control study on carcinoma of the gingiva consisted of 187 cases and 895 matched controls (Sankaranarayanan *et al*., 1989a). After using forward stepwise logistic regression on the four main habits of chewing of betel quid with tobacco, bidi smoking, alcohol drinking and snuff inhalation, the relative risk for smoking bidis for 20 years or less was 2.6 (95% CI, 0.7–9.9) and that for smoking bidis for more than 20 years was 2.1 (95% CI, 1.2–27.9).

The study on cancer of the tongue ($n = 188$) and floor of the mouth ($n = 40$) included 158 men and 70 women (Sankaranarayan *et al*., 1989b). Two controls were selected for each case and matched for age (within 5 years), sex and religion. Forward stepwise logistic regression was used to estimate relative risk for chewing of betel quid with tobacco, bidi smoking, bidi–cigarette smoking and cigarette smoking. A relative risk of 7.5 (95% CI. 2.6–21.7) was noted for men who smoked 20 or more bidis per day.

The study of cancer of the buccal and labial mucosa included 413 cases and 895 controls (Sankaranarayan *et al*., 1990a). When forward stepwise logistic regression was used to create a multivariate model of risk for cancer of the buccal and labial mucosa adjusted for other habits, bidi smoking had a relative risk of 2.9 (95% CI, 1.3–6.6) for a duration of the habit up to 20 years and 1.7 (95% CI, 1.1–2.6) for a habit that continued for 21 years or more.

A hospital-based case–control study was carried out during 1980–84 at the Tata Memorial Hospital, a cancer hospital in Mumbai (Bombay), India, on 713 men who were histopathologically diagnosed with oral cancer and 635 controls free from cancer, benign lesions or infectious diseases (Rao *et al*., 1994). The average age of the case group was

50.4 years and that of the control group was 45.4 years. Those who smoked bidis had a relative risk of 1.6 (95% CI, 1.3–2.0) for oral cancer. Men who smoked hookah and chillum had a relative risk of 5.0 (95% CI, 1.4–22.0). The trends in relative risks by intensity and duration of bidi smoking were both statistically significant ($p < 0.001$). [The Working Group noted that the study had several deficiencies, particularly in the selection of controls that resulted in cigarette smoking apparently being protective for oral cancer. The data analysis seemed to be confined to univariate analysis.]

A hospital-based case–control study was undertaken on 647 male patients with tongue cancer at the Tata Memorial Hospital, in Mumbai, India, between 1980 and 1984 (Rao & Desai, 1998). During the same period, 635 men, the majority of whom had come to the hospital for a check-up and were found to be free of cancer, benign lesions and infection, were selected as unmatched controls. Habits included betel quid, areca nut, tobacco and lime, bidi, cigarettes and other forms of tobacco smoking. Bidi smoking was by far the most common smoking habit. Unconditional logistic regression was used to estimate relative risk after stratification by age and place of residence. Bidi smoking was a significant risk factor for cancer of the base of the tongue (relative risk, 5.9; 95% CI, 4.2–8.2). Bidi smoking did not pose a statistically significant relative risk for cancer of the anterior tongue at any level of smoking intensity, but the relative risks for cancer of the base of the tongue were statistically significant at all levels of smoking intensity and a statistically significant trend was observed. Duration of smoking was not a significant predictor of risk for cancer of the anterior tongue, but it was for cancer of base of the tongue, with a significant trend that peaked at 21–30 years (relative risk, 7.7; 95% CI, 4.8–13.0). A model created with unconditional logistic regression that included bidi smoking, alcohol drinking, illiteracy, non-vegetarian diet and tobacco chewing showed that the greatest risk for cancer of the base of the tongue came from smoking bidis (relative risk, 4.7; 95% CI, 3.5–6.3). Cancer of the anterior tongue was not associated with bidi smoking in this model.

A population-based case–control study of upper aerodigestive tract cancers was conducted in Bhopal, central India (Dikshit & Kanhere, 2000). Men who had cancers that had been recorded during 1986–92 by the Bhopal Population-Based Cancer Registry were potential cases. Those with tongue cancer (not otherwise specified) or registered from death certificate only were excluded. Only those subjects who gave complete information on tobacco use were included, giving 163 lung cancer patients, 247 oropharyngeal cancer patients and 148 oral cavity cancer patients (all squamous-cell carcinomas) as study cases. A total of 260 controls were randomly selected after age stratification of a sample of about 2500 men recruited during 1989–92 in a tobacco habit survey of a random sample of Bhopal voters. After adjustment for age and tobacco quid chewing, the relative risk for smokers (bidis and/or cigarettes) was 1.5 (95% CI, 0.9–2.4). Smoking for more than 30 years led to a significant relative risk for oral cavity cancer of 4.3 (95% CI, 2.0–9.1). The estimated relative risk for the highest of three levels of cumulative years of smoking was 6.0 (95% CI, 2.6–13.7).

A hospital-based case–control study of cancer of the oral cavity was conducted in three areas of southern India (Bangalore, Madras and Trivandrum) between 1996 and

1999 (Balaram *et al*., 2002). A total of 591 incident cases were enrolled (309 men, 282 women). Control subjects were selected from the same hospitals (centres) as cases and were frequency-matched by centre, age and sex. In Madras and Bangalore, the controls were relatives and friends of other cancer patients. In Trivandrum, controls were selected from general medical outpatients or attendees of the cancer clinics who had been found free of malignancy. The control group included 292 men and 290 women. Odds ratios for men who smoked bidis were: for < 20 bidis per day, 2.0 (95% CI, 1.1–3.8); and for ≥ 20 per day, 2.5 (95% CI, 1.4–4.4).

(ii) *Pharyngeal cancer*

A hospital-based case–control study of oropharyngeal cancer was carried out in Nagpur, Maharashtra in Central India (Wasnik *et al*., 1998). The cases were 123 patients newly diagnosed with oropharyngeal cancer, confirmed by histopathology. Each case was matched with two hospital controls on age and sex. For each case, one control was selected from non-cancer patients and the other from patients with cancer at sites other than head and neck. Unconditional logistic regression analysis was used with the major risk factors identified from an initial model. Odds ratios for tobacco smoking, predominantly in the form of bidi and/or chillum, were 2.3 (95% CI, 1.2–3.7) after adjusment for tobacco chewing and outdoor occupation. [The Working Group noted some problems with the data analysis.]

A case–control study was undertaken on 1698 men with pharyngeal and laryngeal cancers seen at the Tata Memorial Hospital, Mumbai from 1980 to 1984 (Rao *et al*., 1999). There were 678 patients with cancer of oropharynx, 593 patients with cancer of the hypopharynx, and 427 patients with cancer of the larynx. A total of 635 controls were selected from male outpatients at the same hospital who had been found to be free from cancer, benign tumours and infectious disease. The estimated relative risk for bidi smoking was 5.6 (95% CI, 4.1–7.6) for cancer of the oropharynx and 2.0 (95% CI, 2.0–3.5) for cancer of the hypopharynx. A dose–response relationship was observed for intensity and duration of bidi smoking for both sites. When unconditional logistic regression was performed with adjustment for alcohol, illiteracy, diet and tobacco chewing, bidi smoking was the most important factor for both sites.

In the study by Dikshit and Kanhere (2000) (described in Section 2.2.2(*b*)(i)), a high relative risk for oropharyngeal cancer among subjects who smoked only bidis (odds ratio, 7.9; 95% CI, 5.1–12.4) and a positive relationship with intensity of bidi smoking were observed.

(iii) *Oral leukoplakia*

Case reports

A case of reverse cigarette smoking was reported from the Hospital ‘De Tjongerschans’, Heerenveen, the Netherlands, where a dentist had referred a 59 year-old woman who had smoked for 40 years with the glowing end inside the mouth, having learnt the habit from her mother who originated from Aruba in the Netherlands Antilles.

Oral examination revealed a thick, leathery palatal mucosa with burnt, charred areas. The buccal mucosa at both sides showed diffuse leukoplakic lesions. Biopsy of the palatal leukoplakia showed hyperkeratosis with slight to moderate epithelial dysplasia. After 4 years of follow-up, no malignant changes were noted (Hogewind *et al.*, 1987).

A 69-year old immigrant from the Philippines was referred to the Department of Stomatology at the School of Dentistry, University of Manitoba in Winnipeg, Canada, with an unusual lesion of the hard palate. She reported having practiced reverse smoking for 10 years, having begun the habit in the Philippines. A white lesion covered her entire hard palate and near the mid-line there was an area of charred tissue. Minor salivary glands stood out as red spots, as in nicotine stomatitis. A biopsy of the hard palate revealed moderate hyperkeratinization without dysplasia. A 50-year-old woman who had emigrated from the Caribbean had a clinical history similar to that of the woman described above. She was diagnosed with hyperkeratinization without dysplasia (Stoykewych *et al.*, 1992).

Cross-sectional and case–control studies (Table 2.2.23)

A cross section of villagers aged 21 years and above, in four villages in three districts of Andhra Pradesh where it was known that reverse chutta smoking was practised, was surveyed for palatal lesions (Van der Eb *et al*., 1993). A random sample of 758 persons was drawn from the electoral rolls and 480 of them (250 women, 230 men) were examined and interviewed by health professionals with special training. Many could not be examined due to bad weather, others due to emigration or death, but refusals were uncommon. Reverse chutta smokers constituted 33.3% of the sample, about two-thirds of which were women; conventional chutta smokers amounted to 12.5% (mainly men); bidi smokers, 4.2% (all men); cigarette smokers, 2.9%; tobacco chewers, 2.1 %; and those with mixed habits, 4.2%. Non-tobacco users constituted 33.5% of the sample, about two-thirds of which were women, and 7.3% were former smokers. Palatal lesions were found with all smoking habits, but were far more common and most severe in reverse smokers. The age and sex-standardized percentages of palatal lesions were as follows: 0.9% of the men and 3.9% of the women who were nonsmokers; 55% of the bidi smokers; 54.7% of the men and 63.3% of the women who were conventional chutta smokers; and 93.0 % of the men and 92.2 % of the women who practised reverse chutta smoking. Palatal lesions found in higher proportions in reverse smokers included preleukoplakia, leukoplakia and palatal keratosis. All but one of the atrophic areas were found in current and ex-reverse chutta smokers and all the nine carcinomas found were in current reverse chutta smokers.

A population-based case–control study of leukoplakia was carried out in Kenya by house-to-house survey using a cluster-sampling technique (Macigo *et al.*, 1996). Individuals with leukoplakia found through oral examination (n = 85) were enrolled as cases. Controls (n = 141) were matched for sex, age and the cluster of origin. Tobacco was smoked in the form of cigarettes and *kiraiku* rolls, a type of local, handmade, smoking sticks, using cured, dried and crushed tobacco, rolled in any one of the following: dried banana leaves and stem peelings, dried corn husks, newspaper or other paper. The relative risk for oral leukoplakia in current cigarette smokers was 8.4 (95% CI, 4.1–17.4) and that

for current *kiraiku* smokers was 10.0 (95% CI, 2.9–43.4). In former *kiraiku* smokers, the relative risk was 4.9 (95% CI, 2.3–10.4). Duration of smoking before cessation showed a trend towards greater risk with increasing duration. A gradual downward trend was seen for the number of years since quitting *kiraiku* smoking; however, the relative risk for an interval of more than 10 years since quitting was still significantly increased. [The Working Group noted that the study did not adequately control for possible confounding with cigarette smoking.]

Intervention studies

A large controlled prospective intervention trial for primary prevention of oral cancer was conducted in India in the districts of Ernakulam (Kerala), Bhavnagar (Gujarat) and Srikakulam (Andhra Pradesh). The intervention cohort consisted of over 12 000 tobacco users of 15 years of age and older in each of the three districts. Members of this cohort were interviewed about their tobacco use and examined for the presence of oral lesions. They took part in an educational programme on tobacco use through annual follow-ups during 1977–88. The control cohort consisted of over 17 000 persons, all tobacco users aged 15 and over in randomly selected villages in the same three districts, who were examined and followed up in a similar manner to that for the intervention cohort, but with minimal educational intervention during 1966–77 (Gupta *et al.*, 1986a). Eight annual follow-up surveys were conducted after the first 2 years, covering a 10-year period (1977–88). The analysis was restricted to tobacco users with an appropriate length of follow-up period. The results are discussed district by district, and are summarized in Table 2.2.24.

Bhavnagar District

The size of the intervention cohort in Bhavnagar was 12 221 and that of the control cohort was 3704, all subjects were men as very few women used tobacco in that area. Both bidis and clay pipes were commonly smoked by men in the Bhavnagar District. A small proportion of men practised chewing habits.

After five years of follow-up, the proportion of individuals re-examined at least once in the intervention cohort was 96.5% and in the control cohort, 83.5%. The proportions of individuals who quit their tobacco habits in the control and intervention cohorts were 9% and 13%, respectively. There was little difference in the incidence rate of leukoplakia between the two cohorts (Gupta *et al.*, 1986b).

Srikakulam District

The size of the intervention cohort in Srikakulam District was 12 038 and that of the control cohort was 7542. Smoking was the major tobacco habit, practised mostly in the form of reverse chutta smoking. Men also smoked chuttas in the conventional manner, and bidis. Women practised only reverse chutta smoking. The proportions of individuals who quit their tobacco habits in the control and intervention cohorts were 3.5% and 17%, respectively.

Incidence rates of oral precancerous lesions (mainly palatal lesions associated with reverse smoking) were substantially lower in the intervention cohort than in the control cohort for all tobacco habit groups. The 5-year age-adjusted incidence rates per 1000 for palatal changes for women who were reverse smokers were 513.9 in the control area and 292.0 in the intervention area and, among men, 427.7 and 163.3, respectively. The rate ratio for the protective effect of intervention on reverse smokers was 0.38 in men and 0.57 in women (Gupta *et al.*, 1986b).

Ernakulam District

At baseline in the intervention cohort, the prevalence of leukoplakia was 2.9% in the intervention cohort and 2.7% in the control cohort (Mehta *et al.*, 1982).

After eight years of follow-up, the expected number of cases of leukoplakia in the intervention cohort was calculated using age- and sex- specific incidence rates from the control cohort. The observed number of leukoplakia was only 41% of the expected number in men and only 28 % of the expected number in women (Gupta *et al.*, 1990).

After 10 years of follow-up, 14.3% of tobacco users in the intervention cohort had discontinued their tobacco habit as compared with 4.5% in the control cohort. Among individuals who reported stopping bidi smoking, only one bidi-associated leukoplakia and one central papillary atrophy of the tongue were found, compared to the expected 5.8 leukoplakia, 6.0 central papillary atrophy and 27.1 other bidi-associated oral mucosal lesions (leukoedema, preleukoplakia and smokers' palate), based on the incidence rates among all other individuals. The differences in observed and expected rates were statistically significant ($p < 0.05$) (Gupta *et al.*, 1992).

The relative risks for malignant transformation for the nodular form of leukoplakia were reported to be 3243.2, for ulcerated leukoplakia 43.8 and for homogeneous leukoplakia 25.6 when compared with individuals with a tobacco habit, but no oral precancerous lesions (Gupta *et al.*, 1989).

[The Working Group noted the 10-year calendar time difference between the intervention and control cohorts.]

The educational intervention that was undertaken in these studies was helpful in reducing the use of tobacco in all areas and in increasing cessation rates in two of the three areas. Spontaneous regression rates of oral precancerous lesions were higher among individuals who reported stopping or reducing their tobacco use than in those who did not. The incidence rates of oral precancer were lower in the intervention cohorts in two of the areas (leukoplakia in Ernakulam and palatal changes in Srikakulam) than in the respective control cohorts.

(*c*) *Lung cancer*

In northern Thailand, hand-rolled cigars called *khii yoo* are commonly smoked. In a hospital-based case–control study conducted in Chiang Mai, Thailand, the odds ratios for lung cancer for *khii yoo* smoking were 1.2 in men and 1.5 in women ($p > 0.05$) (Simarak *et al.*, 1977).

In the case–control study by Dikshit & Kanhere (2000), described in Section 2.2.2(*b*)(i), the age-adjusted relative risk for lung cancer among smokers of bidis only was 11.6 (95% CI, 6.4–21.3) (Table 2.2.25).

A hospital-based case-control study of lung cancer was conducted in Chandigarh, northern India. A total of 235 men with cytologically or histologically confirmed lung cancer was recruited between January 1995 and June 1997. Four hundred and thirty-five male controls were selected from visitors and attendants of the patients. Results were presented both separately and combined for bidi, cigarette and hookah smoking. For the purpose of analysing smokers of different types of tobacco products, cigarette equivalents were calculated by applying a weight of 1 (= 1g of tobacco) to cigarettes, 0.5 to bidis, and 4 hookahs. The odds ratio for bidi smoking was 5.8 (95% CI, 3.4–9.7), and for hookah smoking, 1.9 (95% CI, 0.9–4.4). Risks by intensity of smoking bidis increased at successively higher intensities. The highest odds ratio for 9 pack–years was for bidi (3.9; 95% CI, 2.1–7.1), followed by hookah (1.9; 95% CI, 0.9–4.4) and cigarette (1.9; 95% CI, 0.9–4.4). There was a clear decreasing trend for years since quitting (Gupta *et al.*, 2001).

(*d*) *Laryngeal cancer*

The case–control studies on bidi smoking and laryngeal and oesophageal cancer are summarized in Table 2.2.26.

In a hospital-based case–control investigation in Trivandrum, India, information on 190 men with squamous-cell carcinoma of the larynx confirmed by biopsy and 546 male controls was collected during 1983–84 (Sankaranarayanan *et al*., 1990b). Unconditional logistic regression, sometimes with a forward stepwise approach, was used to produce estimates of relative risk adjusted for age and religion. Occasional users were excluded from the analyses of frequency, duration and age at starting smoking. All levels of intensity of bidi smoking were associated with significant relative risk estimates, ranging from 1.8 (95% CI, 1.1–2.9) to 5.1 (95% CI, 2.7–9.6), with a highly significant trend ($p < 0.001$). When duration of bidi smoking was tested in a forward stepwise logistic regression model adjusted for cigarette smoking, alcohol consumption and the combination of bidi with cigarette smoking, the relative risk for bidi smoking for more than 21 years was 7.1 (95% CI, 4.0–12.5), with a highly significant trend ($p < 0.001$). Daily intensity of bidi and cigarette smoking also exhibited a highly significant trend in this model ($p < 0.001$).

The case–control study described in the section on cancer of the pharynx (Rao *et al*., 1999) also included 427 patients with cancer of larynx. A total of 635 controls were selected from male outpatients at the same hospital who had been found to be free from cancer, benign tumours and infectious disease. Cases and controls were stratified into four 5-year age groups and by place of residence. The estimated relative risk for bidi smoking was 2.3 (95% CI, 1.7–3.2). A dose–response relationship was observed for number of bidis smoked daily. When unconditional logistic regression was performed using five factors, bidi smoking was the most important risk factor.

(*e*) *Oesophageal cancer*

A hospital-based case–control study of oesophageal cancer was carried out during 1983–84 at the Regional Cancer Centre, Trivandrum in Kerala, India (Sankaranarayanan *et al*., 1991). Among 267 cases recruited to the study, 67% were histopathologically confirmed and the remainder were radiologically diagnosed. From outpatients attending the centre and surrounding medical complex during this period, 895 controls with non-malignant or pre-malignant conditions were selected. Relative risks were adjusted for age and religion through unconditional logistic regression. Significant effects were noted in men for all levels of intensity of bidi smoking and for a duration of more than 20 years of bidi smoking (Table 2.2.26). The trends for intensity and for duration of smoking of bidis and of bidis and cigarettes were all significant. In a forward stepwise logistic regression model, duration of bidi smoking and daily frequency of bidi/cigarette smoking emerged as statistically significant factors.

A hospital-based case–control study investigated the risk for oesophageal cancer by subsite and histomorphology at the Kidwai Memorial Institute of Oncology, Bangalore, in Karnataka, India (Nandakumar *et al*., 1996). Of 549 patients (284 men, 265 women) diagnosed with oesophageal cancer between 1982 and 1985, data were collected on 343 (177 men, 166 women) using a structured questionnaire. Of these, 236 cases had a microscopically confirmed diagnosis of squamous-cell carcinoma. For each case, two controls were randomly selected from a database of 1875 patients who were proven not to have cancer or benign tumours. They were matched on sex, 5-year age group, area of residence and calendar time of their hospital visit. Among the men, 12 cases and 15 controls predominantly smoked bidis but also smoked cigarettes, and were combined with the bidi smokers. Similarly, four men who predominantly smoked cigarettes but also smoked bidis were considered to be cigarette smokers. Women were not included in the analyses because few of them practised those habits. After adjusting for tobacco chewing, chewing of betel quid without tobacco, alcohol drinking and cigarette smoking, bidi smoking had an odds ratio of 4.0 (95% CI, 2.3–6.8) for cancer of the oesophagus. Bidi smoking resulted in a significantly elevated risk for all three segments of the oesophagus, but the highest was for the upper third (odds ratio, 7.1; 95% CI, 1.1–46.8), followed by the middle third (odds ratio, 6.0; 95% CI, 2.5–14.5) and the lower third (odds ratio, 3.9; 95% CI, 1.4–10.7).

In a case–control study conducted from February 1994 to March 1997 at the All India Institute of Medicine (AIIMS), New Delhi, 150 patients with histopathologically confirmed oesophageal cancer were enrolled as cases (Nayar *et al*., 2000). An equal number of controls were selected from individuals accompanying patients to the same hospital, after matching for age (± 5 years), sex and socioeconomic status. Both cases and controls had to meet the criterion that they had not suffered from any major illness in the past that had caused them to change their dietary consumption pattern. Data were stratified on socioeconomic status into five groups. Using unconditional stepwise logistic regression, bidi smoking showed an odds ratio of 2.0 (95% CI, 1.2–3.3). This was adjusted for other

risk factors in the model, such as chewing of betel leaf with tobacco and low consumption of vegetables other than leafy vegetables.

(*f*) *Stomach cancer*

A hospital-based case–control study of stomach cancer was conducted at the Cancer Institute (WIA), Madras, located in south India, as part of a multi-centre study (Gajalakshmi & Shanta, 1996; see Table 2.2.27). Patients with stomach cancer confirmed by histology, endoscopy, barium meal or surgery were included in the study. The control pool was formed by cancer patients diagnosed at the Cancer Institute, excluding those with cancer of the oral cavity, pharynx, larynx, lung, urinary bladder, pancreas and gastro-intestinal tract. Each case was matched with a cancer patient from the control pool on age, sex, religion and mother tongue. Details collected on smoking habits included type of tobacco smoked, age at starting smoking, amount smoked per day, and age at cessation (more than 6 months prior to diagnosis of cancer). The odds ratio for stomach cancer for current smoking of any type of tobacco was 2.7 (95% CI, 1.8–4.1); for current bidi smoking the odds ratio was 3.2 (95% CI, 1.8–5.7); that for chutta smoking was 2.4 (95% CI, 1.2–4.9); that for having more than one smoking habit was 8.2 (95% CI, 1.7–38.9). The trend for increasing lifetime exposure to bidi smoking was highly significant ($p < 0.001$). A significant trend for increasing lifetime chutta smoking was also seen. In a multivariate model including tobacco habits, alcohol drinking and various dietary factors, as well as income, education and area of residence, the odds ratios for current smokers, former smokers and ever-smokers were not substantially different from those in the above models.

2.3 Synergistic carcinogenic effects of tobacco smoke and other carcinogens

2.3.1 *Introduction*

This section addresses the combined effects on cancer risk of cigarette smoking and other agents also associated with risk, excluding smokeless tobacco. The chapter is restricted to studies of smoking and exposures to single agents and does not address modification of risk by diet, whether by specific foods, nutrients or micronutrients.

For many cancers, including lung cancer, multiple causal factors are relevant and persons being exposed to more than one risk factor may be subject to risks beyond those anticipated from the individual agents acting alone. The terminology and methods used to characterize the combined effects of two or more agents have been poorly standardized with substantial blurring of concepts derived from toxicology, biostatistics and epidemiology (Greenland, 1993; Mauderly, 1993). Epidemiologists refer to *effect modification* if effects of multiple agents are interdependent whereas toxicologists assess whether the effects of multiple agents are *synergistic* (positive interdependence) or *antagonistic* (negative interdependence). Statisticians test whether there is *interaction* between independent determinants of cancer risk. For the purposes of this report, epidemiological concepts are followed, such that interdependence of effects is termed *effect modification*, and *synergism* and *antagonism* are used to describe the consequences of the interdependence of disease risk when both risk factors are present (Rothman & Greenland, 1998). The term *interaction* is reserved for the statistical approach for testing whether effect modification is present.

In a toxicological paradigm that extends from exposure through dose and finally to biological effects, there are a number of different points at which smoking might influence the effect of another risk factor. The 1985 Report of the US Surgeon General (US Department of Health and Human Services, 1985) set out a broad conceptual framework for considering the joint effect of smoking with an occupational agent, which can be extended more generally to other risk factors. The levels of potential interaction between agents are multiple, ranging from molecular to behavioural (Table 2.3.1). Current research on the molecular basis of carcinogenesis is improving the understanding of potential points of interaction at the mechanistic level, but approaches to assess effect modification remain largely empirical. Some of the potential points of interaction (Table 2.3.1) would have an impact on the level of exposure, others — including the exposure–dose relationship — on the dose–response relation of exposure with risk, either for smoking or for the modifying factor. Typically, epidemiological data do not provide evidence relevant for assessing each of these potential points of interaction of another risk factor with cigarette smoking. In assessing the presence of synergism or antagonism, a model is assumed to predict the combined effect from the individual effects; in the absence of sufficient biological understanding to be certain of the most appropriate model, the choice is often driven by convention or convenience. There is also a potential for the combined effects to vary over the life-span; as the carcinogenesis

process advances, agents are cleared (e.g. chrysotile asbestos fibres are cleared or dissolve in the lung), or exposure to tobacco or the other agent ends. Epidemiological studies generally only capture combined effects over a single interval of time.

In a multi-stage formulation of carcinogenesis, inferences as to the stages at which agents act can be made based on patterns of effect modification, particularly if data are available on the timing of exposure (Doll, 1971; Whittemore, 1977; Thomas & Whittemore, 1988). Effect modification also has implications for prevention, as synergism may increase the disease burden beyond that anticipated from the risk of smoking alone and may place some people, e.g. occupationally exposed workers, at particularly high risk.

The identification of studies addressing effect modification is difficult as authors may not have noted that effect modification was examined and search terms are not sufficiently conclusive. It was also impossible to search all studies involving smoking and potential modifying factors. Consequently, targeted searches were used to find published articles that specifically mentioned interaction, synergism or antagonism. Summary reviews also could be used as a further source of references.

(*a*) *Epidemiological concepts*

The effect of a risk factor for a disease may be estimated on an absolute scale or on a relative scale. In the absolute risk model, the risk ($r(x)$) of disease associated with some factor (x) can be expressed in a simple linear relationship as:

$$r(x) = r_0 + \beta x$$

while in a relative risk relationship, risk is given by:

$$r(x) = r_0 \times (1 + \beta x) = r_0 + r_0 \beta x$$

where r_0 is the background rate of disease in the absence of exposure and β describes the increment in risk per unit increment in exposure to x. Under a relative risk characterization of disease risk, the impact of an exposure on disease risk, $r_0 \beta x$, depends on the background rate. In the absolute risk model, the effect of exposure on disease risk, βx, does not depend on the level of r_0. The selection of the risk model (i.e. absolute or relative), has substantial implications for interpreting the combined effects of two agents and for extending risks observed in one population to another population that may not have comparable r_0 because of differing patterns of risk factors other than the exposure of interest.

These two models can be extended to address the effects of multiple causes of disease. In the example of two exposures, x_1 and x_2 (e.g. radon and smoking), disease risk ($r(x_1,x_2)$) under a relative risk model is given by:

Additive model: $r(x_1,x_2) = r_0 + r_0\beta_1 x_1 + r_0\beta_2 x_2$

Multiplicative model: $r(x_1,x_2) = r_0 \times (1 + \beta_1 x_1)(1 + \beta_2 x_2) =$

$r_0 + r_0\beta_1 x_1 + r_0\beta_2 x_2 + r_0\beta_1 x_1\beta_2 x_2 =$

$r_0 + r_0\beta_1 x_1 + r_0\beta_2 x_2(1 + \beta_1 x_1)$

Comparison of these two models highlights the differing dependence of the effect of x_2 on r_0 and x_1. In assessing the role of x_2 on disease risk, a multiplicative model implies that the effect of x_2 on disease risk depends not only on r_0, but also on the effect of x_1. In contrast, under the additive model, the effect of x_2 depends on r_0 but not on the effect of x_1.

Epidemiologists describe the effect of exposures in causing disease either as a difference on an absolute scale or as a ratio on a relative scale. The preference has been for ratio measures (e.g. the relative risk that compares risk in the exposed group to risk in a referent group, typically the unexposed group). Effect modification is considered to occur when the combined effect of two or more variables is larger or smaller than the anticipated effect predicted by the independent effects, based on the measure used (Greenland, 1993). Current analytical approaches compare the combined effect to predictions based on either additivity or multiplicativity of the individual effects, that is, using either the absolute risk or relative risk models described above. Thus, a factor may be an effect modifier in the additive model and not in the multiplicative model. Epidemiologists have recognized that the appropriate scale for assessing a combined effect depends on the intent of the analysis (Rothman *et al.*, 1980). For public health purposes, an effect greater than additive is considered as synergistic. Biological mechanisms, if sufficiently understood, may suggest an alternative scale for assessment.

Although epidemiological methods have been proposed for assessing effect modification, no strict criteria for determining its presence have been defined. Rothman (1976) developed a synergy index that quantifies departure from independence of effects. Statistical significance alone is recognized to be an insufficient criterion (Greenland, 1993), and the interpretation of patterns of interdependence remains subjective. Additionally, inadequate statistical power often limits the assessment of effect modification (Greenland, 1983) and interpretation of possible effect modification should also consider the consequences of exposure measurement error, which may differ in degree for smoking and the other agent(s).

The concern about limited power extends specifically to studies of smoking and disease. Particularly limiting is the small number of cases that occur among nonsmokers in the studies of occupational agents.

(*b*) *Statistical concepts*

Statisticians have used the term ‘interaction’ to refer to interdependence as detected by a statistical approach or ‘model’. Interaction, which is equivalent to the epidemiological concept of effect modification, has typically been assessed in a regression framework using product terms of the risk factors of interest to test for effect modification (Thomas & Whittemore, 1988; Rothman & Greenland, 1998). For example, interaction between two risk factors, x_1 (e.g. smoking) and x_2 (e.g. radon exposure) could be assessed using the following model:

$$r(x_1, x_2) = 1 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_1 x_2$$

In this linear model, the product or interaction term, $\beta_3 x_1 x_2$, estimates the joint contribution of the two agents to the risk. The model provides an estimate of the value of β_3 and a test of the statistical significance of β_3 for the null hypothesis: $\beta_3 = 0$. This modelling approach inherently assumes a mathematical scale on which the interaction is characterized, the usual choices being additive or multiplicative. Most often, primarily because of computational convenience, the multiplicative scale is used. Alternative approaches for assessing interaction have been described (Thomas, 1981; Breslow & Storer, 1985; Lubin & Gaffey, 1988). These choices more flexibly estimate the combined effects of risk factors without imposing the rigidity of a particular scale. Imprecision and bias from measurement error may also limit estimates obtained from such modelling approaches.

(*c*) *Characterizing the burden of cancer attributable to smoking*

In describing the burden of disease, epidemiologists use a quantity referred to as the attributable risk (Rothman & Greenland, 1998). The attributable risk indicates the burden of disease that could be avoided if exposure to the agent of concern were fully prevented. This measure has been widely used for cigarette smoking to estimate the burden of avoidable tobacco-caused disease.

One form of the attributable risk, the population attributable risk (PAR) describes the proportion of disease in a population associated with exposure to an agent. For a factor, x_1, having an associated relative risk RR_1, PAR is calculated as below, where I and I_0 and P_1 and P_0 are the disease rates and probabilities of exposure in the population under current conditions and under some counterfactual set of conditions of differing exposure (for smoking, generally the complete prevention of smoking), respectively:

$$\begin{aligned} PAR(x) &= \frac{I - I_0}{I} \\ &= \frac{P_1 I_1 + P_0 I_0 - I_0}{P_1 I_1 + P_0 I_0} \\ &= \frac{P_1(RR_1 - 1)}{P_1(RR_1 - 1) + 1} \end{aligned}$$

For diseases caused by several agents, the total burden of disease that is theoretically preventable may exceed the observed number of cases, or 100%, if there are synergistic patterns of effect modification on an additive scale. For example, an estimate of smoking-attributable lung cancer cases can be conceptualized as including those cases caused by smoking, and those caused by radon and smoking in smokers. In the above formula, the attributable risk figure for smoking includes those cases caused by smoking alone and radon and smoking acting together; similarly, the attributable risk figure for radon would include those cases caused by radon alone and those caused by radon acting together with smoking. Combining the attributable risk estimates for smoking and radon counts the jointly determined cases twice. This subtlety of the attributable risk statistic is not uni-

versally appreciated and there is widespread misperception that the attributable risk should add up to 100% when all the various causes of the cancer are considered.

For two factors, x_1 and x_2, the sum of the individual exposure-specific PAR estimates, PAR(x_1) and PAR(x_2), can exceed 100%. However, when evaluating two factors, these PARs are incorrectly determined by contamination of the referent groups; i.e. the subgroup of individuals with $x_1 = 0$ includes subjects for whom x_2 may be 0 or 1 and the subgroup of individuals with $x_2 = 0$ includes persons for whom x_1 may be 0 or 1.

For joint exposures to x_1 and x_2, PAR is defined as:

$$\mathrm{PAR}_{(x1,x2)} = \frac{P_{1,1}(\mathrm{RR}_{1,1} - 1) + P_{1,0}(\mathrm{RR}_{1,0} - 1) + P_{0,1}(\mathrm{RR}_{0,1} - 1)}{P_{1,1}(\mathrm{RR}_{1,1} - 1) + P_{1,0}(\mathrm{RR}_{1,0} - 1) + P_{0,1}(\mathrm{RR}_{0,1} - 1) + 1}$$

The PAR for two exposures, e.g. smoking and radon, is the sum of components due to smoking in the absence of radon exposure, to radon exposure in the absence of smoking, i.e. in never-smokers, and to the combined effect of radon exposure and smoking. PAR(x_1,x_2), calculated with the above formula, cannot exceed 100%.

Finally, the definition of PAR can be generalized for a continuous exposure, x, with exposure distribution f, as

$$\begin{aligned}\mathrm{PAR(x)} &= \frac{I - I_0}{I} \\ &= \frac{\int I(\mathrm{x})\mathrm{f}(\mathrm{x})\mathrm{dx} - I_0}{\int I(\mathrm{x})\mathrm{f}(\mathrm{x})\mathrm{dx}} \\ &= \frac{\int \mathrm{RR}(\mathrm{x})\mathrm{f}(\mathrm{x})\mathrm{dx} - 1}{\int \mathrm{RR}(\mathrm{x})\mathrm{f}(\mathrm{x})\mathrm{dx}}\end{aligned}$$

where RR(x) is the relative risk for exposure level x, relative to zero exposure.

2.3.2 *Asbestos*

Asbestos, a term referring to a group of fibrous silicates, has long been identified as a cause of lung cancer, and was classified by IARC as *carcinogenic to humans* (Group 1) (IARC, 1987). Many studies of asbestos-exposed workers have addressed the combined effect of asbestos and smoking on lung cancer risk. Data available at the time allowed the Working Group to establish that 'the relationship between asbestos exposure and smoking indicated a synergistic effect of smoking with regard to lung cancer' (IARC, 1987). There have been several recent comprehensive reviews on this topic (Erren *et al.*, 1999; Lee, 2001; Liddell, 2001), as well as several frequently-cited earlier reviews (Saracci, 1977; Vainio & Boffetta, 1994). The topic has also been addressed in several reviews on occupational carcinogens in general and smoking (Saracci, 1987; Saracci & Boffetta, 1994).

Tables 2.3.2 and 2.3.3 summarize the characteristics of the principal relevant case–control and cohort studies, respectively, reviewed by Lee (2001), together with one more recent study (Gustavsson *et al.*, 2002). These studies vary widely in design and in the quality and extent of information available on smoking and on asbestos exposure. In the cohort studies, exposure to asbestos was generally at levels that would be considered high in relation to today's occupational standards. Exposure estimates were based on available sources of information including measurements that were generally limited in scope. Types of information included: job and industry, judgement of industrial hygienists, and self-report. The extent of the available information on smoking was also variable and in many of the cohort studies information was collected only at the initiation of follow-up or some other single point in time. In the case–control studies, interviews with the participants or with a surrogate respondent for deceased persons were the principal source of information.

Tables 2.3.4 and 2.3.5, adapted from Lee (2001), provide the relative risks for the four strata created by dichotomous classification of smoking and asbestos exposure. The general pattern of the risk estimates indicated departure from additivity in many of the studies, although the findings of some studies did not indicate synergism (McDonald *et al.*, 1993; McDonald *et al.*, 1999). The extent of departure from additivity varied across studies, from only slightly greater than additive (Gustavsson *et al.*, 2002) to a multiplicative interaction (Hammond *et al.*, 1979).

The three recent reviews include quantitative summaries of the evidence on effect modification. [The Working Group did not attempt to replicate these analyses.]

Erren and colleagues (Erren *et al.*, 1999) identified 17 relevant reports published from 1966 to 1996. Of these, 12 were included in the analysis, which used Rothman's synergy index. The value of the synergy index exceeded unity in all of the 12 studies. After excluding one study and verifying the absence of significant heterogeneity between the studies, the weighted summary value of the synergy index was estimated as 1.66 (95% CI, 1.33–2.06).

Liddell (2001) focused on seven cohort studies and six case–control studies. He also calculated an index of effect modification, termed the relative asbestos effect (RAE), which exceeded unity if the effect was greater in nonsmokers than in smokers. For the cohort studies, the estimate of RAE was 2.04 (95% CI, 1.28–3.25), indicating that the relative risk for asbestos exposure in nonsmokers was twice that in smokers; for the case–control studies, the RAE estimate was 0.83 (95% CI, 0.53–1.30). Liddell set aside the case–control data as being of insufficient quality and found that the data from cohort studies were not consistent with a fully multiplicative interaction. [The Working group noted that Liddell did not test for departure from additivity].

Lee (2001) analysed data from 23 studies, testing for additivity and multiplicativity. The studies reviewed showed strong evidence for departure from additivity. A test of multiplicativity was used that was conceptually comparable to Rothman's synergy index. Although the value of this index varied substantially across studies, the summary value of

the synergy index derived by meta-analysis was 0.90 (95% CI, 0.67–1.20), which was consistent with a multiplicative interaction.

The discrepancy between the analyses, findings and conclusions of Erren *et al.* (1999), Lee (2001) and Liddell (2001) lies in the selection of studies and the approaches used to abstract and analyse the evidence. All three reviews document the range of the evidence and the imprecision with which many of the studies assess effect modification.

The Working Group concluded that the evidence supports synergism between asbestos exposure and smoking in causing lung cancer, but notes that the degree of synergism remains uncertain.

2.3.3 *Radon and other ionizing radiation*

The combined effect of radon and smoking has been investigated in cohort studies of underground miners exposed to radon and radon progeny and in case–control studies of lung cancer and exposure to radon in homes. The Working Group for the *IARC Monograph* on radon 'considered that the epidemiological evidence [did] not lead to a firm conclusion concerning the interaction between exposure to radon decay products and tobacco smoking' (IARC, 1988a). The report of the US National Research Council's Biological Effects of Ionizing Radiation (BEIR) VI Committee provided an in-depth review of the combined effect of smoking and radon on lung cancer risk and the following section is largely based on this report (National Research Council, 1999). The cohort and case–control studies cited in that review, together with more recent studies, are included in Tables 2.3.6 and 2.3.7.

The BEIR VI Committee identified five cohort studies of underground miners that provided information on both smoking and exposure to radon progeny (Table 2.3.6). The extent of information available on smoking was variable and smoking was not systematically evaluated across the follow-up of any of the cohorts. Quantitative estimates of exposure to radon progeny were available for all participants. The data had been analysed by Lubin *et al.* (1994) using a mixture model that flexibly assessed effect modification. The two largest studies, the study of Colorado Plateau uranium miners and the study of Chinese tin miners, provided the strongest evidence of effect modification because of the size of the cohorts and the numbers of lung cancer deaths. Both studies provided evidence against the additive model, as did the overall estimate for the mixture parameter, which indicated a synergistic but submultiplicative interaction.

In modelling the risk for lung cancer, the BEIR VI Committee adopted this submultiplicative interaction. Relative to the overall effect of exposure to radon progeny on lung cancer risk, the risk estimate in ever-smokers was proportionally lower by a factor of 0.9 whereas the relative effect in never-smokers was proportionally higher by 1.9.

Hornung and colleagues (Hornung *et al.*, 1998) reported an analysis of the Colorado Plateau study that incorporated updated smoking information obtained in 1986 from surviving cohort members and next of kin of deceased members. The smoking histories, updated for about two-thirds of the original cohort, showed a substantial rise in the

proportion of former smokers. Multiple analytical approaches were used to explore effect modification. The general finding was that the interaction between smoking and radon was submultiplicative, but there was no strong evidence against a multiplicative interaction.

Further evidence on smoking and exposure to radon progeny has come from a population-based case–control study conducted in Gejiu City, the site of the Yunnan Tin Corporation (Yao *et al.*, 1994). This study included 460 cases, of whom 368 had been miners, and 1043 controls. Tobacco was smoked by study participants as cigarettes or with water pipes or Chinese long-stem pipes; a mixed pattern of smoking was most common. In contrast to the cohort analysis of the Yunnan tin miners, the case–control data were consistent with a multiplicative model, although the best-fitting model was intermediate between additive and multiplicative.

The joint effect of smoking and exposure to radon progeny could plausibly vary with the sequence of the two exposures. Thomas and colleagues (Thomas *et al.*, 1994) analysed the Colorado Plateau data using a case–control approach to assess temporal modification of the interaction between radon progeny and smoking. They characterized the temporal sequence of the two exposures as: simultaneous; radon before smoking; and radon following smoking. Exposure to radon followed by smoking was associated with an essentially additive effect whereas smoking followed by exposure to radon was associated with a more than multiplicative effect on a relative risk scale. Thomas and colleagues interpreted this finding as suggesting that smoking could act to promote radon-initiated cells.

The data from the Colorado Plateau cohort and Yunnan tin miners cohort have been analysed with mechanistic carcinogenic models, based in the Moolgavkar, Venzon and Knudson two-mutation model (Moolgavkar *et al.*, 1993; Luebeck *et al.*, 1999; Hazelton *et al.*, 2001; Little *et al.*, 2002). Under the assumed models, inferences can be made as to the mutations affected by smoking and exposure to radon progeny. In the most recent analysis of the Colorado Plateau cohort data (Little *et al.*, 2002), the findings of a two-stage model implied action of both factors on the first mutation rate and an action of exposure to radon progeny on intermediate cell death or the differentiation rate. A two-stage model was applied by Hazelton *et al.* (2001) to the Yunnan tin miner cohort data, which included estimates of exposure to smoking, arsenic and radon progeny. Various models were fitted; all showed effects of each of the exposures; radon had the smallest effect and smoking the greatest.

Effect modification has also been assessed in case–control studies of lung cancer in the general population (Table 2.3.7). All studies made estimates of radon concentration in the current and past homes of persons with lung cancer and of appropriate controls. Information on smoking was obtained by interview with the index respondent or with a surrogate for deceased persons. Measurement error is an unavoidable limitation of these studies, as exposure to radon throughout the lifetime is considered relevant to risk for lung cancer in adulthood.

Because most cases of lung cancer occur in smokers, the case–control studies included few never-smokers and consequently effect modification cannot be characterized with great precision. The available studies do not provide evidence for effect modification, considered

on the multiplicative scale. [The Working Group noted that the studies have not been systematically analysed for the presence of synergism, assessed as departure from additivity].

The combined effect of smoking and exposure to radiation has been assessed in a few populations exposed to low-linear energy transfer (LET) radiation. These populations included atomic bomb survivors (Prentice *et al.*, 1983; Kopecky *et al.*, 1986), persons receiving therapeutic irradiation for breast cancer (Kaldor *et al.*, 1992; Neugut *et al.*, 1994; Van Leeuwen *et al.*, 1995), and workers subjected to mixed exposure to external gamma radiation and internal emitters (Petersen *et al.*, 1990).

Of the cancer risks associated with exposure to radiation in atomic bomb survivors, relative risks for lung cancer are among the highest (Mabuchi *et al.*, 1991). A series of studies conducted by the Radiation Effects Research Foundation have explored the effect of smoking on lung cancer in the atomic bomb survivors. Kopecky *et al.* (1986) reported an analysis of the combined effects of smoking and radiation in a selected cohort for which information was available on smoking. A total of 351 cases of lung cancer were reported in a cohort of 29 332 exposed survivors. Poisson regression models were used to assess the effects of exposure to radiation (using the T65 radiation dosimetry), and smoking, with control for other factors including age at the time of the bombing. Using an additive model for the excess relative risk, Kopecky *et al.* (1986) found that both exposure to radiation and cigarette smoking were determinants of lung cancer risk; an interaction term for the two exposures was not statistically significant ($p = 0.72$). While Kopecky *et al.* (1986) expressed a preference for the additive model based on these analyses, further analyses by the BEIR IV Committee (National Research Council, 1988) showed that the data were equally compatible with a multiplicative model.

Three studies have examined modification by cigarette smoking of the risk for lung cancer following therapeutic irradiation.

Neugut *et al.* (1994) conducted a case–control study of Connecticut women with a second primary cancer following an initial diagnosis of breast cancer. The cases ($n = 94$) were women with lung cancer as the second primary cancer whereas the controls ($n = 598$) had a second malignancy of a type not associated with smoking or radiation. The pattern of the increased risk associated with both smoking and radiation therapy for the initial breast cancer was consistent with a multiplicative interaction; however, the consistency of the data with different models was not formally assessed.

Van Leeuwen *et al.* (1995) used a nested case–control design to assess risk for lung cancer in relation to radiation and smoking in a cohort of 1939 patients who had received treatment for Hodgkin disease in the Netherlands. The 30 cases identified during an 18-year follow-up were matched to 82 controls. Radiation doses to the region of the lung where the case developed cancer were estimated and information on smoking was obtained from several sources. There was a significantly greater increase in risk among smokers in relation to estimated radiation dose than among nonsmokers. However, in reviewing the findings, Boivin (1995) showed that the pattern of combined effects was consistent with additivity of the excess relative risks. This study was limited by the small number of lung cancer cases and by the potential modifying effects of chemotherapy.

Therapy for small-cell carcinoma of the lung includes aggressive chemotherapy and radiation. Tucker *et al.* (1997) carried out a multi-centre study in North America of 611 persons treated for small-cell carcinoma of the lung and who remained cancer-free for at least two years after the therapy. The risks varied with smoking status with the highest risk being found in those who continued to smoke after the initial diagnosis of lung cancer (relative risk = 21); no second lung cancers were observed in the 13 never-smokers. The authors reported that the interaction was not statistically significant when a model was used to assess interaction.

2.3.4 *Arsenic*

The combined effect of smoking and arsenic on lung cancer risk has been examined in occupational groups exposed to arsenic through work in smelting or metal mining. Table 2.3.8 summarizes the studies included in two relevant reviews (Hertz-Picciotto *et al.*, 1992; Saracci & Boffetta, 1994).

Hertz-Picciotto *et al.* (1992) used data from six studies (Rencher *et al.*, 1977; Pershagen *et al.*, 1981; Enterline, 1983; Pershagen, 1985; Enterline *et al.*, 1987; Järup & Pershagen, 1991) to evaluate the pattern of joint effects. Although the data available from the different studies were not uniform, the analysis indicated a pattern of combined effects that was consistently greater than additive.

2.3.5 *Alcohol drinking*

The combined effects of smoking and alcohol consumption on cancers of the oral cavity, pharynx, larynx and oesophagus have been examined extensively, and to a lesser degree for cancer of the liver (Table 2.3.9). The studies varied in their methods and in the approaches used to assess effect modification, which ranged from descriptive to formal estimation of interaction terms in multivariate models.

(*a*) *Cancers of the upper aerodigestive tract*

For cancers of the oral cavity and pharynx, the evidence comes entirely from case–control studies carried out in Asia, Australia, Europe and the United States. In the majority of the studies, evaluation of effect modification was descriptive, without formal assessment of interaction. Overall, however, the pattern of odds ratios for smoking, across categories of alcohol consumption, is consistent with synergism. In two studies with relatively large numbers of cases and controls, the pattern of increasing cancer risk with increasing alcohol consumption is strong (Mashberg *et al.*, 1993; Kabat *et al.*, 1994). In both studies, the pattern of odds ratios for men and women was consistent with synergism and a test for interaction was statistically significant for both sexes.

Seven case–control studies and one cohort study reported on joint effects of tobacco smoking and alcohol drinking on the risk for oesophageal cancer. Generally, the studies support a positive departure of joint effects from additivity. Since multiple logistic

regression models were used for analysing most of these studies, some also were tested for departure from multiplicativity. These tests for interaction are inadequate to assess synergy as defined in this monograph.

Most of the case–control studies of laryngeal cancer provide strong evidence for synergism. The studies were carried out in a number of locations around the world. Only the study in Shanghai (Zheng *et al.*, 1992) did not yield evidence consistent with synergism. In a number of studies, tests for interaction were carried out and reported to be 'non-significant.' These were tests for departure from the multiplicative models, typically multiple logistic regression models, used to analyze the case–control data, and not tests for departure from additivity.

Several studies reported on findings on cancer of the 'mixed upper aerodigestive tract', comprising studies of patients with squamous cell carcinomas, regardless of the specific site within the head and neck region. These studies also provided strong evidence for synergism.

(*b*) *Liver cancer*

Alcohol consumption is an established cause of liver cancer (IARC, 1988b) and of hepatic injury, which may lead to hepatic cirrhosis. Six case–control studies were identified that included information on the joint effect of smoking and alcohol consumption on liver cancer risk. In three studies, odds ratios for smokers were greater if they were also in the higher category of alcohol consumption (Chen *et al.*, 1991; Yu *et al.*, 1991; Kuper *et al.*, 2000). In one study (Kuper *et al.*, 2000), there was a statistically significant and super-multiplicative interaction between heavy smoking and heavy drinking in causing liver cancer.

2.3.6 *Infectious agents*

(*a*) *Hepatitis B*

Two case–control studies were identified that provided evidence on risk for liver cancer associated with smoking by serological status for hepatitis B infection (Table 2.3.10). The results are conflicting; the study conducted in Greece (Trichopoulos *et al.*, 1987) showed generally lower odds ratios in subjects who were seropositive for hepatitis B surface antigen compared with those who were negative for the antigen, whereas the study from China, Province of Taiwan (Chen *et al.*, 1991) showed greater risks in subjects who were positive for hepatitis B surface antigen.

(*b*) *Human papillomavirus*

For cervical cancer (squamous-cell type), evidence suggests that human papillomavirus (HPV) is a necessary factor, and implies that the risk of smoking cannot be estimated in the absence of HPV infection. Because the absolute risk of cervical cancer in the absence

of HPV infection, is hence by definition zero, the incremental risk associated with smoking is interpreted as indicating synergism (Table 2.3.11).

(*c*) Helicobacter pylori

A case–control study of stomach cancer in Moscow examined the combined effect of smoking and *H. pylori* infection (Zaridze *et al.*, 2000). In non-infected persons, the odds ratio, comparing ever- to never-smokers was 1.2 (95% CI, 0.8–1.8) whereas in infected persons, the odds ratio was 1.6 (95% CI, 1.0–2.4). The odds ratios did not vary significantly with infection status. No other studies were identified.

2.3.7 *Others*

(*a*) *Nickel*

Only one study addressed the combined effect of occupational exposure to nickel and cigarette smoking. Andersen and colleagues (Andersen *et al.*, 1996) reported the findings of a cohort study of workers (n = 4764) at the Falconbridge nickel refinery (Norway). Information on smoking was obtained primarily from medical records at the refinery and from co-workers. Assessment of effect modification was restricted to 1337 men who were in the same birth cohorts as a population comparison group. The results were consistent with a combined effect of nickel exposure and smoking that is multiplicative: the relative risk for unexposed smokers was 6.1; the relative risk for exposed never-smokers was 3.6; and relative risk for exposed smokers was 23.

(*b*) *Silica (silicon dioxide)*

Exposure to silica is common among miners, sand-blasters and many other occupational groups. Crystalline silica has been classified by IARC as *carcinogenic to humans* (Group 1) (IARC, 1997) and is also known to cause silicosis, a fibriotic disorder of the lungs. Workers with silicosis have an increased risk for lung cancer that may be the direct consequence of the silica particles deposited in the lung, or an indirect consequence of the lung fibrosis.

Studies that have investigated the combined effect of smoking with silica exposure are summarized in Table 2.3.12 (Saracci & Boffetta, 1994). Both studies on silica exposure and on silicosis were included. No consistent patterns of effect modification were evident in either group of studies.

(*c*) *Chloromethyl ethers*

The chloromethyl ethers include chloromethyl methyl ether and bis(chloromethyl)-ether; these compounds were used in the chemical industry as intermediates in organic synthesis and in the production of ion exchange resins. The strong association of exposure to this agent with lung cancer was first reported by Figueroa *et al.* (1973) who described 14 cases; three were in never-smokers and the histology for 13 of the cases showed that

only one was not a small-cell carcinoma. On follow-up of workers in the plant, nonsmokers were found to comprise a higher proportion of cases than in the general population (Weiss *et al.*, 1979). In a small cohort ($n = 51$) apparently drawn from the same plant (Weiss, 1980), the standardized mortality rate for lung cancer death was markedly higher for never-smokers and former smokers together, compared with current smokers. The authors interpreted this analysis as indicating antagonism between smoking and exposure to chloromethyl ethers. [The Working Group noted the limited information available on the joint effect of smoking and exposure to chloromethyl ethers.]

Table 2.3.1. Examples of levels of interaction between smoking and another agent

Exposure
• Work assignments of smokers and nonsmokers are different.
• Absenteism rates differ for smokers and nonsmokers.
Exposure–dose relationships for the lung
• Differing patterns of physical activity and ventilation for smokers and nonsmokers
• Differing patterns of lung deposition and clearance in smokers and nonsmokers
• Differing morphometry of target cells in smokers and nonsmokers
Carcinogenesis
• Other carcinogens and tobacco smoke carcinogens act at the same or different steps in a multistage carcinogenic process.
• Smokers and non-smokers differ on other, unmeasured modifying factors.

Table 2.3.2. Characteristics of case–control studies on the combined effect of asbestos exposure and smoking in the causation of lung cancer

Reference[a]	Location	Years of study	Study type and population	Controls	No. of cases[b]	Source of diagnosis
Martischnig *et al.* (1977)	Gateshead, UK	1972–73	Hospital-based; shipbuilding area	Patients	201	Confirmed clinical
Blot *et al.* (1978, 1980, 1982)	Georgia, Virginia, Florida, USA	1970–78	Shipbuilding areas	Patients and decedents, no chronic obstructive pulmonary disease	1072	Death certificates, medical records
Rubino *et al.* (1979)	Balangero, Italy	1946–75	Nested case–control study in chrysotile miners and millers	Alive when case died	12	Death certificates, medical records
Pastorino *et al.* (1984)	Lombardy, Italy	1976–79	Industrial areas	Population	204	Confirmed clinical
Kjuus *et al.* (1986)	Telemark and Vestfold, Norway	1979–83	Hospital-based; industrial and shipbuilding areas	Patients, no chronic obstructive pulmonary disease, other diseases precluding employment in heavy industry	176	Medical records
Garshick *et al.* (1987)	USA	1981–82	Railroad workers	Decedent, no cancer, accident, suicide, unknown cause	1081	Death certificates
De Klerk *et al.* (1991)	Wittenoom, Australia	1979–86	Nested case–control study in crocidolite miners and millers	Alive, no asbestos-related disease	40	Death certificates, medical records
Minowa *et al.* (1991)	Yokosuka, Japan	1979–82	Shipbuilding area	Decedent, no cancer, pneumoconiosis, accident, suicide	96	Confirmed clinical or autopsy
Bovenzi *et al.* (1993)	Trieste, Italy	1979–81, 1985–86	Industrial and shipbuilding area	Decedent, no chronic obstructive pulmonary disease, smoking-related cancer	516	Autopsy records
Gustavsson *et al.* (2002)	Stockholm, Sweden	1985–90	All men aged 40–75 years, residents of Stockholm County	1. Alive 2. Decedent, no tobacco-related disease	1038	Regional cancer register

Table 2.3.7. Case–control studies on the combined effect of smoking and radon exposure at home in the causation of lung cancer

Reference	Study location Years of study	No. of cases: Never-smoker/total	Findings
Axelson *et al.* (1988)	Sweden 1960–81	15/177	Increased risk for non- and occasional smokers vs. regular smokers in rural areas
Svensson *et al.* (1989)	Sweden 1983–85	35/210	Greater risk for smokers than never-smokers
Blot *et al.* (1990)	China 1985–87	123/308	Nonsignificantly greater risk in smokers ($p = 0.15$)
Schoenberg *et al.* (1990)	USA 1982–83	61/433	Exposure response strongest in light smokers; inverse in heaviest smokers
Ruosteenoja (1991)	Finland 1980–85	4/238	No pattern observed when heavier smokers compared with light smokers
Pershagen *et al.* (1994)	Sweden 1980–84	178/1360	Higher excess relative risk in current smokers than in never-smokers. Additivity rejected by data ($p = 0.02$)
Darby *et al.* (1998)	UK 1988–93	26/982	No evidence for heterogeneity of excess relative risk
Pisa *et al.* (2001)	Italy 1987–93	14/138	Interaction described as multiplicative, but analyses of interaction not significant
Wang *et al.* (2002)	China 1994–98	765/2009	No evidence for heterogeneity of excess relative risk

Table 2.3.8. Studies on the combined effects of smoking and occupational exposure to arsenic on lung cancer

Reference Country and years of study	Study design	Source population	Exposure assessment (tobacco or arsenic)	No. of cases/ deaths	Smoking categories	Relative risks			Interaction/ excess risk (%)[a]	Comments
						Exposure categories				
Rencher *et al.* (1977) USA 1959–69	Proportional mortality cohort	522 workers at Utah copper smelter who died in 1959–69	Smoking history obtained from work supervisors of deceased employees	31 deaths		*Mine*	*Concentrator*	*Smelter*	69	
					Nonsmoker	1.0	1.1	4.7		
					Smoker	4.7	4.7	13.1		
Pershagen *et al.* (1981) Sweden 1928–77	Nested case–control	Cohort of 3958 workers at Ronnskar smelter employed for at least 3 months		76 deaths, 152 deceased controls		*No*	*Yes*		M; 131	Overlap of 41 cases with Pershagen (1985) and all 76 cases with Järup & Pershagen (1991)
					Nonsmoker	1.0	3.0			
					Smoker	4.9	14.6			
Welch *et al.* (1982) USA 1938–77	Cohort	1800 workers from Anaconda, MT, smelter: heavy exposure and a 20% random sample of other exposure categories	Arsenic categories based on quantified exposure estimates for one point in time	80 deaths		*Low*	*Medium*		M	Multiplicative interaction for (high + very high) vs low exposure
					Nonsmoker	1.0	0.9			
					Smoker	1.3	3.3			
						High	*Very high*			
					Nonsmoker	3.0	6.6			
					Smoker	3.8	8.5			
Pinto *et al.* (1978); Enterline (1983) USA 1949–73	Cohort	527 workers from Tacoma,WA, smelter who lived beyond age 65 and retired in 1949–73		32 deaths		*No*	*Yes*		(I); 91	
					Nonsmoker	1.0	5.1			
					Smoker	7.2	20.7			

Table 2.3.8 (contd)

Reference Country and years of study	Study design	Source population	Exposure assessment (tobacco or arsenic)	No. of cases/ deaths	Smoking categories	Relative risks Exposure categories			Interaction/ excess risk (%)[a]	Comments
Pershagen (1985) Sweden 1961–79	Case–control	Residents in region where the Ronnskar smelter is located		212 deaths, 424 deceased controls		*None*	*Residential*		Residential: 92 Mining: 105 Smelting: 71	Overlap of 52 cases with Järup & Pershagen (1991)
					Nonsmoker	1.0	2.3			
					Smoker	8.3	17.5			
						Mining	*Smelting*			
					Nonsmoker	10.4	8.4			
					Smoker	35.2	26.2			
Enterline *et al.* (1987) USA 1949–80	Nested case–control	Cohort of 2288[b] workers employed at 6 copper smelters for ≥ 3 years in 1946–76, terminating employment at age > 44 and after 1949	Arsenic exposure very low compared with other smelters	55 cases, 126 controls		*None*	*Mean exposure*		64	Included cases from study by Rencher *et al.* (1977). Fitted logistic model; mean exposure level over the six plants calculated as cumulative time-weighted average of 281.03 µg/m^3-years.
					Nonsmoker	1.0	2.1			
					Smoker for 20 years	2.4	5.1			
Taylor *et al.* (1989) China 1971–84	Retrospective nested case–control	Past and present workers at Yunnan Tin Corporation	Arsenic categories based on quantified exposure estimates	107 cases, 107 controls		*Low*	*Medium*	*High*	~ A	Cases alive in 1985 Tobacco smoked in a water pipe; very few nonsmokers; interaction calculated for heavy *vs* light smokers and high *vs* low exposure
					Light	1.0	3.2	5.0		
					Medium	1.0	4.9	4.4		
					Heavy	1.4	8.9	4.9		
Tsuda *et al.* (1990) Japan 1972–89	Cohort	141 certified arsenic poisoning patients	Employment in arsenic mines	8 deaths		*No*	*Yes*		(> M)	Standardized mortality ratio using sex- and age-specific mortality rate of all Japanese in 1975, 1980 or 1985
					SMR		264			
					Nonsmoker	0	1247			
					Smoker	0				
Järup & Pershagen (1991) Sweden 1928–81	Nested case–control	Cohort of 3916 workers at Ronnskar smelter employed at least 3 months from 1928–67	Smokers of > 10 g tobacco/ day; cumulative arsenic exposure	107 cases, 214 deceased controls excluding smoking-related causes		*Low*	*Medium*	*High*	Low: A Medium: ~ A High: I; 127	
					Nonsmoker	1.0	1.4	5.6		
					Smoker	40.1	9.4	29.2		

Adapted from Hertz-Picciotto *et al.* (1992); Saracci & Boffetta (1994)

[a] Terms for interaction were taken from Saracci and Boffetta (1994); terms in parentheses are based on the assumption that the relative risk is 10. A, additive; I, intermediate; M, multiplicative; the numbers are the percentage by which observed exceeds predicted excess relative risk and are taken from Hertz-Picciotto *et al.* (1992).

[b] Original paper reported 5392 workers in the six plants considered.

Reference	Study type	Place, year	Study population	HPV exposure	Smoking categories	Relative risk (95% CI)	Comments
Basu *et al.* (1991)	Cross-sectional study	New York, USA	75 women referred to a colposcopy clinic for abnormal Pap smear		Smoker HPV-positive	Cases vs non-cases (%) 53.5 *vs* 36.7 66.7 *vs* 53.3	Difference not statistically significant. Discrepancies between text and table for percentage of HPV-positive women among non-cases
Ylitalo *et al.* (1999)	Nested case–control (see Table 2.1.10.6)	Uppsala County, Sweden, 1965–95	Cohort: ~ 281 000 women Cases: 422 patients diagnosed with cervical carcinoma *in situ* Controls: 422 controls, matched on date of entry into cohort and birth year	HPV 16/18 DNA negative before diagnosis (n = 138)	Nonsmoker Former smoker Current smoker 1–9 years of smoking 10–19 of smoking ≥ 20 of smoking 0.15–3.95 pack–years 4.00–7.95 pack–years ≥ 8.00 pack–years	1.0 1.5 (0.7–3.4) 1.8 (0.9–3.6) 1.5 (0.7–3.4) 1.7 (0.8–3.5) 2.0 (0.7–5.9) 1.4 (0.7–2.9) 2.7 (1.2–6.4) 1.6 (0.7–3.5)	Logistic regression models. Risk estimates adjusted for education, marital status, oral contraceptive use, age at sexual debut, number of sexual partners, age at menarche and parity. [No formal test for interaction]
				HPV 16/18 DNA positive before diagnosis (n = 178)	Nonsmoker Former smoker Current smoker 1–9 years of smoking 10–19 years of smoking ≥ 20 years of smoking 0.15–3.95 pack–years 4.00–7.95 pack–years ≥ 8.00 pack–years	1.0 2.1 (1.04–4.3) 2.3 (1.3–4.3) 2.3 (1.1–5.2) 2.5 (1.3–4.7) 1.8 (0.8–4.1) 2.3 (1.1–4.8) 3.4 (1.6–7.3) 1.6 (0.8–3.2)	
Kjellberg *et al.* (2000)	Case–control	Northern Sweden, 1993–95	Cases: 137 women with high grade CIN Controls: 253 healthy population-controls, matched on age	HPV Ab–	Never-smoker Ever-smoker	1.0 5.6 (2.5–10.9)	Risk estimates adjusted for age [although matched on age]. No evidence of interaction. [No numbers provided]
				HPV Ab+	Never-smoker Ever-smoker	5.2 (2.5–10.9) 10.5 (5.0–22.4)	

Table 2.3.11 (contd)

Reference	Study type	Place, year	Study population	HPV exposure	Smoking categories	Relative risk (95% CI)	Comments
Hildesheim *et al.* (2001)	Cross-sectional	Costa Rica, 1993–94	Population: 989 HPV positive women Cases: 146 prevalent high-grade squamous intraepithelial lesions or cervical cancer Controls: women with or without low grade squamous intraepithelial lesions	All HPV positive	Never-smoker Former smoker Current smoker < 10 years smoking ≥ 10 years smoking 1–5 cigs/day ≥ 6 cigs/day	1.0 2.4 (1.2–5.1) 2.3 (1.3–4.3) 2.6 (1.2–5.3) 2.2 (1.2–4.2) 2.3 (1.3–3.9) 2.7 (1.1–6.7) *p* for trend = 0.0007	Logistic regression model. Risk estimates for overall analysis adjusted for age, HPV type, number of pregnancies and number of cigarettes/day. Risk estimates for high-risk analysis adjusted for age, number of pregnancies and number of cigarettes/day. No association was found between smoking habit of husband/live-in partner and high-grade squamous intraepithelial lesions/cancer among nonsmoking women. HPV testing for 44 different HPV types.
				High risk HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68)	Never-smoker Former smoker Current smoker < 10 years smoking ≥ 10 years smoking 1–5 cigs/day ≥ 6 cigs/day	1.0 1.7 (0.8–4.0) 2.3 (1.2–4.3) 2.2 (1.0–4.8) 2.0 (1.0–3.8) 1.8 (0.99–3.3) 3.1 (2.2–7.9) *p* for trend = 0.003	

Table 2.3.12. Studies on the combined effect of tobacco smoking and silica exposure in the causation of lung cancer

Reference	Study design	Country, years of study	Source population	No. of cases and controls	Smoking categories (highest *vs* lowest exposure)	Silica exposure	Relative risk		Interaction[a]	Comments
							Non-smoker	Smoker		
Forastiere *et al.* (1986)	Retrospective case–control	Italy, 1968–84	Male residents in region with pottery industry	72 deaths, 319 controls	Cigarettes per day 0; 1–20; > 20	Ceramic workers without silicosis with silicosis	1.5 0	4.1 1.8	~ M (> M)	Deceased cases and controls; all silicotics were ceramic workers.
Mastrangelo *et al.* (1988)	Case–control	Italy, 1978–80	Workers in quarrying and tunnelling	309 cases, 309 controls	Nonsmoker Ever–smoker	No silicosis Silicosis	1.3 5.3	0.9 1.7	~ A ~ A	Unadjusted analysis
Hessel *et al.* (1990)	Case–control	South Africa, 1975–79	Miners, mainly in gold mines, with silicosis	231 deaths, 318 controls	Cigarettes per day 0; 1–10; 11–20; ≥ 21	Hilar gland silicosis Parenchymal silicosis	1.1 1.6	0.8 0.9	(< A) (< A)	Unmatched odds ratios
Siemiatycki *et al.* (1990)	Case–control	Canada, 1979–85	Male residents of Montreal, aged 35–70 years	479 cases, 875 controls	Pack–years 0; 1–< 30; 30–< 60; ≥ 60	Substantial	2.6	1.5	I	Adenocarcinoma excluded; silica exposure estimated from job titles; adjusted for age, socio-economic status, job history, education, marital status and asbestos exposure
Chiyotani *et al.* (1990)	Cohort	Japan, 1979–83	3335 patients with pneumoconiosis qualifying for workmen's compensation (58% silicotics)	60 deaths	Nonsmoker Former smoker Current smoker	Pneumoconiosis	1.8	6.1	(> M)	
Amandus & Costello (1991)	Cohort	USA, 1959–75	9912 metal miners; white males	132 deaths	Nonsmoker Former smoker Current smoker	Silicosis Silicosis in low radon mines	2.2 5.1	1.3 1.7	~ A (~ A)	Adjusted for age; 'interaction between silicosis and cigarette smoking habits not a statistically significant factor related to lung mortality'
Hnizdo & Sluis-Cremer (1991)	Cohort	South Africa, 1968–86	2132 white gold miners with silicosis, aged 45–54 years	77 deaths	Pack–years ≥ 26 *vs* ≤ 25	≥ 31 *vs* ≤ 30 dust particle–years	1.4	1.9		'Combined effect of dust and smoking is more than additive.'

Table 2.3.12 (contd)

Reference	Study design	Country, years of study	Source population	No. of cases and controls	Smoking categories (highest *vs* lowest exposure)	Silica exposure	Relative risk		Interaction[a]	Comments
							Non-smoker	Smoker		
Amandus *et al.* (1991)	Cohort	USA, 1940–83	760 silicotics among dusty trades workers	33 deaths	Never-smoker Ever-smoker	Silicosis	SMR 1.7	SMR 3.4	(> M)	Standardized mortality ratios using US male population as reference group
Chia *et al.* (1991)	Cohort	Singapore, 1970–84	159 granite workers with silicosis	9 cases	Nonsmoker Smoker	Silicosis	1.3	2.2	(> M)	
Hnizdo *et al.* (1997)	Nested case–control	South Africa, 1970–86	2260 white gold miners, aged 45–54 years	78 cases, 386 controls	Pack–years: < 10; 10–29; ≥ 30	Without silicosis With silicosis	1.0 4.1	11.7 48.9		'Strong multiplicative combined effect of smoking and the presence of silicosis on the risk of lung cancer'
Hughes *et al.* (2001)	Nested case–control	USA, 1940–84	2670 male industrial sand workers	123 deaths, 219 controls	Nonsmoker Ever-smoker					'No indication of an interaction effect of cigarette smoking and cumulative exposure'

Adapted from Saracci & Boffetta (1994)

[a] Numbers in parentheses are based on the assumption that the relative risk due to smoking is 10; A, additive; I, intermediate; M, multiplicative

3. Carcinogenicity Studies in Experimental Animals

3.1 Inhalation exposure: mainstream tobacco smoke

This section summarizes the information available on the effects of exposure to mainstream tobacco smoke and the occurrence of cancer in animals and includes data from the previous *IARC Monographs* on tobacco smoking (IARC, 1986) and subsequent publications to date (see Table 3.1).

Although the evidence for the carcinogenicity of tobacco smoke emerged first in humans, there was a need for an inhalation model in experimental animals in which the carcinogenicity of different types of tobacco and tobacco products could be studied. The availability of animal models also permits the investigation of various modifying factors in the development of cancer.

Early inhalation studies in rodents were reviewed by Wynder and Hoffmann (1967). From about 1960 onwards, the species of animal selected most often for carcinogenicity studies was the Syrian golden hamster, which has a low background incidence rate for spontaneous pulmonary tumours and is prone to few interfering respiratory infections. The discovery that inhalation of tobacco smoke caused carcinomas in the larynx of hamsters enabled the establishment of a model system in which the carcinogenicity of tobacco smoke for hamsters has been repeatedly confirmed (see below). Many bioassays have also been conducted in mice and rats and the results are summarized below.

To enable the responses of animals to tobacco smoke inhalation to be studied, it was necessary to develop methods and equipment to deliver smoke in a standardized, effective way. A number of devices have been employed, some involving whole-body exposure and some 'nose-only' exposure. Usually, in order to simulate human smoking patterns, a 2-s puff from a burning cigarette is diluted with air and forced into a chamber for a short period, followed by an air purge. However, animals that are being forced involuntarily to inhale the smoke suffer avoidance reactions and change their breathing patterns to shallow, hesitant inspirations with reduced minute volumes. This behaviour affects the doses delivered to the different parts of the respiratory system. Because rodents are obligatory nose-breathers and because rodents and dogs have more convoluted and intricate nasal turbinate patterns than humans, the dynamics of particle deposition in the upper respiratory tract might be expected to be different (see Wynder & Hoffmann, 1967;

Table 3.1. Selected studies of carcinogenicity in response to exposure to mainstream tobacco smoke in mouse, rat and hamster

Strain	Sex	No. of treated animals/ group	Route	Type of exposure	Concentration of exposure agent	Exposure duration	Lung burden	Tumour incidence	Reference
Mouse									
C57BL	M	100	Nose-only	Mixture of fresh non-filter cigarette smoke/air (1/39, v/v)	Nicotine,0.1 mg/mL; CO, 0.064% (v/v)	12 min/day, lifetime	Nicotine, 14–17 µg	4/100 (alveologenic AdC) [$p = 0.06$], 0/100 (controls)	Harris & Negroni (1967)
	F	100						4/100 (alveologenic AdC) [$p = 0.06$], 0/100 (controls)	
C57BL	NG	126	Whole-body	Gas phase of 12 cigarettes puffed 2 s/min	NG	90 min/day, lifetime (~27 mo)	NG	7/126 (lung A) [NS], 3/90 (controls)	Otto & Elmenhorst (1967)
BLH	NG	126			NG		NG	40/126 (lung A) [NS], 19/60 (controls)	
Snell	M	160	Whole-body	Whole fresh cigarette smoke	NG	2 puffs, once/day, lifetime (26 mo)	Nicotine, 5 µg	7/107 (lung A), 8/106 (controls); 11/107 (lung AdC), 5/106 (controls)	Leuchtenberger & Leuchtenberger (1970)
	F	118						2/65 (lung A), 1/78 (controls); 5/65 (lung AdC), 3/78 (controls)	
	M	100		Gas phase of fresh cigarette smoke	NG		NG	1/44 (lung A), 8/106 (controls); 10/44 (lung AdC) ($p = 0.005$), 5/106 (controls)	
	F	89						3/44 (lung A), 1/78 (controls); 5/44 (lung AdC), 3/78 (controls)	
C57BL	M	100 (2 ×)	Nose-only	Mixture of fresh flue-cured or air cured cigarette smoke/air (1/39, v/v)	NG	12 min/day on alternate days; lifetime	NG	9/162[a] (flue-cured) [$p = 0.07$], 7/189[a] (air-cured) [$p > 0.05$], 3/160[a] (controls)	Harris *et al.* (1974)
	F	100 (2 ×)						7/164[a] (flue-cured) [$p = 0.04$], 0/173 (air-cured), 1/159[a] (controls)	
	M	100		Gas phase of flue-cured cigarette smoke	NG		NG	3/8[a] [$p > 0.05$], 3/160[a] (controls)	Harris *et al.* (1974)

Table 3.1 (contd)

Strain	Sex	No. of treated animals/ group	Route	Type of exposure	Concentration of exposure agent	Exposure duration	Lung burden	Tumour incidence	Reference
(C57BL/ Cum × C3H/Anf Cum)F_1	F	1014 and 2053	Nose-only	10% smoke from US reference cigarettes	NG	Smoke 20 s/min, 6–8 min/day, 5 days/wk, 110 wks	Particulate deposition, 125–200 µg	19/978 (alveolar AdC), 7/651 (sham-exposed controls); shorter latency of tumour occurrence in smoke-exposed group suggested ($p = 0.10$)	Henry & Kouri (1986)
Rat									
Wistar	F	408	Nose-only	Mixture of cigarette smoke/air (1/5)	NG	15 s/min, 2 × 11 min/day, 5 days/ wk, lifetime (140 wks)	NG	4/408 (1 lung C + 3 lung neoplasms of uncertain malignancy), 0/104 (controls), 0/104 (sham treated controls)	Davis *et al.* (1975a)
Fischer 344	F	80	Nose-only	Mixture of non-filter cigarette smoke/air (1/10)	18.4 mg smoke particulate and 0.89 mg nicotine/cigarette	1 cigarette/h, 7 cigarettes/day, 5 days/wk, 128 wks termination at 160 wks	Particulate deposition, 1.75 mg/day	10/80 (1 nasal AdC, 1 nasal C, 5 pulmonary A, 1 pulmonary C, 2 alveologenic C) ($p < 0.05$), 3/93 (controls) 21/80 (subcutaneous sarcomas at forelimb ulceration sites) ($p < 0.05$), 0/93 (controls)	Dalbey *et al.* (1980)

CO, carbon monoxide; AdC, adenocarcinoma; NG, not given; A, adenoma; NS, not significant; mo, month; wk, week; C, carcinoma; LCS, low cigarette smoke; HCS, high cigarette smoke

[a] Most of these lung tumours are adenomas.

Nagano *et al.*, 1982; Proctor & Chang, 1983; Reznik, 1983). Therefore, these exposure systems are not fully representative of the exposure pattern of smokers.

Under experimental conditions, the smoke in the chamber can be assayed for total particulate matter and carbon monoxide, and animals can be examined at intervals to determine the levels of carboxyhaemoglobin, nicotine or cotinine in their blood, and the deposition and retention of particulate matter in tissues, which gives some indication of the doses administered. In typical experiments, rodents were exposed to the smoke of seven to 10 cigarettes per day on 5–7 days per week (Dalbey *et al.*, 1980; Wehner *et al.*, 1981) and were found to have carboxyhaemoglobin levels of 20–40% (Bernfeld *et al.,* 1974).

3.1.1 *Mouse*

A number of early investigations of the effects of mainstream tobacco smoke on tumour development in mice were conducted using the C57BL strain. This strain is relatively resistant to the development of both spontaneous and chemically induced lung tumours (Shimkin & Stoner, 1975). [Therefore, the lack of tumour response in the first few investigations described below may have been due to the choice of this strain.]

Groups of 100 male and 100 female young adult C57BL mice were exposed (nose only) for 12 min/day to a mixture of fresh cigarette smoke and air (1/39, v/v) every other day for life. [The cigarettes were made from a composite blend of flue-cured tobaccos typical of the major brands of untipped cigarette smoked in the United Kingdom (Harris *et al*., 1974).] The concentration of nicotine in the mixture was about 0.1 mg/mL and that of carbon monoxide, 0.064% (v/v). The nicotine content in the lungs of mice that died during exposure was 14–17 μg. Groups of 100 males and 100 females served as controls. No lung tumours, either adenomas or carcinomas, were found in control mice, but lung tumours (alveologenic adenocarcinomas) were found in 4/100 male and in 4/100 female mice exposed to tobacco smoke [$p = 0.06$]. Some of the adenocarcinomas were transplantable. Mice exposed to smoke often showed emphysema and marked peribronchial and perivascular infiltration with lymphocytes, independent of the presence of tumours (Harris & Negroni, 1967).

A total of 126 C57BL and 126 BLH mice [sex and initial group sizes unspecified] were exposed to the gas phase of 12 cigarettes [type unspecified] puffed for 2 s/min. The gas phase was generated by passing the smoke through a Cambridge filter that retained the particulate matter. The mice were exposed in a 200-L chamber for 90 min daily (approximately the maximal tolerated dose) until death (approximately 27 months). The survival rates for animals that received more than 12 months of treatment were not affected by treatment in either strain of mice [numbers not provided]. The percentages of mice with lung adenomas were 5.5% and 32% (7/126 and 40/126) in exposed C57BL and BLH mice and 3.4% and 22% (3/90 and 19/60) in C57BL and BLH controls, respectively. The percentages of BLH mice with lung adenomas that survived for at least 10 months were 37% of the treated group and 31% of the controls. The difference in incidence of

adenoma between the control and treated groups was stated not to be statistically significant (Otto & Elmenhorst, 1967). [The Working Group noted the incomplete reporting of the experiment.]

A group of 50 male C57BL6/Mil mice, 6 weeks of age, was exposed to cigarette smoke from 85-mm unfiltered cigarettes [type unspecified] in a vacuum chamber for 15 min, five times per week, for 63 weeks. The nicotine content in the lungs of mice that were killed ranged from 14 to 27 μg. When the nasal cavity and respiratory tree were examined microscopically, the incidences of hyperplasia and metaplasia were found to be increased in exposed mice. These conditions were considered to be secondary to inflammation. No tumour was found (Wynder *et al.*, 1968). [The Working Group noted the relatively short duration of the study.]

Groups of Snell's mice, 3–4 months of age at the start of treatment, were exposed to two puffs (15-mL puff volume, 2-s duration, 58-s interval between puffs) of either whole fresh cigarette smoke [type unspecified] (160 males and 118 females) or to the gas phase (100 males and 89 females); 117 males and 83 females served as controls. Animals were exposed in individual containers once a day (except during holidays and weekends) for life. When body weight loss was 4 g or more, animals were withdrawn from exposure treatment for periods varying from 2 days to 2 months. Two popular brands of unfiltered cigarettes were used; each cigarette was smoked to a butt length of 23 mm. The gas phase was produced by passing the smoke through a Cambridge filter. The efficiency of exposure was assessed by determining the carbon monoxide concentration in blood and the nicotine content of the lungs (about 5 μg). Survival after 12 months of age was distinctly reduced by treatment, being about 92% (184/200), 60% (172/278) and 40% (88/189) in the control, whole smoke-treated and gas phase-treated groups, respectively. After 12 months of age, the occurrence of pulmonary tumours was earlier in exposed mice than in controls. At the end of the experimental period (26 months), the numbers of mice that survived 12 months or more that had pulmonary adenomas were 8/106 and 1/78 male and female controls, 7/107 and 2/65, respectively ($p = 0.475$), male and female animals exposed to whole smoke and 1/44 and 3/44, respectively ($p = 0.15$), male and female animals exposed to the gas phase. The proportions of mice with pulmonary adenocarcinomas were 5/106 male and 3/78 female controls, 11/107 ($p = 0.15$) male and 5/65 ($p = 0.35$) female animals exposed to whole smoke and 10/44 ($p = 0.005$) male and 5/44 ($p = 0.15$) female animals exposed to the gas phase (Leuchtenberger & Leuchtenberger, 1970).

Groups of 100 male and 100 female C57BL mice, aged 14–18 weeks, were exposed (nose only) to a mixture of fresh cigarette smoke and air (1/39, v/v) for a 12-min period, generally on alternate days, for life. Groups were exposed to the whole smoke of two different types of cigarette, one made from flue-cured and the other from air-cured tobacco. The latter more closely resembled flue-cured cigarettes than typical air-cured cigarettes which contain, for example, burley tobacco. A further group of animals was exposed to the gas phase only of smoke from the flue-cured cigarette; this was generated by passing the whole smoke through a Cambridge filter to remove the particulate matter. A group of 200 males and 200 females served as controls. The experiments with whole smoke were repeated

under similar conditions with another group of 100 male and 100 female mice. Mean survival time in eight of 10 groups of mice exposed to whole smoke was 4–14 weeks longer than that in controls. The incidences of lung tumours in controls were 3/160 males and 1/159 females; those in mice exposed to the whole smoke of cigarettes made from flue-cured tobacco were 9/162 males and 7/164 females [$p = 0.07$ and 0.04], respectively; the incidences in mice exposed to the gas phase of cigarettes made from flue-cured tobacco were 3/81 males [$p > 0.05$] and 2/88 females [$p > 0.05$]; and those in mice exposed to the whole smoke of cigarettes made from air-cured tobacco were 7/189 males [$p > 0.05$] and 0/173 females. The majority of the lung tumours were adenomas (Harris *et al*., 1974).

A group of 117 female BALB/c mice, 9 weeks of age, was exposed to smoke from 'high-tar'(16 mg tar, 1.1 mg nicotine) cigarettes diluted with air (7:1, air:smoke) for 7–8 min per day on 5 days per week for 95 weeks; the exposure was discontinued for 3 weeks starting between the 48th and 49th week of treatment. An untreated group of 130 females served as controls. Groups of approximately 16 control and 16 exposed mice were killed after 56, 64, 72 and 80 weeks of treatment. Twenty control and 10 exposed mice survived until termination of the experiment after 95 weeks. The incidence of bronchial adenomas was calculated by the authors to be 3.8 times higher in the exposed groups of mice than in the control groups after 83 weeks, but to be similar in the two groups after 95 weeks of exposure. The authors also reported an increase in the incidence of lymphomas after both 83 weeks (2.6 times) and 95 weeks (3.2 times) of exposure (Keast *et al*., 1981). [The Working Group noted that insufficient numerical data were provided in relation to the number of animals at risk.]

Two thousand and fifty-three (C57BL/Cum × C3H/AnfCum)F_1 mice were exposed (nose only) to cigarette smoke from University of Kentucky reference 2R1 cigarettes on 5 days/week for 110 weeks and observed until death. In addition, 1014 mice were sham-exposed and 449 mice were held as cage controls. The deposition of smoke particulates was estimated to be about 125–200 μg total particulate matter/lung/day. The only lung cancers observed were diagnosed as alveolar adenocarcinomas. These adenocarcinomas were observed in 19/978 smoke-exposed mice and 7/651 sham-exposed mice. The difference between the incidence in smoke- and sham-exposed groups was not significant, but the data suggested that the tumours occurred with a shorter latency in the smoke-exposed group ($p = 0.10$). Other changes associated with exposure to smoke were increased incidence of pigmented alveolar macrophages, otitis media and head and neck fibrosarcomas (Henry & Kouri, 1986). [The Working Group noted that both parent strains are relatively resistant to the development of spontaneous and chemically induced lung tumours.]

3.1.2 *Rat*

A group of 408 female Wistar rats, 10 weeks of age, was exposed (nose only) to a mixture of smoke and air in a ratio of 1:5 generated from T29 cigarettes (especially manufactured from a composite blend of flue-cured tobaccos, representing the major untipped cigarette brands smoked in the United Kingdom during 1967–68), for 15 s/min during

11 min, twice a day on 5 days per week for life. After 1 year, the rats received 5% carbon dioxide in air instead of air for 5 min before the start of each smoke exposure session and also for the 45-s/min interval during which smoke was not generated. Measurement of an arsenious sulfate tracer showed that 8.5% and 17.5% of the delivered tar was recovered in the lungs of rats subjected to the air and the air/carbon dioxide regimens, respectively. Two control groups of 102 animals were kept, one sham-exposed and one untreated. The smoke-exposed and sham-exposed animals had lower body weights than the untreated controls. About 25% of the treated rats were still alive at 100 weeks compared with 73% of 102 untreated controls and 66% of 102 sham-exposed controls. All treated animals had died by 140 weeks; the control animals had all died by 160 weeks. Three of the smoke-exposed rats had pulmonary squamous neoplasms of uncertain malignancy, and one had an invasive squamous-cell carcinoma of the lung. No lung tumour was observed in the sham-treated or untreated controls. The incidence of benign mammary tumours was lower in the smoke-exposed rats than in the sham-exposed or untreated controls (Davis *et al*., 1975a). [The Working Group noted that the daily exposure period was very brief.]

A group of 18 female Wistar rats, 13–14 weeks of age, was exposed (nose only) to the gas phase of smoke (produced by passing the smoke through a Cambridge filter) from a standard British reference cigarette diluted 1:5 with air. Exposure took place for 15 s followed by exposure to air for 45 s during 11 min, twice daily on 5 days per week for life. A control group of 16 animals was kept. Average period of survival was 100 weeks for treated animals and 114 weeks for controls. No lung tumour was reported in either the exposed or the control rats (Davis *et al*., 1975b). [The Working Group noted the small number of animals used and the short duration of the period of exposure each day.]

A group of 80 female Fischer 344 rats, 12–14 weeks of age, was exposed (nose only) to a mixture of smoke and air in a ratio of 1:10 for 28–30 s/min followed by air for 30 s during standard smoking of a US reference untipped cigarette (average, 8.4 periods of exposure/cigarette). The mean smoke particulate and nicotine levels recorded during chamber monitoring were 18.4 mg and 0.89 mg per cigarette, respectively. The animals were exposed to 1 cigarette/h, 7 cigarettes per day, on 5 days per week for 128 weeks, followed by observation for a further 6 months. The mean pulmonary particulate deposition during exposure was 0.25 mg/cigarette (total, 1.75 mg/rat per day). A group of 63 rats served as untreated controls and 30 rats were sham-exposed. The length of survival of smoke-treated, sham-treated and untreated controls was not significantly different, but smoke- and sham-treated animals had lower mean body weights. Because the tumour incidences in untreated and sham-treated controls were similar, the two groups were combined (93 animals). One alveologenic carcinoma was observed in one control rat and one pulmonary adenomatoid lesion in two other control rats. Ten respiratory tract tumours were observed in seven smoke-exposed rats: one nasal adenocarcinoma, one nasal squamous-cell carcinoma, five pulmonary adenomas, two alveologenic carcinomas and one squamous-cell carcinoma ($p < 0.05$). Of the smoke-exposed animals, 21 developed subcutaneous sarcomas at sites of ulceration on the forelimbs ($p < 0.05$), four rats developed benign tumours of the oral tissues ($p < 0.1$) and four developed adrenal gland

tumours (one adenoma and three carcinomas) ($p < 0.1$). No such tumours occurred in controls. The incidences of tumours of the pituitary gland, uterus and ovary, haematolymphatic system and mammary gland were lower in smoke-exposed rats than in controls (Dalbey *et al*., 1980).

Three groups of 80 female Fischer 344 rats were exposed to a mixture of smoke and air in a ratio of 1:10. The smoke was generated from three research cigarettes [source not specified] containing 25.4 mg tar, 0.16 mg nicotine; 13.3 mg tar, l.06 mg nicotine; or 25.7 mg tar, 1.91 mg nicotine, respectively (see also Griest *et al*., 1980). Each rat was exposed to smoke for 28 s/min followed by air for 30 s during standard smoking of the cigarettes, to provide 10–11 exposures/cigarette. The animals were exposed to eight cigarettes per day during a 16-h period, on 7 days per week for 96 weeks, at which time all survivors (50–70% of animals) were killed. Groups of 80 animals served as untreated and sham-treated controls. The occurrence of squamous metaplasia of the laryngeal and tracheal epithelium was significantly increased in smoke-exposed rats. One squamous-cell carcinoma of the lung was observed in a rat exposed to 'low-tar medium-nicotine' smoke; the incidences of other tumours were similar in treated and in control animals (Wehner *et al*., 1981). [The Working Group noted that, in contrast to the study described previously, all surviving animals were killed at 104 weeks of age and that the method for sampling for histopathology was not fully reported.]

In an experiment in which combined exposure of CDF®(Fischer 344)/CrlBR rats to mainstream tobacco smoke and $^{239}PuO_2$ was studied, two groups of rats (6 weeks of age) were subjected to whole-body exposure for 6 h/day, 5 days per week, for 126 weeks to mainstream cigarette smoke diluted to concentrations of either 100 or 250 mg total particulate matter/m^3 (LCS and HCS groups). A significant increase in the occurrence of lung tumours was found in females exposed to smoke only but not in males. The incidences of benign and/or malignant lung tumours in female rats were 0/113, 4/145 (3%) and 6/83 (7%; $p < 0.05$; one-sided Yates test) in the groups treated with filtered air alone, and the LCS and HCS groups, respectively. The corresponding tumour incidences for males were 3/119 (2.5%), 3/173 (2%) and 7/78 (8%), respectively (Finch *et al*., 1995).

3.1.3 *Syrian hamster*

In a study involving 4440 hamsters, three groups of 80 male and 80 female Syrian golden hamsters, 8 weeks of age, were exposed to a mixture of smoke and air in a ratio of 1:15. The smoke was generated during a 7–10-min period from 30 German reference cigarettes, once, twice or three times a day on 5 days per week until death. Two groups of 80 males and 80 females were exposed either to the smoke of black (dark air-cured)-tobacco cigarettes twice a day, or to the vapour phase of German reference cigarettes, generated from 30 cigarettes during a 10-min period twice a day. Eight hundred animals served as untreated controls. The average length of survival was 52–65 weeks for treated males and 41–49 weeks for treated females. When compared with untreated controls, a shorter survival time and loss of body weight were noted in animals exposed

to smoke. In all treated groups, 'the most remarkable and severe alterations' were observed in the larynx, and their severity depended on duration of treatment and dosage. The incidence of laryngeal leukoplakias ranged from an average of 11.3% in animals exposed to the reference cigarette for 10 min to 30.6% in those exposed for 30 min; the incidence in animals exposed to smoke from black-tobacco cigarettes was 10%, and slight leukoplakia was observed in 1–5% of control animals. The incidences of laryngeal carcinomas were 0.6–10.6% in animals exposed to smoke from the reference cigarette and 1.25% in animals exposed to smoke from black-tobacco cigarettes. No such tumour was observed in control animals or in those exposed to the vapour phase (Dontenwill *et al*., 1973).

Similar results were obtained in a study involving 2160 hamsters exposed to the smoke from German reference cigarettes or a modification thereof (Dontenwill *et al*., 1977a).

A modification of the method of Dontenwill (above) was used in a study of inbred Syrian golden hamsters. Groups of 102 male BIO® 87.20 and BIO® 15.16 hamsters (13 weeks of age) were exposed to smoke (1:5 in air) from University of Kentucky 1R1 reference cigarettes twice a day on 5 days per week for up to 100 weeks. Groups of 60 animals served as sham-exposed or cage controls for each strain. Exposure to smoke for up to 100 weeks had no effect on length of survival; however, a reduction in body weight was noted. Over 90% of the smoke-exposed animals of both strains showed hyperplastic or neoplastic changes in the larynx; and benign squamous-cell papillomas of the larynx were observed in both strains. Laryngeal cancer occurred nearly five times more frequently in strain BIO® 15.16, however, and two animals of this strain developed nasopharyngeal tumours. The incidences of tumours at locations other than the respiratory tract were similar in the two strains (Bernfeld *et al*., 1974).

Groups of 35–64 male BIO® 15.16 inbred Syrian golden hamsters, 60–70 days of age, were exposed to concentrations of 11% or 22% smoke from commercial British filter-tipped cigarettes or filter-tipped cigarettes composed of tobacco and Cytrel® (a tobacco substitute), or cigarettes made of 100% Cytrel® twice a day (12-min sessions of 27 smoke exposures/min) on 7 days per week for up to 74–80 weeks. Groups of 40 sham-exposed animals and 51 caged animals served as controls. Survival rates were markedly reduced in all groups after 59 weeks of age; a reduction in body weight was noted in treated animals when compared with controls. Laryngeal carcinomas occurred in 47.4% (27/57) of the animals exposed to smoke from the British filter-tipped cigarettes; the first tumours occurred after 59 weeks in the hamsters treated with the 22% smoke concentration. The incidence of this type of tumour was dose-related and decreased as the proportion of Cytrel® in the blends increased. No such tumour was observed in controls. Laryngeal papillomas, laryngeal epithelial hyperplasia and a few tracheal papillomas were also observed in treated animals. Histopathological findings at other sites did not appear to be related to smoke inhalation (Bernfeld *et al*., 1979).

A group of 51 male Syrian golden hamsters, 2 months of age, was exposed three times a day for 10 min, 5 days per week, for life, to smoke from University of Kentucky 1Rl

reference cigarettes. Another group of 51 male hamsters served as sham-exposed controls. The smoke-exposed animals survived longer (mean, 19.6 months) than the sham-exposed animals (mean, 15.3 months). The smoke-exposed animals had significantly higher incidences of epithelial lesions of the larynx than the sham-exposed controls (22% versus 0%, $p < 0.01$) and also had a significantly higher total number of tumours than sham-exposed controls (28% versus 6%; $p < 0.05$). The laryngeal changes in the smoke-exposed group ranged from inflammatory conditions, with growth abnormalities of the epithelium, to squamous-cell papilloma formation (Wehner *et al*., 1974, 1975a,b, 1976).

3.1.4 *Rabbit*

Thirty rabbits were exposed daily in individual compartments to the smoke from 20 cigarettes (2 puffs/min, 2 cigarettes at each treatment period) for up to 66 months. No tumour that could be related to the exposure was observed in any of the exposed rabbits or in 31 controls that survived for 24 months or more (Holland *et al*., 1958, 1963). [The Working Group noted that details of the types of cigarettes, method of smoke generation and doses delivered were not provided.]

3.1.5 *Dog*

Groups of male beagle dogs, 1.7–3.3 years old, trained to inhale cigarette smoke through tracheostomata, were exposed to one of three different treatments: (1) smoke from seven untipped cigarettes containing 34.8 mg tar and 1.85 mg nicotine per day (62 dogs), (2) smoke from seven cigarettes containing the same tobacco, but with filter tips, containing 17.8 mg tar and 1.17 mg nicotine (12 dogs) or (3) smoke from 3.5 untipped cigarettes containing the same tobacco per day (12 dogs). Eight non-exposed tracheotomized dogs served as controls. The body weights of the dogs in the various groups did not differ significantly. Between day 57, when the training period ended, and day 876, when killing of the surviving dogs began, 28 dogs died: 24 in the first group, two in the second, two in the third and none in the control group. Extensive examination of the lungs and bronchial tree at autopsy and microscopically was carried out. Lesions of the lung (reported as tumours), described as 'bronchiolo-alveolar, invasive and noninvasive', were found in 23/62 of dogs in group 1; two of the lesion-bearing dogs in this group also had small bronchial lesions. Non-invasive bronchiolo-alveolar lesions were also found in 4/12 dogs in group 2, 7/12 dogs in group 3 and 2/8 control dogs. The bronchiolo-alveolar lesions tended to be multiple, with as many as 20 per lung lobe, and were found in 41 of the 203 lung lobes from the 29 dogs with such lesions. No distant metastasis was found (Auerbach *et al*., 1970; Hammond *et al*., 1970). [The Working Group noted that no data were given on specific smoking parameters or measures of exposure. They also noted the small number of control dogs used and the unusually high incidence of lung lesions in these animals; these are lesions that rarely occur spontaneously in dogs. The focal inflammatory lesions usually found in the lungs of animals exposed to smoke were not men-

tioned in the report of this study. Examination of the upper respiratory tract and other organ systems was not reported. The authors' interpretation of the photomicrographs as representing neoplasia was not considered to be entirely convincing.]

As part of a study on the combined effects of radon daughters or uranium ore dust and cigarette smoke on the induction of respiratory tumours (see below), 19 male and female beagle dogs, 24–30 months of age, were exposed to cigarette smoke only. The dogs were exposed to the smoke of 10 University of Kentucky 1R1 reference cigarettes per day (three in the morning, four at midday and three in the afternoon) on 7 days per week for 48–60 months; individual masks permitted smoke to be inhaled at every 10th breath. Eight dogs served as sham-exposed controls. Carboxyhaemoglobin levels in smoke-exposed dogs increased with the duration of the experiment, from 2% at 19 months to 4.7% after 50 months; the corresponding mean values for sham-exposed dogs were 1.4% and 1.8%, respectively. Smoke-exposed animals killed after 49 (six dogs), 60 (six dogs), 64 (six dogs) and 65 months (three dogs) were available for analysis. No significant respiratory lesion and no lung tumour was found in either group (Cross *et al*., 1982). [The Working Group noted the small sizes of the groups and the limited evidence of smoke delivery.]

3.2 Inhalation exposure in conjunction with administration of known carcinogens and other agents

3.2.1 *Mouse*

(*a*) *4-(*N-*Nitrosomethylamino)-1-(3-pyridyl)-1-butanone*

A 6-month bioassay in strain A/J mice was conducted to determine whether chronically inhaled mainstream cigarette smoke would either induce lung tumours or promote lung cancer induced by the tobacco-specific nitrosamine, 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK). Groups of 20 female A/J mice were exposed to filtered air or cigarette smoke, injected with NNK, or exposed to both cigarette smoke and NNK. At 7 weeks of age, mice were given a single intraperitoneal injection of NNK at a dose of 100 mg/kg bw and, 3 days later, they were exposed to cigarette smoke for 6 h/day, 5 days per week, for 26 weeks at a mean concentration of 248 mg total particulate matter/m^3. Animals were killed 5 weeks after cessation of exposure for gross and histopathological evaluation of lung lesions. No significant differences in survival between exposure groups were observed. A biologically significant level of exposure to cigarette smoke was achieved as indicated by the reductions in body weight, increases in lung weight and increases in carboxyhaemoglobin levels in blood of about 17%. Tumour incidences were similar between the groups exposed to cigarette smoke and filtered air, and the groups treated with NNK and with cigarette smoke + NNK. Incidences in either of the latter groups were higher than in the groups exposed to cigarette smoke and filtered air. Tumour multiplicity in tumour-bearing animals did not differ significantly between any of the

three groups (filtered air, NNK, cigarette smoke + NNK) in which tumours were observed. Thus, exposure to cigarette smoke neither induced lung tumours nor promoted NNK-induced tumours (Finch *et al*., 1996). [The Working Group noted that the animals were killed 5 weeks after cessation of exposure, which may have been an insufficiently long period to permit tumour development. See also Witschi *et al*. (1997).]

(*b*) *Influenza virus*

The possible interaction between various types of influenza virus and the inhalation of cigarette smoke in the induction of lung tumours in mice has been examined in a series of studies (Harris & Negroni, 1967; Harris *et al*., 1974; Wynder *et al*., 1968). No additive or synergistic effect was observed.

3.2.2 *Rat*

Selected studies are summarized in Table 3.2.

(*a*) *Benzo[*a*]pyrene*

A group of 84 female Wistar rats received a single intratracheal instillation of 2 mg benzo[*a*]pyrene (with infusine and carbon black) followed by exposure to cigarette smoke (cigarette T29, specially manufactured from a composite blend of tobacco representing the major plain cigarette brand smoked in the United Kingdom, diluted 1:5 with air), twice daily, five times per week for life. Three developed squamous-cell carcinomas of the lung. A squamous-cell carcinoma of the lung was observed in one of the 84 rats treated with the benzo[*a*]pyrene mixture alone, and four squamous-cell neoplasms (of which only one was clearly malignant) occurred among 408 rats exposed to cigarette smoke only. The mean survival times were 65 weeks for animals exposed to the smoke plus benzo[*a*]pyrene mixture, 63 weeks for animals exposed to smoke alone and 108 weeks for rats treated with the benzo[*a*]pyrene mixture alone. No lung tumour was observed in untreated or sham-exposed controls (Davis *et al*., 1975a).

Groups of 35 male Wistar rats (weighing 50–70 g) were fed either vitamin A-deficient feed or a conventional diet and were exposed to three weekly intratracheal initiation doses of 20 mg benzo[*a*]pyrene mixed with ferric oxide during the 6th–8th week of the study, or subjected to cigarette smoke from the 2nd to 24th week or the 10th–24th week, or subjected to both types of treatment. The animals were exposed to five cigarettes, 1 h/day in 8.2-L chambers. Animals were killed after the 24th week. Inhalation of cigarette smoke during the initiation and post-initiation phases of carcinogenesis resulted in higher lung tumour multiplicity (2.14 tumours/animal) than that observed in rats exposed during the post-initiation phase only (1.33 tumours/animal) or in the rats treated with benzo[*a*]pyrene only (1.22 tumours/animal). This enhancement of tumour multiplicity was increased further by vitamin A deficiency (2.86 versus 1.67 or 1.83 tumours/animal, respectively). These tumours were classified histopathologically as squamous-cell carcinomas (Gupta *et al*., 1990).

Table 3.2. Selected studies of carcinogenicity in response to exposure to mainstream tobacco smoke in conjunction with exposure to known carcinogens or other agents in rat and hamster

Strain	Sex	No. of treated animals/ group	Agent co-administered	Type of exposure to cigarette smoke	Exposure duration	Tumour incidence	Reference
Rat							
Wistar	F	84–408	Benzo[*a*]pyrene (2 mg) + infusine + carbon black; intratracheally	British reference cigarette smoke/air (1/5)	1 cigarette, twice/day, 5 days/wk, lifetime	3/84 (lung C), 1/84 (lung C; benzo[*a*]pyrene alone), 4/408 (3 A + 1 malignant neoplasm; cigarette smoke only), 0/204 (controls + sham-exposed controls)	Davis *et al.* (1975a)
Wistar	M	35	Benzo[*a*]pyrene (20 mg) + Fe_2O_3; intratracheally (3 weekly doses) during 6th–8th wk of the study	Cigarette smoke (5 cigarettes/8.2 L air)	1 h/day, during 2nd–24th week or 10th–24th week of the study	Conventional diet: 2nd–24th wk, 2.14 lung C/animal; 10th–24th wk, 1.33 lung C/animal; benzo[*a*]pyrene control, 1.22 lung C/animal. Vitamin A-deficient diet: 2nd–24th wk, 2.86 lung C/animal; 10th–24th week, 1.67 lung C/animal; benzo[*a*]pyrene control, 1.83 lung C/animal	Gupta *et al.* (1990)
Sprague-Dawley	NG	28–50	Radon progeny (4000, 500 or 100 WLM)	French reference cigarette smoke (9 cigarettes/ 500 L air)	10–15 min session, 4 days/wk, 1 year	4000 WLM: 34/50 (lung C) [$p = 0.0015$]; 17/50 (lung C; radon progeny alone) 500 WLM: 8/30 (lung C); 2/28 (lung C; radon progeny alone) 100 WLM: 1/30 (lung C); 0/50 (radon progeny alone)	Chameaud *et al.* (1982)
CDF® (Fischer 344)/ CrlBR	M, F	NG	$^{239}PuO_2$ aerosol, 1 wk (6th wk of the study)	Cigarette smoke/air, 100 mg (LCS) or 250 mg (HCS) total particulate matter/m^3	6 h/day, 5 days/wk, 126 wks	49–61% (lung tumours, LCS + $^{239}PuO_2$) 72–74% (HCS + $^{239}PuO_2$) 20–33% ($^{239}PuO_2$) 2–3% (LCS) 7–8% (HCS)	Finch *et al.* (1995)

Table 3.2 (contd)

Strain	Sex	No. of treated animals/ group	Agent co-administered	Type of exposure to cigarette smoke	Exposure duration	Tumour incidence	Reference
Hamster							
Syrian golden/ M + F	M + F	(80 + 80)	DMBA (0.5 mg); intra-tracheally	German ref. cigarette smoke/air (1/15)	Smoke of 30 cigarettes for 7–10 min: twice/day, 5 days/wk, lifetime	32/160 (laryngeal C), 17/160 (laryngeal C; smoke only), 0/160 (DMBA alone)	Dontenwill *et al*. (1973)
Syrian golden	NG	20–40	DMBA (0.24 mg); intra-laryngeally	Cigarette smoke/air (1/7)	Cigarette smoke 2 × 10 min/day, 5 days/wk, 48 wks	3/40 (laryngeal C), 0/20 (smoke only), 0/20 (DMBA alone)	Hoffmann *et al*. (1979)
Syrian golden	M	10–30	NDEA (100 mg/kg bw); subcutaneously	Cigarette smoke/air (1/7)	Smoke of 30 cigarettes for 9 min: twice/day, 5 days/wk, 12 wks	Non-filter cigarettes (2.10 ± 1.74 P+H/animal) [$p < 0.01$] and filter cigarettes (1.93 ± 1.55 P + H/animal) [$p < 0.01$] versus sham-exposed (0.97 ± 1.03 P + H/animal)	Takahashi *et al*. (1992)
Syrian golden	M	30	NDEA (10 mg/hamster); subcutaneously (12 weekly doses)	Non-filter cigarette smoke/air (1/7)	Smoke of 30 cigarettes for 6 min: twice/day, 5 days/wk, 58 wks	14/30 (nasal cavity tumours) ($p < 0.05$), 5/30 (NDEA alone)	Harada *et al.* (1985)

C, carcinoma; A, adenoma; NG, not given; WLM, work-level-months; LCS, low cigarette smoke; HCS, high cigarette smoke; DMBA, 7,12-dimethylbenz[*a*]anthracene; NDEA, *N*-nitrosodiethylamine; P + H, epithelial hyperplasias and papillomas

(*b*) *Chrysotile*

Yoshimura and Takemoto (1991) exposed male Wistar rats intratracheally to 15 mg asbestos (chrysotile) fibres. One month later, the rats were exposed to cigarette smoke in an exposure chamber (smoke from 10 cigarettes/day, 6 days per week, for 1 month). In the group exposed both to asbestos and to cigarette smoke, 4/29 rats developed lung carcinomas, as compared with 1/31 of the rats exposed to asbestos alone. No mesotheliomas were found in the rats treated with asbestos alone, whereas 2/29 rats exposed to a combination of asbestos and cigarette smoke developed mesotheliomas. [The Working Group noted the small numbers of animals per group.]

(*c*) *Radon progeny*

Groups of 28–50 Sprague-Dawley rats were exposed to radon progeny at cumulative doses of 4000, 500 or 100 work-level-months (WLM)[1], with or without concurrent exposure to cigarette smoke by inhalation on 4 days per week for 1 year. Of the 50 rats exposed to 4000 WLM radon progeny without exposure to smoke, 17 developed carcinomas of the lung. In the same group, 34 carcinomas were seen in 50 rats exposed to radon and cigarette smoke. In the groups of rats exposed to 500 WLM radon progeny, two carcinomas of the lung were seen in the 28 rats exposed to radon only as compared with 8/30 rats exposed to radon and cigarette smoke. No lung tumour was observed in any of the 50 rats exposed to 100 WLM radon only, whereas one carcinoma was observed among 30 rats exposed to 100 WLM radon and cigarette smoke. Histopathological evaluation of the lung tumours indicated that approximately 75% were squamous-cell carcinomas, 20% were adenocarcinomas and the remainder were undifferentiated carcinomas (Chameaud *et al*., 1982).

(*d*) *Plutonium oxide*

Beginning at 6 weeks of age, CDF®(Fischer 344)/CrlBR rats were subjected to whole-body exposure for 6 h/day, on 5 days per week, to either filtered air or mainstream cigarette smoke diluted to concentrations of either 100 or 250 mg total particulate matter/m^3 (LCS and HCS groups, respectively). At 12 weeks of age, rats were removed from the smoke exposure chambers and exposed nose-only to either filtered air or plutonium oxide ($^{239}PuO_2$) aerosol, and were returned to the smoke chambers 1 week later for 30 months of continued exposure to either filtered air or cigarette smoke. The incidences of lung tumours in animals exposed to cigarette smoke only are given in Section 3.1.2. In both sexes, there was a pronounced interaction between exposure to smoke and $^{239}PuO_2$ in producing lung tumours. Tumour incidence reached 72–74% in HCS + $^{239}PuO_2$-exposed rats and 49–61% in LCS + $^{239}PuO_2$-exposed rats, whereas the incidence was 20–33%,

[1] WLM is defined as any combination of the short-lived radon daughters in 1 L of air that will result in an ultimate emission of 1.3×10^5 MeV of potential alpha energy in their decay through ^{214}Po. WLM is equivalent to 170 h of exposure to 1 WL.

2–3% and 7–8%, respectively, in rats exposed to $^{239}PuO_2$, LCS or HCS alone. The most prevalent malignant neoplasms were adenocarcinomas, followed by squamous-cell carcinomas and adenosquamous carcinomas. In groups exposed to both agents, there was increased tumour multiplicity, an increased proportion of neoplasms of the squamous phenotype, and several animals with airway-associated lung neoplasms (Finch *et al*., 1995). [The Working Group noted the incomplete reporting of the study.]

3.2.3 *Syrian hamster*

Selected studies are summarized in Table 3.2.

(*a*) *Benzo[*a*]pyrene*

A group of 40 Syrian golden hamsters received a single intratracheal administration of 5 mg benzo[*a*]pyrene mixed with ferric oxide, followed by exposure to cigarette smoke twice for 10 min daily, five times per week, for 48 weeks. Two papillomas of the larynx and three epithelial hyperplasias of the larynx were observed. No such lesion was observed in control groups of 20 hamsters that received benzo[*a*]pyrene plus ferric oxide or smoke alone, and no lung tumour was observed (Hoffmann *et al.*, 1979).

(*b*) *Blue Cape asbestos*

Groups of 80 male and 80 female Syrian golden hamsters were exposed to a single intratracheal instillation of asbestos, followed by exposure to cigarette smoke twice daily, five times per week for life. No significant difference in the occurrence of laryngeal lesions or tumours was observed when compared with another group of hamsters exposed to cigarette smoke alone. No laryngeal tumour occurred in a control group exposed to a single dose of asbestos alone (Dontenwill *et al*., 1973).

(*c*) *7,12-Dimethylbenz[*a*]anthracene*

Three groups of 80 male and 80 female Syrian golden hamsters received 500 μg 7,12-dimethylbenz[*a*]anthracene (DMBA) intratracheally, followed by a 10-min exposure to cigarette smoke twice daily, five times per week for life, or were treated either with cigarette smoke or DMBA only. A total of 32 squamous-cell carcinomas of the larynx were observed in animals treated with both DMBA and cigarette smoke, in comparison with 17 in hamsters exposed to cigarette smoke only and none in hamsters treated with DMBA alone. A similar trend in the incidence of laryngeal leukoplakia was also observed. No increase was observed in the incidences of tumours at other sites in animals treated with both DMBA and cigarette smoke, when compared with animals treated with DMBA alone. Mean survival rates were comparable in all groups (Dontenwill *et al.*, 1973). Similar results were reported from other experiments in which Syrian golden hamsters were exposed to DMBA and cigarette smoke (Kobayashi *et al*., 1974; Hoffmann *et al*., 1979).

(*d*) *4-(*N-*Nitrosomethylamino)-1-(3-pyridyl)-1-butanone*

Groups of 10 male and 9–10 female Syrian golden hamsters received a single subcutaneous injection of NNK at doses ranging from 1 to 10 mg, followed by exposure to University of Kentucky 1R1 reference cigarette smoke twice daily for 69 weeks. Tumours of the respiratory tract were observed in NNK-treated hamsters; their incidence was not affected by exposure to cigarette smoke (Hecht *et al.*, 1983).

(*e*) N-*Nitrosobis(2-oxopropyl)amine*

The influence of tobacco smoke on *N*-nitrosobis(2-oxopropyl)amine (NBOPA)-induced carcinogenesis of the pancreatic duct and respiratory tract was investigated using a two-stage carcinogenesis model in hamsters. Five-week-old male hamsters were divided into five groups. Group 1 ($n = 30$) was injected subcutaneously with NBOPA at a dose of 10 mg/kg bw once a week for 3 weeks for tumour initiation and exposed to cigarette smoke over the same period. Group 2 ($n = 30$) was exposed to cigarette smoke for 26 weeks after the NBOPA initiation. Group 3 ($n = 30$) was given NBOPA initiation alone and group 4 ($n = 10$), 26 weeks of exposure to cigarette smoke alone. Group 5 ($n = 10$) served as a sham-exposed negative control. The experiment was terminated 30 weeks after the first NBOPA injection. The incidence of pancreatic carcinomas was significantly decreased in group 1 (5/29, $p < 0.01$) relative to group 3 (17/30), whereas the incidence in group 2 (12/29) was not significantly less than that in group 3. In contrast, the incidence of proliferative lesions of the larynx and trachea (hyperplasias) was significantly higher in group 2 (11/29, $p < 0.01$) than in group 3 (2/30). The incidence of pulmonary hyperplasias was also higher in group 2 (13/29, $p < 0.05$) than in group 3 (5/30), although that of pulmonary adenomas or adenocarcinomas was lower in group 2 (14/29, $p < 0.01$) than in group 3 (24/30). Exposure to cigarette smoke in the NBOPA-initiation phase (group 1) did not affect the development of respiratory lesions. No animals in groups 4 or 5 developed any tumours of the pancreas or respiratory tract. These results suggest that exposure to cigarette smoke inhibits pancreatic carcinogenesis when given in the initiation phase, whereas it modulates (enhances or suppresses) the development of proliferative lesions in the respiratory tract if applied during the promotion stage to hamsters pre-treated with NBOPA (Nishikawa *et al*., 1994). [The Working Group noted the small size of the experimental groups and the short duration of the study.]

(*f*) N-*Nitrosodiethylamine*

The potential short-term promoting effects of cigarette smoke on the development of tumours in the respiratory system were investigated in male Syrian golden hamsters. A dietary supplement of vitamin C (1%) was given to groups of 30 male Syrian hamsters exposed to cigarette smoke in air (1/7) from 30 unfiltered cigarettes for 6 min, twice a day, 5 days a week and also receiving 12 weekly subcutaneous injections of *N*-nitrosodiethyl-amine (NDEA) (total dose, 10 mg/hamster) to determine whether or not high doses of vitamin C could prevent the development of tumours by NDEA in the respiratory tract.

The experiment was terminated 58 weeks after initiation of the treatments. Treatment with NDEA resulted in the development of both benign and malignant tumours of the respiratory tract, and co-exposure to cigarette smoke potentiated the development of tumours in the nasal cavity (14/30 versus 5/30, $p < 0.05$) (Harada *et al*., 1985).

Three groups (1, 2 and 3) of 30 animals each received a single subcutaneous injection of 100 mg/kg bw NDEA and were then exposed to smoke from untipped cigarettes (NC), from filter-tipped cigarettes (FC) and sham smoke, respectively, from week 1 to week 12. In addition, groups 4, 5 and 6 (10 animals each) did not receive treatment with NDEA, but were exposed to the NC smoke, FC smoke or sham smoke, respectively, for the same time period. In the NDEA-treated groups, epithelial hyperplasias and/or papillomas were induced; in groups 1 and 2, the incidences and numbers of these lesions per animal were significantly higher than in group 3 (2.10 ± 1.74 and 1.93 ± 1.55 versus 0.97 ± 1.03, $p < 0.01$) (Takahashi *et al*., 1992).

3.2.4 *Dog*

Nineteen male and female beagle dogs, 24–30 months old, were exposed by inhalation to a combination of radon (105 nCi/L [3900 Bq/L]), radon progeny (605 WLM) and uranium ore dust (12.9 mg/m^3) for 4 h/day, on 5 days per week, for 54 months. A second group of 19 beagle dogs was exposed to the smoke from 10 cigarettes/day on 7 days per week at intervals between exposures to radon progeny and uranium ore dust. Lifespan was shorter in both groups than in controls. Eight dogs exposed to radon alone had nine respiratory tumours (two nasal carcinomas, six pulmonary carcinomas, one pulmonary fibrosarcoma); and 2/19 dogs in the group that received radon plus cigarette smoke had respiratory tumours (one nasal carcinoma and one pulmonary carcinoma) (Cross *et al*., 1982). [The Working Group noted the small sizes of the groups and the incomplete reporting.]

3.3 Administration of tobacco-smoke condensate[1]

Selected studies are summarized in Table 3.3.

Attempts to induce tumours with tobacco products were reported as early as 1911 (for a summary of early studies, see Wynder & Hoffmann, 1967). In the 1950s, Wynder *et al*. (1953) painted the skin of CAF_1 mice with cigarette-smoke condensate (CSC) suspended in acetone. After 24 months, 48/81 mice had developed skin papillomas and 36/81 had developed skin epidermoid carcinomas at the sites of application.

[1] The terms 'smoke condensate' and 'tar' are often used interchangeably. Cigarette-smoke condensates are produced by passing smoke through cold traps and recovering the material retained within them. This material is often washed from the traps with a volatile solvent, which is later removed, and unknown amounts of the volatile and semivolatile constituents are lost. Total particulate matter (TPM) is that material which is retained in a high-efficiency particulate filter. If this material is washed from the filter and concentrated as above, semivolatiles are lost. In the USA, the term 'tar' as used in official reports of tar yield is equivalent to TPM less nicotine and water.

Table 3.3. Selected studies of carcinogenicity in response to exposure to cigarette-smoke condensate in mouse, rat and rabbit

Strain	Sex	No. of treated animals/ group	Type of exposure	Exposure dosage and duration	Tumour incidence	Reference
Mouse						
CAF1	M + F, 1:1	44–112	Skin painting (dorsal) of CSC	CSC/acetone solution (40 mg CSC/ application), × 3/wk, lifetime	36/81 (skin epidermoid C), 0/30 (acetone controls)	Wynder *et al*. (1953)
ICR Swiss	F	5200	Skin painting (dorsal) of CSC	CSC/acetone solution (150 mg or 300 mg CSC/week), × 6/wk, 78 wks	482/5200 (skin C), 3/800 (acetone controls)[a]	Gargus *et al.* (1976)
ICR Swiss	F	4900	Skin painting (dorsal) of CSC	CSC/acetone solution (25 mg or 50 mg CSC/application), × 6/wk, 78 wks	1157/4900 (skin C), 0/800 (acetone controls)	Gori (1976)
ICR/Ha Swiss	F	100	Topical application with CSC to oral mucosa (lips and oral area)	CSC/acetone (26 mg CSC/application), × 5/wk, 15 months	52/81 (lung tumours)[b] ($p < 0.0001$), 20/89[b] (acetone controls)	DiPaolo & Levin (1965)
Initiation study						
ICR/Ha Swiss	F	30	Skin painting (dorsal) with CSC active fraction with or without subsequent painting of the skin with croton oil	CSC active fraction/acetone (2.5 mg of 0.6% CSC/application), 10 × on alternate days Croton oil (2.5%), × 3/wk, up to 15 months, 10 days after last CSC active fraction application	After 12 and 15 months: 4/30 (skin C), 0/65 (croton oil controls)	Hoffman & Wynder (1971)
Promotion study						
Swiss	F	30–50	Skin painting (dorsal) of CSC with or without initiation by DMBA application	DMBA (75 µg); CSC/acetone (75 mg CSC/application, start: 1 wk after DMBA application), × 2–3/wk, 12 months – animals observed 3 months later	DMBA: 2/30 (skin C) (7 %) 2 × CSC: 1/40 (skin C) (3 %) DMBA + 2 × CSC: 8/30 (skin C) (27 %) 3 × CSC: 11/50 (skin C) (22 %) DMBA + 3 × CSC: 11/30 (skin C) (37 %)	Wynder & Hoffmann (1961)

CSC, cigarette-smoke condensate; wk, week; C, carcinoma; DMBA, 7,12-dimethylbenz[*a*]anthracene; DMSO, dimethyl sulfoxide; NG, not given; yrs, years

[a] Skin papillomas

[b] Mostly adenomas

[c] Incidence in animals that died 43–107 weeks after injection

[d] 4 × 10 rats/group terminated before 120 weeks

During the next decade, methods of generating CSC and of treating animals were refined and standardized within and between laboratories. Currently, cigarettes are machine smoked, generally using a 35-mL puff drawn for 2 s each minute. The condensate is collected in glass vessels at low temperatures and removed using a volatile solvent, such as acetone, under reduced pressure. In some studies, animals have also been treated with a diluted suspension of CSC in a suitable solvent. Some of the variables that have not been standardized between different laboratories include choice of animal (or strain), dose and frequency of treatment, choice of solvent, conditions of storage of CSC, the puff profile of the smoking machine and the number of cigarettes that are puffed simultaneously.

Nevertheless, when mouse skin has been used as the test tissue in experiments carried out over the last 35 years, the results from various laboratories have been similar with respect to the overall degree of carcinogenic activity of CSC and to the major differences in activity between CSC from cigarettes of different design (Wynder *et al*., 1957; Davies & Day, 1969; Dontenwill *et al.*, 1972; Bernfeld & Homburger, 1976; Gargus *et al.*, 1976; Gori, 1976; Dontenwill *et al*., 1977b; Gori, 1977; Lee *et al*., 1977; Gori, 1980). Subtle differences in smoking technique, CSC storage conditions and procedures for animal exposure do not appear to affect the results critically.

Animal studies conducted before 1964 provided a measure of support for the epidemiological demonstration that cigarette smoke is an important human carcinogen. Since that time, the mouse-skin studies have served primarily to determine whether differences in cigarette design affect the carcinogenic effects of CSC and whether these effects can be correlated with the chemical composition of the condensates. In addition, mouse-skin studies may help to elucidate the mechanisms through which CSC induces tumours in animal tissues. For example, it has been shown that CSC contains tumour initiators (Hoffmann & Wynder, 1971) and that CSC and some of its fractions and components can exhibit tumour-promoting activity (see, for example: Wynder & Hoffmann, 1961; Bock *et al*., 1969; Hoffmann & Wynder, 1971; Lazar *et al*., 1974; Van Duuren & Goldschmidt, 1976).

3.3.1 *Skin application*

(*a*) *Mouse*

CSC produces both benign and malignant tumours on mouse skin. The carcinogenic potency of the CSC depends on tobacco variety, composition of cigarette paper and the presence of additives (see, for example, Wynder *et al*., 1957; Davies & Day, 1969; Dontenwill *et al*., 1972; Gargus *et al.*, 1976; Gori, 1976; Dontenwill *et al*., 1977b; Gori, 1977, 1980). The tumours induced are usually of epidermal origin. Ohmori *et al.* (1981) reported a low, but significant incidence of mastocytomas in a series of experiments in which mouse skin was treated with CSC.

An example of mouse skin studies is given in a series of four publications (see Gargus *et al.*, 1976; Gori, 1976, 1977, 1980) that reported the results of skin-painting experiments

in which more than 100 variables of CSC were tested in female ICR Swiss mice. These data permitted an evaluation of the overall carcinogenicity of CSC and of intralaboratory variation in bioassay results over time, because, in these studies, University of Kentucky 1R1 and SEB cigarettes stored at –20 °C were tested in four series of studies begun in 1970, 1972, 1974 and 1975, and the results (Table 3.4) are representative of the tumour response found in such studies. The purpose of the studies was to investigate possible relationships between biological activity and cigarette design as well as the chemical characteristics of cigarette smoke. The CSC derived from reference cigarettes and specially modified cigarettes was applied generally at two dose levels, usually 25 mg and 50 mg per 0.1-mL application, 6 days a week, for 78 weeks. Acetone was used as the solvent. In some instances, 3-, 6- and 12.5-mg doses were also given, and, for a single type of CSC, doses of 10 mg and 20 mg were given twice daily or five times a week for 78 weeks. Solvent-treated and untreated controls were kept. Test group sizes usually comprised 100 animals, but up to 800 controls were used; 6400–9200 mice were used for each of the four sets of experiments. A skin tumour was observed in 3/800 acetone-treated controls; otherwise, no tumours and no carcinomas were found in control animals. Skin tumours, frequently malignant, were found in every CSC-treated group. [These extensive studies reported differences in the activity of CSCs from cigarettes of different design. The Working Group of the *IARC Monographs* on tobacco smoking (IARC, 1986) noted that, although the trends of the differences were often consistent, different statistical procedures were used to analyse the data, and insufficient data were provided to permit a uniform analysis for quantitative comparison of these data.]

Cigar and pipe smoke condensates have also been tested on mouse skin. In one such study, a 1:1 (w/v) acetone solution of nicotine-free cigar or pipe tar was painted three

Table 3.4. Skin tumour[a] incidences in ICR Swiss mice after skin painting with smoke condensate from reference cigarettes[b,c]

Series	Date of start of study	Reference cigarette				
		1R1	SEBI	SEBII	SEBIII	SEBIV
I	1970	82/200	84/200	–	–	–
II	1972	98/200	115/200	383/800	–	–
III	1974	49/100	51/100	–	46/100	–
IV	1975	95/200	–	–	87/200	326/800

[a] Not corrected for interim deaths; tumours classified as 'papillomas' and 'carcinomas' in series I and II, as 'papillomas' and 'other malignancies' in series III, and as 'tumours' in series IV.

[b] From Gargus *et al.* (1976) and Gori (1976, 1977, 1980)

[c] Age of animals at start: 'approximately' 6 weeks in series I and II; 'at least' 6 weeks in III and IV.

times a week on the skin of female Swiss mice. A 1:1 acetone solution of whole CSC was also employed. At the end of 19 months, skin papillomas were produced in 65% and carcinomas in 41% of 46 mice treated with the nicotine-free cigar tar, papillomas in 69% and carcinomas in 33% of 45 mice treated with the nicotine-free pipe tar, and papillomas in 47% and carcinomas in 33% of 86 mice treated with CSC. No tumour was produced in 23 acetone-treated controls. At 9 months, when the first tumours appeared, 78% of the controls and 70–91% of the tar-treated animals were still alive (Croninger *et al*., 1958). [The Working Group recognized that the nicotine-free cigar and pipe tars were prepared in a manner that would cause unknown changes in their composition.]

(*b*) *Rat*

McGregor (1976) and McGregor and Myers (1982) reported that CSC appeared to act as a co-carcinogen with β-irradiation on rat skin. CSC alone was reported to induce one benign tumour in 72 normal rats and six benign skin tumours in 78 rats in which the skin keratin layer had been removed before painting the skin. [The Working Group noted that the data, as presented, are not adequate to permit evaluation of these reports.]

(*c*) *Syrian hamster*

Bernfeld and Homburger (1983) reported that Syrian golden hamster skin is not responsive to CSC applied alone. [The Working Group noted that only 16 of the 50 animals treated with CSC alone were observed for up to 46–47 weeks.]

(*d*) *Rabbit*

CSC was applied using a brush to the inner surface of the ears of 38 rabbits five times a week as a 50% w/v suspension in acetone. On alternate weeks, the accumulated surface tar was removed using an acetone-soaked cotton ball or forceps. After 4–6 years of treatment, all of the rabbits had developed large papillomas, and four had skin cancer. Of seven control animals treated with acetone, none developed cancer, but five had small papillomas on the ears (Graham *et al*., 1957).

3.3.2 *'Initiation–promotion' skin-painting studies*

Mouse

A number of investigators have found that CSC and its fractions can act as co-carcinogens when applied together with other agents. In one assay for tumour-initiating activity, 50 μL of an acetone solution containing 2.5 mg of a CSC fraction (0.6% of the whole tar) was applied to the dorsal skin of female ICR/Ha Swiss mice during the second telogen phase of hair growth. This procedure was repeated on alternate days until a total of 10 doses had been applied. Ten days after the last initiating dose, the mice were painted three times a week with 2.5% croton oil in acetone. After 12 months, 67% (20/30) of mice had developed papillomas and 13% (4/30) had carcinomas; after 15 months, 73% (22/30)

had papillomas and 13% (4/30) carcinomas The first tumour appeared within 4 months of start of initiating treatment. Sixty-five mice treated with croton oil only developed no tumours (Hoffmann & Wynder, 1971).

Groups of 30 female Swiss mice were painted twice weekly with 75 mg CSC (solution of 50% CSC in acetone) for 12 months. Of animals that had been treated first (one week before) with 75 μg DMBA, 13/30 (43%) developed skin papillomas and eight (27%) had carcinomas 15 months after initiation. In mice that did not receive DMBA treatment, only 4/40 (10%) had papillomas and one (3%) had a carcinoma. Of 50 mice painted three times weekly with CSC, 22 (44%) developed skin papillomas and 11 (22%) had carcinomas. Of 30 animals treated first (one week before) with a single dose of DMBA, 19 (63%) developed skin papillomas and 11 (37%) had carcinomas. Of mice treated with DMBA alone, 3/30 (10%) had skin papillomas and two (7%) had carcinomas. When a 10% solution of the phenolic fraction of CSC in acetone was applied three times weekly to 30 mice pre-treated with DMBA, nine animals (30%) developed papillomas, but no carcinomas. No tumour was seen in mice that had not received DMBA initiation (Wynder & Hoffmann, 1961). [The Working Group noted that the data do not establish that this effect was due to promotion or whether it represented an additive effect of two weak tumorigenic stimuli.]

3.3.3 *Topical application to oral mucosa*

Mouse

The lips and oral areas of groups of 100 ICR/Ha Swiss mice were painted five times a week for 15 months with approximately 26 mg CSC in an acetone suspension**.** Control groups of 100 mice were either untreated or treated with acetone alone. The study was terminated after 18–19 months, at which time 81–90% of the animals were still alive. Of the surviving mice in the experimental group, 64% (52/81, $p < 0.0001$) developed lung tumours, in contrast to 22% (20/89) in the control groups. In addition, 21% of the treated animals developed tumours of other organs, primarily lymphomas, in contrast to 3–8% in the two control groups (DiPaolo & Levin, 1965).

3.3.4 *Intrapulmonary administration*

(*a*) *Rat*

Stanton *et al.* (1972), following up the earlier studies of Blacklock (1961), injected 0.05 mL beeswax:tricaprylin (v/v) containing 24 mg CSC into the lungs of female Osborne Mendel pathogen-free rats after thoracotomy. The pellets thus formed were large enough to entrap bronchioles. The residues of the pellets could be recognized for more than 2 years after treatment. Fourteen of 40 rats that died between 43 and 107 weeks developed squamous-cell carcinomas. The non-polar constituents of CSC appeared to be an important, but not the sole contributor to this activity. Thus, when the beeswax:tricaprylin

mixture contained 12 mg of the heptane-soluble fraction of CSC, squamous-cell carcinomas developed in 5/18 rats. No tumour was seen in any of the 63 rats that died 43–107 weeks after injection with beeswax:tricaprylin alone.

These observations were confirmed by Dagle *et al.* (1978) using CSC from two different types of cigarette. They observed a dose-dependent incidence of lung carcinomas when either condensate was injected in beeswax:tricaprylin. No carcinoma was induced by beeswax:tricaprylin alone. With the highest dose of CSC (67 mg), the prevalence of carcinoma reached 42% in 120 weeks. No difference was observed in tumour response to the two CSCs.

Groups of Wistar rats were injected intratracheally with CSC or CSC fractions without vehicle every 2 weeks for life. There was a dose-dependent increase in the mean grade of squamous metaplasia in the groups treated with CSC and with several fractions of CSC. After treatment with CSC and most fractions, no tumours were observed, but after treatment with a fraction containing most of the polynuclear aromatic hydrocarbons of cigarette smoke, 5/54 rats developed neoplastic lung lesions (Davis *et al*., 1975c). [The Working Group noted that the relatively infrequent dosage employed by Davis *et al.* may have been less adequate as a stimulus than prolonged release of the material from a lipid vehicle that persists at the injection site.]

(*b*) *Hamster*

CSC and the 'nitromethane-soluble' fraction of CSC were found to be weak carcinogens when injected in beeswax directly into hamster lung (Ketkar *et al*., 1979). The method used was similar to that used by Stanton *et al.* (1972) in rats; 0.03 mL of a 1:1 beeswax: tricaprylin mixture was used as the solvent. A group of 31 hamsters injected with 50 mg CSC developed one bronchogenic adenoma; two animals exhibited metaplasia. When 25 mg of the nitromethane fraction of CSC was given to another group of 31 animals, three developed bronchogenic adenomas and nine had metaplasia.

3.3.5 *Gavage study*

Mouse

The carcinogenicity of smoke condensates of Indian bidi [Indian sun-cured tobacco wrapped in *tendu* leaf (*Diospyros melanoxylon* or *Diospyros ebenum)* and smoked] was administered to male Swiss albino mice by oral gavage in suspensions of 1 mg condensate/0.1 mg dimethyl sulfoxide, 5 days per week, for 55 weeks. Animals were killed when moribund or 90 weeks after the beginning of treatment. Lung, liver, stomach and oesophagus were fixed in formalin and processed for histological examination. Four hepatic haemangiomas, one stomach papilloma, one stomach carcinoma and one oesophageal carcinoma were found in 15 mice that received bidi smoke condensate. No tumours were seen in untreated controls (15 mice) or dimethyl sulfoxide controls (15 mice) (Pakhale *et al*., 1988).

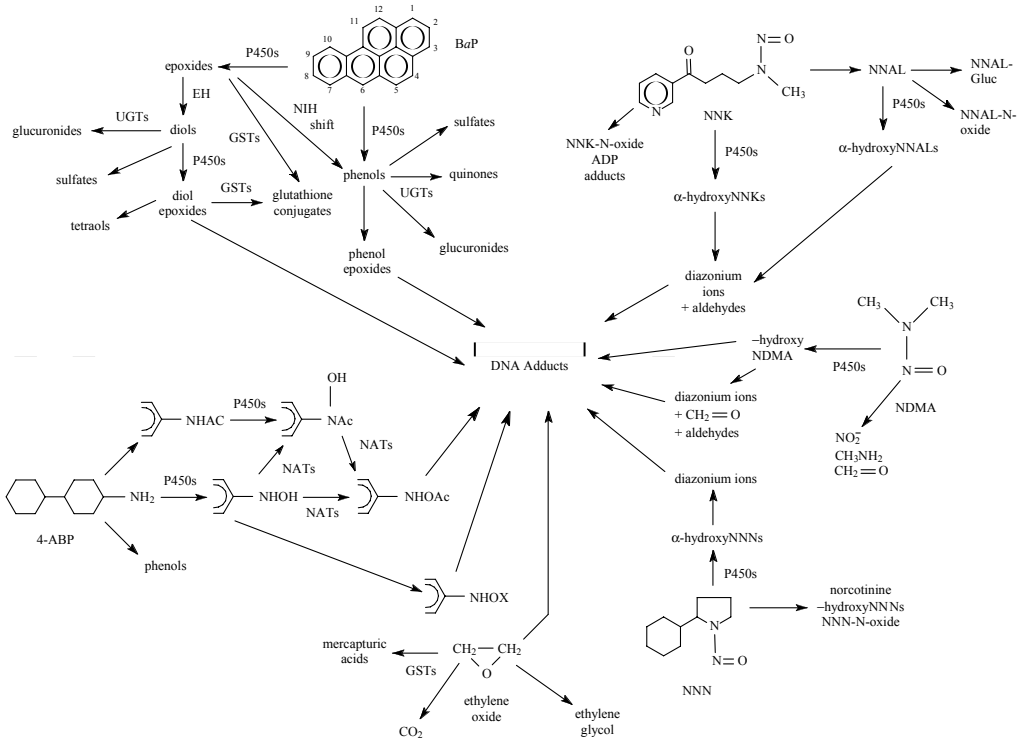
4. Other Data Relevant to an Evaluation of Carcinogenicity and its Mechanisms

4.1 Absorption, distribution, metabolism and excretion

4.1.1 *Humans*



The Working Group attempted to provide extensive coverage of the published literature since 1985, in some cases referring to recent reviews.

(*a*) *Introduction*

Most carcinogens are enzymatically transformed to a series of metabolites as the exposed organism attempts to convert them to forms that are more readily excreted. The initial steps are usually carried out by cytochrome P450 (P450) enzymes that oxygenate the substrate (Guengerich, 1997). Other enzymes such as lipoxygenases, cyclooxygenases, myeloperoxidase and monoamine oxidases may also be involved, but less commonly. If the oxygenated intermediates formed in these initial reactions are electrophilic, they may react with DNA or other macromolecules to form covalent binding products known as adducts. This process is called metabolic activation. Alternatively, these metabolites may undergo further transformations catalysed by glutathione *S*-transferases, uridine-5′-diphosphate (UDP)-glucuronosyltransferases, epoxide hydrolase (EH), *N*-acetyltransferases (NATs) (Kadlubar & Beland, 1985), sulfotransferases and other enzymes (Armstrong, 1997; Burchell *et al*., 1997; Duffel, 1997). Such reactions frequently, but not always, result in detoxification.

Figure 4.1 presents an overview of the metabolism of the six tobacco smoke carcinogens for which the formation of DNA adducts has been demonstrated in human tissues, namely, benzo[*a*]pyrene (IARC, 1983a, 1987), 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK) (IARC, 1985a; Hecht *et al.*, 1994), *N*-nitrosodimethylamine (NDMA) (IARC, 1978a; Shuker & Bartsch, 1994), *N*′-nitrosonornicotine (NNN) (IARC, 1985b; Hecht *et al.*, 1994), ethylene oxide (IARC, 1994a), and 4-aminobiphenyl (4-ABP) (IARC, 1972; Kadlubar, 1994). The major metabolic activation pathway of benzo[*a*]pyrene is conversion to a 7,8-diol-9,10-epoxide, which is highly carcinogenic and reacts with DNA to form adducts with the exocyclic N^2 of guanine (Cooper *et al*., 1983). In competition with this process are detoxification pathways leading to phenols, diols and their conju-

Figure 4.1. Metabolism of six tobacco smoke carcinogens which produce DNA adducts that have been identified in the lungs of smokers

Clockwise from top left: benzo[*a*]pyrene (B*a*P), 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK), *N*-nitrosodimethylamine (NDMA), *N*′-nitrosonornicotine (NNN), ethylene oxide and 4-aminobiphenyl (4-ABP)
P450s, cytochrome P450s; EH, epoxide hydrolase; UGTs, uridine-5′-diphosphate-glucuronosyl transferases; GSTs, glutathione *S*-transferases; NNAL, 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanol; NATs, *N*-acetyltransferases; gluc, glucuronide; 'NIH shift', phenomenon of hydroxylation-induced intramolecular migration; ADP, adenosine diphosphate; Ac, acetyl
In the 4-ABP scheme, X represents conjugates such as glucuronide or sulfate.

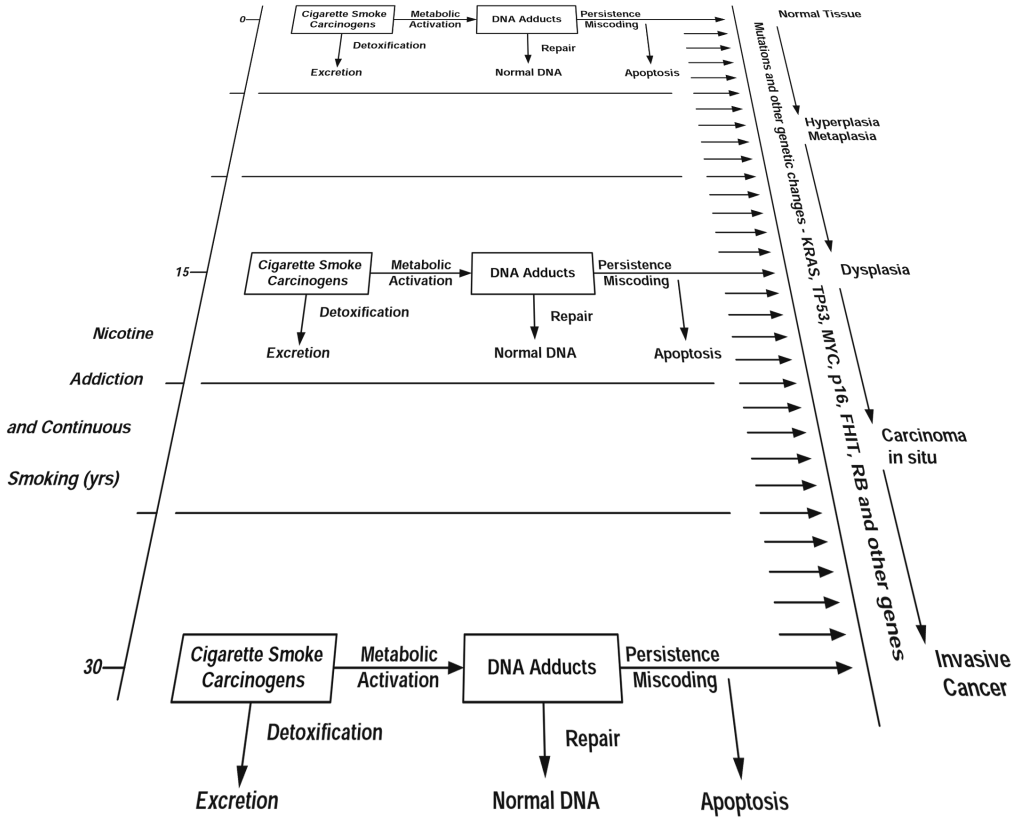
gates as well as other metabolites. The major metabolic activation pathways of NNK and its main metabolite, 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanol (NNAL), involve hydroxylation of the carbons adjacent to the *N*-nitroso group (α-hydroxylation) which leads, via diazonium ions, to the formation of two types of DNA adduct: methyl adducts such as 7-methylguanine and O^6-methylguanine (IARC, 1985a), and pyridyloxobutyl adducts (Hecht, 1998). Glucuronidation of NNAL and pyridine-*N*-oxidation of NNK and NNAL are detoxification pathways. The metabolic activation of NDMA occurs by α-hydroxylation leading, via methyl diazonium ions, to the formation of 7-methylguanine

and O^6-methylguanine. Denitrosation, producing nitrite and methylamine, is considered to be a detoxification pathway (Preussmann & Stewart, 1984). Aldehydes are also formed in the metabolism of NNK and NDMA. Their role in carcinogenesis is unclear. α-Hydroxylation of NNN can lead to the formation of pyridyloxobutyl adducts whereas detoxification occurs by β-hydroxylation, pyridine-*N*-oxidation and denitrosation/oxidation to produce norcotinine (Hecht, 1998). Ethylene oxide reacts directly with DNA to form 7-(2-hydroxyethyl)guanine and other adducts. There are competing detoxification pathways involving glutathione conjugation (IARC, 1994b). 4-ABP is metabolically activated by *N*-hydroxylation. Conjugation of the resulting hydroxylamine with acetate or other groups such as sulfate ultimately produces nitrenium ions that react with DNA to produce adducts mainly at C-8 of guanine. Acetylation of 4-ABP can be a detoxification pathway if it is not followed by *N*-hydroxylation. Ring hydroxylation and conjugation of the phenols result in detoxification (Kadlubar & Beland, 1985).



The balance between metabolic activation and detoxification varies between individuals exposed to these genotoxic components of tobacco smoke and is likely to affect cancer risk because DNA adducts are absolutely central to the carcinogenic process induced by these agents (Hecht, 1999; Tang *et al*., 2001). DNA adducts, if unrepaired, can cause miscoding during replication resulting in permanent mutation.

Cells have DNA repair systems that can remove adducts and restore the DNA to its normal structure (Memisoglu & Samson, 2000; Pegg, 2000; Hanawalt, 2001; Norbury & Hickson, 2001). There are interindividual differences in their capacity for DNA repair that can affect cancer risk (Wei *et al*., 2000). Moreover, DNA repair systems are not completely efficient or error-free, and some adducts escape repair and persist in DNA. These persistent DNA adducts can cause miscoding. For example, when the O^6-position of guanine in DNA is methylated following metabolic activation of NNK, the resulting DNA adduct, O^6-methylguanine, is misread by DNA polymerases as adenine, and thymine is inserted during replication (Loechler *et al.*, 1984). The consequence is the permanent conversion of a G:C base pair to an A:T base pair. This mutation and others can activate oncogenes such as *KRAS* or inactivate tumour-suppressor genes such as *TP53*. There are considerable data to indicate that mutations in *KRAS* and *TP53* result directly from the reaction of these genes with metabolically activated carcinogens (Hecht, 1999). Many genetic abnormalities occur during the process of lung cancer induction. These include loss of heterozygosity, microsatellite alterations, mutations in *RAS* oncogenes, *MYC* amplification, *BCL-2* expression, mutations in the *TP53*, *RB*, *CDKN2A* and *FHIT* tumour-suppressor genes, expression of telomerase activity and others (Figure 4.2) (Wistuba *et al*., 1997; Sekido *et al*., 1998). Although the temporal sequence of mutations is somewhat unclear, we do know that carcinogens can, through the process just described, cause irreversible damage to critical genes involved in the control of cellular growth. Smokers are subjected to a chronic barrage of metabolically activated carcinogens that cause these multiple changes (Figure 4.2). This constant assault on genes is entirely consistent with genetic derangements that lead to six proposed hallmarks of cancer:

— self-sufficiency in growth signals;

— insensitivity to anti-growth signals;
— evasion of apoptosis;
— tissue invasion and metastasis;
— sustained angiogenesis; and
— limitless replicative potential (Hanahan & Weinberg, 2000).

Figure 4.2. Scheme linking cigarette smoke carcinogens with genetic changes in lung and lung cancer development

Adapted from Hecht (2002a)
This scheme may also apply to other cancers.
A key aspect is the chronic exposure of DNA to metabolically activated carcinogens resulting in the formation of DNA adducts and consequent genetic changes. This chronic barrage of DNA damage, taking place daily over a period of many years, is fully consistent with multiple genetic changes in lung cancer (it does not always take 30 years to get lung cancer; it may take only five years). Some cigarette smoke carcinogens may operate through other mechanisms. The time periods and sequence of genetic changes are uncertain. For further details see Sekido *et al.* (1998); Hecht (1999, 2002a).

Urinary carcinogen metabolites, carcinogen-protein adducts, and carcinogen-DNA adducts have been used as biomarkers to assess the uptake, metabolic activation and detoxification of tobacco carcinogens in humans. These are discussed in the following sections.

(*b*) *Effects of tobacco smoke on human enzyme activities and metabolism*

(i) *Enzyme induction*

In-vivo studies

The induction by tobacco smoke of several phase I and phase II enzymes in human tissues, including P4501A1, P4501A2, P4502E1 and some isoforms of UDP-glucuronosyltransferase has been widely reported (Anttila *et al.*, 1991; Guengerich *et al.*, 1991; Bock *et al.*, 1994). Similarly, the pharmacological interactions between tobacco smoking and drugs, many of them as a consequence of enzyme induction, have been reviewed (Zevin & Benowitz, 1999). The consequences of this induction are evident in the altered rate of metabolism of many drugs and carcinogens (Zevin & Benowitz, 1999). For example, smoking decreases the activity of H_2-receptor antagonists in reducing nocturnal gastric secretion (Boyd *et al.*, 1983). The metabolic enzymes are also induced by polycyclic aromatic hydrocarbons (PAHs), which may therefore be the components of tobacco smoke that are largely responsible for its enzyme-inducing activity. Cigarette smoke contains a variety of ligands that bind to the Ah receptor, which is known to mediate induction of P4501A1 and P4501A2 (Zevin & Benowitz, 1999).

Pulmonary P4501A1 activity (reflected by aryl hydrocarbon hydroxylase (AHH) activity) is elevated in smokers, and a highly significant correlation between enzyme activity and levels of PAH–DNA adducts has been reported (Geneste *et al.*, 1991; Alexandrov *et al.*, 1992). Among smokers, women with lung cancer had higher levels of *CYP1A1* mRNA and bulky DNA adducts than men with lung cancer (Mollerup *et al.*, 1999).

Smoking results in induction of P450 activity in the human placenta. Evidence for this comes from in-vitro experiments in which placental microsomes were incubated with benzo[*a*]pyrene in the presence of calf thymus DNA; higher levels of DNA adducts result from incubation of microsomes of smokers than of those from nonsmokers (Kim *et al.*, 1992). AHH activity is higher in placental microsomes from women who smoke than from women who do not, but EH activity is not (Vaught *et al.*, 1979). Placental P450 activity, as measured by in-vitro oxidation of 7-ethoxyresorufin, was found to be 10- to 30-fold higher for female smokers than for nonsmokers (Manchester & Jacoby, 1981). In another study, placental microsomes from 32 female smokers were twice as active in benzo[*a*]pyrene metabolism as microsomes prepared from the placentas of 25 nonsmokers, but the in-vitro formation of DNA adducts in the presence of calf thymus DNA was not significantly higher in smokers (Sanyal *et al.*, 1994). In a recent study, maternal smoking was found to be significantly associated with levels of placental *CYP1A1* mRNA ($p < 0.01$) but not with levels of PAH–DNA adducts measured by competitive enzyme-linked immunosorbent assay (ELISA) (Whyatt *et al.*, 1998).

In humans, cigarette smoking significantly enhances CYP2E1 activity in alcoholic patients, as measured by increased metabolism of chlorzoxazone *in vivo* (Girre *et al.*, 1994). CYP2E1 bio-activates some substrates in tobacco smoke and other pro-carcinogens and several hepatotoxins (Guengerich *et al.*, 1991).

The levels of three enzymes involved in DNA repair in the peripheral blood cells of 20 smokers and 17 nonsmokers were compared. O^6-Alkylguanine–DNA–alkyltransferase activity was the same in both groups, but the activities of methylpurine (MeP) and 2,6-diamino-4-hydroxy-5*N*-formamidopyrimidine–DNA glycosylase were lower in nonsmokers; the difference was statistically significant only for MeP (Hall *et al.*, 1993). Exposure of human buccal cell cultures to organic extracts of tobacco (bidi) smoke condensate and betel leaf decreased O^6-methylguanine–DNA methyltransferase activity (Liu *et al.*, 1997).

In-vitro studies

Although there have been many in-vitro studies of the properties of tobacco carcinogens, their effects are not always the same as those of the complex mixture of tobacco smoke. For example, exposure of human U937 cells (human [histiocytic] lymphoma cell line) to tobacco smoke increased the expression of haeme oxygenase-1 (HO-1) and inhibited the activity of nuclear factor-κB (NF-κB) (Favatier & Polla, 2001). However, the tobacco-specific nitrosamine NNK activates NF-κB and induces cyclooxygenase (COX)-1 expression in U937 cells (Rioux & Castonguay, 2000).

(ii) *Enzyme inhibition*

In-vivo studies

Cigarette smoking has been demonstrated to reduce the level of monoamine oxidase B in the brain by about 40%, relative to the levels in nonsmokers or former smokers, although the effect is probably not caused by nicotine. This enzyme plays a key role in dopamine pharmacokinetics (Fowler *et al.*, 1996a). Measurable reductions in monoamine oxidase B were not observed when nonsmokers smoked only one cigarette, implying that the reduction seen in smokers requires chronic exposure and that it may be a gradual response (Fowler *et al.*, 1999). The activity of the enzyme was also significantly lower in the platelets of 23 heavy smokers (≥ 20 cigarettes/day) than in those of 41 nonsmokers ($p < 0.001$) (Yong & Perry, 1986). Smoking cessation resulted in an increase in the activity of platelet monoamine oxidase B, which started after a week of abstinence and was approximately back to normal values after 4 weeks. Low baseline activity of monoamine oxidase B is related to more intense withdrawal symptoms (Rose *et al.*, 2001). Similarly, the activity of monoamine oxidase A was markedly reduced (average, 28%) in the brains of smokers compared with nonsmokers (Fowler *et al.*, 1996b). The emerging view is that, whereas nicotine does not reduce monoamine (A and B) oxidase activity by itself, the reduction of this enzyme by other components of tobacco smoke may lead to the potentiation of nicotine's effect by slowing down the catabolism of certain neurotransmitters, i.e. norepinephrine, dopamine and serotonin (Berlin & Anthenelli, 2001).

The activity of EH in human lung was measured in samples obtained from patients undergoing open chest surgery for lung cancer and non-neoplastic pulmonary disease. In 10 'non-recent' smokers (who had not smoked for > 1 month prior to surgery), levels of cytosolic EH activity, but not of microsomal EH activity, were significantly higher than in nine 'recent' smokers (who had smoked in the month prior to surgery). Cytosolic EH activity was positively correlated with the number of days since smoking cessation ($p < 0.05$) and was inversely correlated with the number of cigarettes smoked per day ($p < 0.01$) (Petruzzelli *et al.*, 1992).

Emphysema is associated with decreased levels of α_1-antitrypsin, a plasma protease that inhibits neutrophil elastase activity. Cigarette smoking is associated with a decrease in neutrophil elastase inhibitory capacity in the lower respiratory tract, increasing the risk for the development of emphysema (Ogushi *et al.*, 1991). Elastase activity in human leukocytes can be suppressed *in vitro* by cigarette smoke extract (Ejiofor *et al.*, 1981). Serum antioxidant activity is significantly lower in smokers than in nonsmokers and, although there is a compensatory increase in ceruloplasmin levels, this increase is insufficient to prevent the suppression of elastase inhibitory capacity of α_1-antitrypsin by cigarette smoke extract (Galdston *et al.*, 1984).

In-vitro studies

Numerous studies have reported enzyme inhibition in cultured cells treated with tobacco smoke, tobacco smoke condensate or extract, or known components of tobacco smoke.

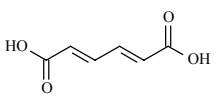
A number of tobacco alkaloids, including *N*-*n*-octanoylnornicotine and *N*-(4-hydroxyundecanoyl) anabasine have been shown to inhibit aromatase activity in cultures of the human breast cancer cell lines, MDA-MB-231 and SK-BR-3, decreasing the estrogen biosynthesis (Kadohama *et al.*, 1993). In cultured MA-10 Leydig tumour cells, tobacco alkaloids (nicotine, cotinine, anabasine) and aqueous extract of cigarette smoke inhibited progesterone synthesis and cell growth by a cytotoxic mechanism; this mechanism could reduce fertilization, implantation and early development of human embryos (Gocze & Freeman, 2000).

The activity of lecithin:cholesterol acyltransferase, which is believed to play a pivotal role in facilitating high-density lipoprotein-mediated removal of cholesterol from peripheral tissues such as arterial cells, is inhibited in human blood plasma by cigarette smoke extract and by a number of aldehydes present in tobacco smoke (i.e. acrolein (IARC, 1995a), hexanal, formaldehyde (IARC, 1995b), malonaldehyde (IARC, 1999a) and acetaldehyde (IARC, 1999b)). The inhibition of the enzyme activity is probably involved in the mechanism of smoking-induced atherosclerosis (Chen & Loo, 1995). There is evidence that the mechanism for this inhibition is based on the covalent modification of the two free cysteine residues (Cys-31 and Cys-184) of the enzyme (Bielicki *et al.*, 1995). Further studies have shown that the activity of another enzyme implicated in protecting against atherosclerosis, plasma paraoxonase, is also inhibited through modification of its thiol groups by cigarette smoke extract (Nishio & Watanabe, 1997). However, exposure

to gas-phase cigarette smoke from four cigarettes over an 8-h period did not inhibit paraoxonase in human plasma under conditions in which the activity of plasma lecithin:cholesterol acyltransferase was inhibited by > 80% and platelet-activating factor acetylhydrolase by 50% (Bielicki *et al.*, 2001).

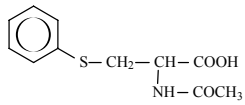
Thiol depletion by cigarette smoke may be induced by α,β-unsaturated aldehydes such as acrolein. The activation of respiratory burst by neutrophils stimulated by phorbol myristate acetate (PMA) was impaired by exposure to gas-phase cigarette smoke, either through depletion of cellular glutathione or by inhibition of NADPH oxidase activation. These effects also occurred when neutrophils were exposed to acrolein (Nguyen *et al.*, 2001). Subsequent experiments demonstrated that acrolein inhibits neutrophil apoptosis and that enzymes relevant to this process were either induced by acrolein, e.g. extracellular signal-regulated kinase (ERK) and p38 mitogen-activated protein kinases (p38 MAPKs), or their activation was prevented, e.g. caspase-3 (Finkelstein *et al.*, 2001). In human bronchial fibroblasts, reactive aldehydes such as acrolein have also been shown to be cytotoxic and to inhibit the DNA repair enzyme O^6-methylguanine–DNA methyltransferase, possibly by reacting with the cysteine thiol group at the active site of the enzyme; no effect on uracil–DNA glycosylase was observed (Krokan *et al.*, 1985).

The activity of aldehyde dehydrogenase (ALDH) in human blood cells *in vitro* was found to be inhibited by cigarette smoke condensate in a dose-dependent manner. This inhibition was associated with the non-volatile fraction of the condensate. The lower levels of ALDH activity observed in alcoholics could be due, in part, to smoking, as alcoholics are frequently also heavy smokers (Helander *et al.*, 1991).



Platelet-activating factor (PAF) (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is a potent pro-inflammatory agent whose degradation is regulated by PAF acetyl hydrolase (PAF-AH), a plasma enzyme. The activity of this enzyme is inhibited in a dose-dependent manner by cigarette smoke extract, which may explain the increase in plasma PAF concentration noted in smokers and may be relevant to the development of smoking-induced cardiovascular and pulmonary diseases (Miyaura *et al.*, 1992).

(*c*) *Biomarkers of tobacco smoke carcinogens*



(i) *Urinary compounds*

Urinary carcinogens and their metabolites are practical and useful biomarkers of the uptake of tobacco smoke constituents. They can provide important information about exposure to tobacco smoke carcinogens, carcinogen doses and mechanisms of carcinogenesis. The use of urinary compounds as biomarkers for investigating the links between tobacco and cancer has been reviewed (Hecht, 2002b). The structures of the compounds discussed below are illustrated in Figure 4.3.

trans,*trans*-Muconic acid (*trans*, *trans*-2,4-hexadienedioic acid), *S*-phenylmercapturic acid and other benzene metabolites

S-Phenylmercapturic acid (*S*-PMA) and *trans*,*trans*-muconic acid (*tt*-MA) are believed to be the most sensitive biomarkers for exposure to low levels of benzene (IARC, 1982, 1987; Stommel *et al*., 1989; van Sittert *et al*., 1993; Boogaard & van Sittert, 1995, 1996; Qu *et al.*, 2000). A recent review has summarized the literature on this subject (Scherer *et al*., 1998). One pathway of benzene metabolism proceeds via ring oxidation and ring cleavage to *trans, trans*-muconaldehyde and finally to *tt*-MA. This metabolite has been widely used as a biomarker of benzene uptake. Significantly elevated levels of *tt*-MA were found in the urine of smokers in 11 of 13 studies (Lee, B.L. *et al.*, 1993; Melikian *et al.*, 1993; Lauwerys *et al.*, 1994; Melikian *et al.*, 1994; Ong *et al.*, 1994; Rauscher *et al.*, 1994; Ghittori *et al.*, 1995; Ruppert *et al.*, 1995; Boogaard & van Sittert, 1996; Buratti *et al.*, 1996; Ghittori *et al.*, 1996; Kivistö *et al.*, 1997; Ruppert *et al.*, 1997). The levels of *tt*-MA were 1.4–4.8 times higher in smokers than in nonsmokers and the additional amount of *tt*-MA excreted by smokers ranged from 0.022 to 0.20 mg/g creatinine (Scherer *et al.*, 1998). However, sorbic acid (*trans*, *trans*-2,4-hexadienoic acid), a widely used food preservative that can be transformed metabolically to *tt*-MA, can also contribute to background levels of *tt*-MA, thereby decreasing its specificity as a benzene biomarker (Scherer *et al*., 1998; Pezzagno *et al*., 1999).

S-PMA is formed by normal degradation of the glutathione conjugate of benzene epoxide. Levels of *S*-PMA were reported to be significantly higher in smokers (1.71 μmol/mol creatinine) than in nonsmokers (0.94 μmol/mol creatinine) whereas levels of *tt*-MA in smokers and nonsmokers were not significantly different (Boogaard & van Sittert, 1996).

Phenol (IARC, 1999c), hydroquinone (IARC, 1999d), catechol (IARC, 1999e) and 1,2,4-trihydroxybenzene are also urinary metabolites of benzene. Mixed results have been obtained in studies of the relationship of the levels of these metabolites in urine to occupational exposure to benzene because background levels are high (Inoue *et al*., 1988, 1989; Ong *et al*., 1995, 1996; Qu *et al*., 2000). There was no difference in levels of urinary catechol between smokers and nonsmokers; diet being a major source of these metabolites, the contribution of smoking is comparatively small (Carmella *et al*., 1982).

1- and 2-Naphthol

1-Naphthol and 2-naphthol (1- and 2-hydroxynaphthalenes) are metabolites of naphthalene (IARC, 2002) that are excreted in urine as glucuronide and sulfate conjugates. The levels of these metabolites are higher in smokers than in nonsmokers (Hansen *et al*., 1994; Heikkilä *et al*., 1995; Jansen *et al*., 1995; Andreoli *et al*., 1999; Kim *et al*., 1999; Yang, M. *et al*., 1999; Nan *et al.*, 2001). For example, Nan *et al*. (2001) found levels of 3.94 ± 1.89 μmol (geometric mean ± geometric standard deviation)/mol creatinine 2-naphthol in smokers as opposed to 1.55 ± 2.19 μmol/mol creatinine in nonsmokers ($p < 0.01$). There is some indication that urinary naphthols may be particularly appropriate as biomarkers of inhalation exposure to PAHs, possibly because of the high volatility of

naphthalene (Jansen *et al*., 1995; Yang, M. *et al*., 1999; Nan *et al*., 2001). It has been proposed that urinary 2-naphthol is a better biomarker of inhalation exposure than urinary 1-naphthol (Nan *et al*., 2001), because it correlated more closely with urinary cotinine level than did 1-naphthol (Yang, M. *et al*., 1999). Levels of urinary 2-naphthol can be affected by genetic polymorphisms in carcinogen metabolizing enzymes such as *CYP2E1* and *GSTM1* (Yang, M. *et al.*, 1999; Nan *et al*., 2001).

Polycyclic aromatic hydrocarbons

Hydroxyphenanthrenes and phenanthrene dihydrodiols

Phenanthrene (IARC, 1983b, 1987) is the simplest of the PAHs with a bay region and is a reasonable model for studies of the metabolism of carcinogenic molecules of PAHs with bay regions. Hydroxyphenanthrenes and phenanthrene dihydrodiols have been quantified in human urine. Heudorf and Angerer (2001), using high-performance liquid chromatography (HPLC) with fluorescence detection, reported highly significant differences in concentrations of 2-, 3- and 4-hydroxyphenanthrene between smokers and nonsmokers and dose–response relationships to cigarettes smoked per day, but such relationships were not found with 1-hydroxyphenanthrene. For example, the amounts of 3-hydroxyphenanthrene were 473 ± 302 ng (mean ± SD)/g creatinine in 100 smokers and 305 ± 209 ng/g creatinine in 288 nonsmokers (p = 0.001). Jacob *et al*. (1999) measured phenanthrene metabolites by gas chromatography–mass spectrometry (GC–MS). They found no significant differences in urinary concentrations of hydroxyphenanthrenes or phenanthrene dihydrodiols between 20 smokers and 10 nonsmokers. [The Working Group noted that the study size was small.] It should be noted that there are important sources of phenanthrene exposure other than smoking (Grimmer *et al*., 1993; Angerer *et al*., 1997; Grimmer *et al*., 1997).

Jacob *et al*. (1999) found a lower ratio of phenanthrene-1,2-dihydrodiol to phenanthrene-3,4-dihydrodiol in the urine of smokers than in nonsmokers suggesting that smoking induces formation of phenanthrene-3,4-dihydrodiol via induction of P4501A2. Similar results were obtained by Heudorf and Angerer (2001) who found that the ratio of 1- plus 2-hydroxyphenanthrene to 3- plus 4-hydroxyphenanthrene decreased with increased number of cigarettes smoked per day. Both studies also reported a decreased ratio of phenanthrene metabolites to 1-hydroxypyrene with increased smoking, reflecting greater intake of pyrene than phenanthrene in smokers.

1-Hydroxypyrene

Pyrene (IARC, 1983c, 1987) is a non-carcinogenic component of all environmental mixtures of PAHs. The major urinary metabolite of pyrene is 1-hydroxypyrene glucuronide (Sithisarankul *et al.*, 1997). Jongeneelen and colleagues pioneered the development of a method for measurement of 1-hydroxypyrene in urine (Jongeneelen *et al.*, 1985). It has been measured in hundreds of studies of occupational and environmental exposure to PAHs. Several reviews of the data on the effects of smoking have been published (Jongeneelen, 1994; Van Rooij *et al*., 1994; Levin, 1995; Heudorf & Angerer, 2001;

Jongeneelen, 2001). Most studies have measured significantly higher levels of 1-hydroxypyrene in smokers than in nonsmokers. Some representative data from recent investigations of urinary 1-hydroxypyrene are summarized in Table 4.1; these data are from non-occupationally exposed individuals. The levels of 1-hydroxypyrene in the urine of nonsmokers vary considerably and are likely to be influenced by environmental pollution and diet. In most studies, the concentrations of 1-hydroxypyrene in the urine of smokers are about twice as high as those in the urine of nonsmokers, although greater differences have been reported. These concentrations may be influenced by genetic polymorphisms in carcinogen metabolizing enzymes (Alexandrie *et al*., 2000; Nerurkar *et al*., 2000; Nan *et al*., 2001; van Delft *et al*., 2001).

Table 4.1. 1-Hydroxypyrene in the urine of smokers and nonsmokers: selected recent studies

Level of 1-hydroxypyrene[a]		Increase[b]	Reference
Nonsmoker	Smoker		
0.233 µg/g C[c]	0.408 µg/g C	1.8-fold	Roggi *et al*. (1997)
0.55 nmol/L urine	1.04 nmol/L urine	1.9-fold	Sithisarankul *et al*. (1997)
0.89 µmol/mol C	0.176 µmol/mol C (< 15 cig/day)	2.0-fold	Merlo *et al*. (1998)

*Benzo[*a*]pyrene metabolites*

The concentrations of benzo[*a*]pyrene in cigarette smoke are quite low. In laboratory animals its metabolites are excreted mainly in the faeces. Therefore, benzo[*a*]pyrene metabolites are difficult to quantify in the urine of smokers.

3-Hydroxybenzo[*a*]pyrene is a major metabolite of benzo[*a*]pyrene *in vitro* and is excreted in urine as its glucuronide. Several methods for quantitation of 3-hydroxybenzo-[*a*]pyrene in human urine have been described (Grimmer *et al*., 1997; Gündel & Angerer, 2000; Simon *et al*., 2000). In occupationally exposed workers, the levels reported are quite low, ranging from about 1 to 14 (median value) ng/L urine. Limited data are available on the levels of 3-hydroxybenzo[*a*]pyrene in smokers. One small study reported 0.1–0.8 ng/L urine in three smokers as opposed to < 0.1–0.2 ng/L in three nonsmokers (Simon *et al*., 2000). In workers in China occupationally exposed to coal smoke, elevated levels of 3-hydroxybenzo[*a*]pyrene and 9-hydroxybenzo[*a*]pyrene have been reported in the urine (Mumford *et al*., 1995).

r-7,*t*-8,9,*c*-10-Tetrahydroxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene (*trans-anti*-B*a*P-tetraol) is a hydrolysis product of *r*-7,*t*-8-dihydroxy-*t*-9,10-epoxy-7,8,9,10-tetrahydro-benzo[*a*]pyrene, the major established ultimate carcinogenic metabolite of benzo[*a*]-pyrene. This metabolite has been quantified in the urine of psoriasis patients treated with a coal-tar ointment and in coke-oven workers and smokers. Concentrations of *trans-anti*-B*a*P-tetraol in the urine of smokers were lower than in the other two groups, ranging from not detected to 0.2 fmol/μmol creatinine. It was detected in urine samples of nine out of 21 smokers (Simpson *et al*., 2000).

Benzo[*a*]pyrene metabolites can be converted to benzo[*a*]pyrene by treatment with hydrogen iodide. This reaction has been employed as the basis for a technique to deter-mine urinary metabolites of benzo[*a*]pyrene and several other PAHs (Becher & Bjørseth, 1983; Becher *et al*., 1984; Venier *et al*., 1985; Haugen *et al*., 1986; Buckley *et al*., 1995). In individuals who were not exposed occupationally, the concentrations of benzo[*a*]-pyrene measured by this method ranged from 4 to 19 ng/mmol creatinine in nonsmokers ($n = 5$) and 18 to 102 ng/mmol creatinine in smokers ($n = 4$) (Becher *et al*., 1984). The disadvantages of this method include different conversion rates for various metabolites and low analytical recoveries (Buckley *et al*., 1995).

The presence of an unstable benzo[*a*]pyrene–DNA adduct, 7-(benzo[*a*]pyren-6-yl)-adenine, was reported in the urine of three out of seven smokers and measured in one as 0.6 fmol/mg creatinine (the concentrations were not quantifiable in the other two smokers) (Casale *et al*., 2001).

Aromatic amines and heterocyclic aromatic amines

Aromatic amines, but not their metabolites, have been quantified in human urine. In one study, smokers excreted 6.3 ± 3.7 μg/24 h 2-toluidine (*ortho*-toluidine, see IARC, 2000), whereas the concentrations in the urine of nonsmokers were 4.1 ± 3.2 μg/24 h, a non-significant difference (El Bayoumy *et al*., 1986). Another investigation reported higher concentrations of *ortho*-toluidine in the urine of smokers than in that of non-smokers (0.6 and 0.4 ng/L urine, respectively) (Riffelmann *et al*., 1995). There appear to be important sources of human uptake of *ortho*-toluidine other than cigarette smoke. Smokers excreted amounts of 4-ABP (78.6 ± 85.2 ng/24 h) similar to those measured in nonsmokers (68.1 ± 91.5 ng/24 h) and the amounts of 2-aminonaphthalene (2-naphthyl-

amine) (IARC, 1974, 1987) excreted by smokers (84.5 ± 102.7 ng/24 h) and nonsmokers (120.8 ± 279.2 ng/24 h) were also similar (Grimmer *et al*., 2000).

DNA adducts have been detected by ^{32}P-postlabelling in urinary bladder biopsies and in exfoliated urothelial cells isolated from the urine of smokers and nonsmokers. At least four adducts may have been related to smoking, one of which was qualitatively similar to the *N*-(deoxyguanosin-8-yl)-4-aminobiphenyl adduct (Talaska *et al*., 1991a,b).

Of the heterocyclic aromatic amines found in cigarette smoke, analyses of urinary metabolites have been carried out on only one, 2-amino-1-methyl-6-phenylimidazo-[4,5-*b*]pyridine (PhIP) (IARC, 1993a) (reviewed in Kulp *et al*., 2000). Most studies have focused on the effects of diet, but one found no effect of smoking on levels of PhIP in urine, after adjustment for ethnicity (Kidd *et al*., 1999).

N-Nitrosamines

N-*Nitrosoproline (IARC, 1978b, 1987) and other nitrosamino acids*

Ohshima and Bartsch (1981) demonstrated that *N*-nitrosoproline (NPRO) could be formed endogenously in humans after the ingestion of proline and nitrate. This finding led to the development of a test for endogenous nitrosation by measurement of NPRO in the urine of people who had ingested proline and nitrate, or proline alone with or without ascorbic acid, an inhibitor of nitrosation (Bartsch *et al*., 1989). The test is safe because NPRO is not metabolized and has not been shown to be carcinogenic. The NPRO test has been applied in several studies designed to compare endogenous nitrosation between smokers and nonsmokers. The results indicate that endogenous formation of NPRO occurs in smokers, and that thiocyanate catalysis may be important (Bartsch *et al*., 1989; Tsuda & Kurashima, 1991; Tricker, 1997). However, mixed results have been obtained in population-based studies (Tricker, 1997).

Several other nitrosamino acids are present in human urine. The major ones are *N*-nitrososarcosine (NSAR) (IARC, 1978c), *N*-nitrosothiazolidine 4-carboxylic acid (*N*-nitrosothioproline) (NTCA) and *trans*- and *cis*- isomers of *N*-nitroso-2-methylthiazolidine 4-carboxylic acid (NMTCA) (Bartsch *et al*., 1989; Tsuda & Kurashima, 1991). NTCA and NMTCA are formed by the reaction of formaldehyde or acetaldehyde with cysteine, followed by nitrosation. Some studies have demonstrated increased concentrations of urinary NTCA and NMTCA in smokers (Tsuda & Kurashima, 1991). Total nitrosamino acids correlated with urinary nicotine plus cotinine in smokers (Malaveille *et al*., 1989), but mixed results have been obtained in other studies (Tricker, 1997). Collectively, the available data support the concept that higher concentrations of nitrosamines can be formed endogenously in smokers than in nonsmokers under some conditions.

4-(*N*-nitrosomethylamino)-4-(3-pyridyl)butyric acid (*iso*-NNAC) was suggested as a potential monitor of the endogenous nitrosation of nicotine (Djordjevic *et al*., 1991). *iso*-NNAC was found in the urine of four of 20 cigarette smokers (at levels of 44, 65, 74 and 163 ng/day). However, no evidence for its formation after the oral administration of nicotine or cotinine to abstinent smokers could be found (Tricker *et al*., 1993).

Volatile nitrosamines

Low-molecular-weight nitrosamines such as NDMA and *N*-nitrosopyrrolidine (NPYR) (see IARC, 1978d, 1987) are extensively metabolized, but small amounts of the unchanged compounds have been quantified in urine (Tricker, 1997). One investigation found that smokers excreted higher levels of NDMA than nonsmokers (Conney *et al*., 1986), but two other studies reported no effect of smoking on the amounts of volatile nitrosamines in urine (Mostafa *et al*., 1994; van Maanen *et al*., 1996).

*4-(*N*-Nitrosomethylamino)-1-(3-pyridyl)-1-butanol, its glucuronides and other metabolites of 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone* (see Figure 4.1)

4-(*N*-Nitrosomethyl(amino)-1-(3-pyridyl)-1-butanol (NNAL), like NNK, is a pulmonary carcinogen with particularly strong activity in the rat (Hecht, 1998). Glucuronidation of NNAL at the pyridine nitrogen gives NNAL-*N*-Gluc while conjugation at the carbinol oxygen yields NNAL-*O*-Gluc (Carmella *et al.*, 2002). NNAL-*N*-Gluc and NNAL-*O*-Gluc both exist as a mixture of two diastereomers and each diastereomer is a mixture of *S*- and *R*-rotamers (Upadhyaya *et al*., 2001). The NNAL glucuronides are collectively referred to as NNAL-Gluc.

NNAL and NNAL-Gluc can readily be determined in urine by gas chromatography–thermal energy analysis (GC–TEA) with nitrosamine-selective detection (Carmella *et al*., 1993, 1995; Hecht *et al*., 1999a). The presence of these metabolites in human urine has also been established by mass spectrometry methods, but these are less convenient and sensitive than GC–TEA (Carmella *et al*., 1993; Parsons *et al*., 1998; Carmella *et al*., 1999; Hecht *et al*., 2001). The amounts typically excreted are about 1 nmol NNAL/24 h and 2.2 nmol NNAL-Gluc/24 h (Hecht *et al.*, 1999a); unchanged NNK is not detected. The investigations of NNAL and NNAL-Gluc in the urine of smokers are summarized in Table 4.2. In all studies to date, these biomarkers have been found to be absolutely specific to tobacco exposure and have not been detected in the urine of nonsmokers unless they had been exposed to secondhand tobacco smoke. Because NNAL is not present in cigarette smoke (see Section 1), the NNAL and NNAL-Gluc in urine originate from the metabolism of NNK. Most investigations to date have demonstrated a correlation between NNAL plus NNAL-Gluc and cotinine. The ratio of NNAL-Gluc:NNAL varies at least 10-fold in smokers and, because NNAL-Gluc is a detoxification product of NNK whereas NNAL is carcinogenic, this ratio could be a potential indicator of cancer risk (Carmella *et al*., 1995; Richie *et al*., 1997). In human urine, (*R*)-NNAL-*O*-Gluc is the predominant diastereomer of NNAL-*O*-Gluc (68%) whereas (*R*)-NNAL is only slightly in excess (54%) over (*S*)-NNAL (Carmella *et al*., 1999). (*R*)-NNAL is the more tumorigenic enantiomer of NNAL in A/J mouse lung in which it is as tumorigenic as NNK (Upadhyaya *et al*., 1999). NNAL and NNAL-Gluc are released only slowly from the human body after smoking cessation (Hecht *et al.*, 1999a) and this finding has been linked to the particularly strong retention of (*S*)-NNAL (Upadhyaya *et al.*, 1999) [possibly at a receptor site].

Table 4.2. 4-(*N*-Nitrosomethylamino)-1-(3-pyridyl)-1-butanol (NNAL) and its glucuronides (NNAL-Gluc) in urine of smokers: biomarkers of 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK) uptake

Study group	Main findings	Reference
11 smokers (9F)[a] 7 nonsmokers	NNAL (0.23–1 μg/24 h (1.1–4.8 nmol/24 h)) and 2 diastereomers of NNAL-*O*-Gluc (0.57–6.5 μg/24 h (1.5–17 nmol/24 h)) identified in urine of smokers, NNAL-GluC in 1/7[b] nonsmokers' urine. NNK not detected	Carmella *et al*. (1993)
61 smokers (31F)	NNAL and NNAL-*O*-Gluc: day-to-day levels stable in smokers' urine; NNAL-Gluc: NNAL ratios fairly stable, over a 4–5 day period; range of NNAL-Gluc:NNAL ratios 0.7–10.8	Carmella *et al*. (1995)
11 smokers (6F)	NNAL + NNAL-*O*-Gluc increased by 33.5% ($p < 0.01$) on days 2 and 3 when watercress was consumed compared with baseline period	Hecht *et al*. (1995)
19 smokers	NNAL-Gluc:NNAL ratio and NNAL plus NNAL-Gluc fairly stable over a 2-year period in one individual	Meger *et al*. (1996)
61 smokers (33F)	NNAL-Gluc:NNAL ratio higher in Caucasians than African Americans	Richie *et al*. (1997)
13 smokers (F)	Indole-3-carbinol caused significant decreases in levels of NNAL and NNAL-Gluc and increased NNAL-Gluc: NNAL ratio	Taioli *et al*. (1997)
30 smokers (18F)	Enantiomeric distribution of NNAL, 54% (*R*-NNAL); diastereomeric distribution of NNAL-Gluc, 68% (*R*-NNAL)	Carmella *et al*. (1999)
27 smokers (13F)	NNAL and NNAL-Gluc highly persistent after smoking cessation: 34.5% of baseline amount remained after 1 week, 15.3% after 3 weeks. No effect of nicotine patch use on levels or persistence of NNAL or NNAL-Gluc	Hecht *et al*. (1999a)
23 smokers (13F)	Reduction in smoking caused a significant decrease in NNAL-Gluc, but not NNAL	Hurt *et al*. (2000)
20 smokers (M)	Levels of NNAL and NNAL-Gluc were 1494 ± 1090 and 1724 ± 946 pmol/day (mean ± SD), respectively[c]	Meger *et al*. (2000)
10 smokers (4 F)	NNAL-*N*-Gluc identified in urine, comprises 50 ± 25% of total NNAL-Gluc	Carmella *et al*. (2002)

[a] Number and letter in parentheses represent number and sex of subjects; F, female; M, male
[b] One nonsmoker appeared to excrete NNAL-*O*-Gluc (~0.7 μg/24 h); the urine of all the other nonsmokers were negative.
[c] [In the original paper, numbers given in the text and table were different; data given in the text are reported here.]

In rodents, NNK and NNAL undergo metabolic oxidation at the pyridine nitrogen giving NNK-*N*-oxide and NNAL-*N*-oxide, respectively. Both metabolites are less tumorigenic in rodents than NNK and NNAL (Hecht, 1998; Upadhyaya *et al.*, 1999). In humans, analysis of the urine of smokers for NNAL-*N*-oxide found that it was present at lower concentrations than NNAL; NNK-*N*-oxide was not detected in the urine of smokers. Thus, pyridine-*N*-oxidation is a relatively minor detoxification pathway of NNK and NNAL in humans (Carmella *et al*., 1997).

4-Hydroxy-4-(3-pyridyl)butanoic acid (hydroxy acid) and 4-oxo-4-(3-pyridyl)butanoic acid (keto acid) are metabolites of NNK resulting from the α-hydroxylation metabolic activation pathway. These metabolites were investigated as potential biomarkers of NNK metabolic activation in humans, but they are also formed from nicotine, which is 1400–13 000 times more abundant in cigarette smoke than is NNK. Since hydroxy acid is chiral, it was thought possible that one enantiomer would be formed preferentially from NNK, whereas the other would be produced from nicotine. Studies in rats demonstrated that this was plausible (Trushin & Hecht, 1999). However, hydroxy acid is a more abundant nicotine metabolite in humans than in rats and consequently even the minor enantiomer, as formed from nicotine, was far greater in concentration than that which would be produced from NNK. Because of the abundant metabolism of nicotine to hydroxy acid and keto acid (see Section 4.1.1.e), these metabolites cannot be used as biomarkers of tobacco-specific nitrosamine metabolism in humans (Hecht *et al*., 1999b; Trushin & Hecht, 1999).

Products of oxidative DNA damage

Cigarette smoke contains free radicals and induces oxidative damage (Pryor, 1997; Arora *et al*., 2001). The gas phase of freshly generated cigarette smoke contains large amounts of nitric oxide (NO) and other unstable oxidants. The particulate phase is postulated to contain long-lived radicals which are an equilibrium mixture of semiquinones, quinones and hydroquinones that causes redox cycling (Pryor, 1997; Hecht, 1999). The presence of such free radicals and oxidants can lead to oxidative DNA damage resulting in the formation of products such as 8-oxo-7,8-dihydro-2′-deoxyguanosine (8-oxodG)[1], [8-hydroxy-2′-deoxyguanosine (8-OHdG)], thymine glycol, thymidine glycol and 5-hydroxymethyluracil. Repair of these modified DNA constituents ultimately leads to their being excreted in urine. 8-OHdG has been quantified frequently in the urine of smokers and nonsmokers and the results have been reviewed. Cigarette smoking usually results in modest increases in the levels of 8-OHdG in urine; 16–50% higher than those in nonsmokers, although negative results have also been reported (Loft & Poulsen, 1998; Priemé *et al*., 1998; Renner *et al*., 2000; Besarati Nia *et al*., 2001). Four weeks of smoking cessation caused a decrease in the excretion of 8-OHdG by 21% (Priemé *et al.*, 1998). A longitudinal study showed that intra-individual variation in the levels of urinary 8-OHdG

[1] There is an equilibrium (50–90%) between 8-oxo-dG and 8-OHdG. The compound will be called 8-OHdG throughout this document.

was greater than the increase due to smoking, suggesting that there may be a complex pattern of factors determining the levels of this biomarker in urine (Kasai *et al*., 2001; Pilger *et al*., 2001). No effect of smoking on urinary concentrations of 5-hydroxymethyluracil was observed (Pourcelot *et al*., 1999).

Thioethers and mercapturic acids

Conjugation of electrophiles with glutathione ultimately results in the excretion of mercapturic acids (*N*-acetylcysteine conjugates) in the urine (van Doorn *et al*., 1979, 1981). A method for determination of total thioethers in urine has been applied in numerous studies comparing smokers and nonsmokers reviewed by van Doorn *et al*. (1981), IARC (1986) and Scherer *et al*. (1996). Cigarette smokers excrete significantly higher levels of thioethers in urine than nonsmokers. There is considerable interindividual variation when diet, a major source of sulfur-containing compounds, is not controlled (Aringer & Lidums, 1988; Scherer *et al*., 1996). The assay of total thioethers in urine provides no information about the structure of the electrophiles which are ultimately detected in urine as conjugates.

More specific methods have been applied to investigate the presence of mercapturic acids in human urine (Scherer *et al*., 2001a). 3-Hydroxypropylmercapturic acid, a likely detoxification product of acrolein, has been detected in the urine of smokers (Mascher *et al*., 2001).

Alkyladenines and alkylguanines

Reaction of alkylating agents with DNA results in the formation of alkyladenines and alkylguanines among other products (Singer & Grunberger, 1983). Alkylation at the 3-position of deoxyadenosine or at the 7-position of deoxyguanosine weakens the glycosidic bond, which readily breaks either spontaneously or is cleaved by glycosylases, ultimately resulting in the excretion of 3-alkyladenines and 7-alkylguanines in urine. 3-Alkyladenines have been more extensively investigated as biomarkers of exposure to alkylating agents than 7-alkylguanines because background levels in urine are expected to be lower. However, substantial amounts of 3-methyladenine occur in the diet (Prévost *et al*., 1993; Fay *et al*., 1997). Nevertheless, two controlled studies have demonstrated increased excretion of 3-methyladenine in the urine of smokers compared with that of nonsmokers (Kopplin *et al*., 1995; Prévost & Shuker, 1996). Background levels of 3-ethyladenine are lower than those of 3-methyladenine (Prévost *et al*., 1993). Two studies demonstrated convincing increases in urinary concentrations of 3-ethyladenine in smokers, indicating the presence in cigarette smoke of an unidentified ethylating agent (Kopplin *et al*., 1995; Prévost & Shuker, 1996). There was no effect of smoking on the concentration of 3-(2-hydroxyethyl)adenine in urine (Prévost & Shuker, 1996). One population-based study found greater amounts of both 3-methyladenine and 7-methylguanine in the urine of smokers than of nonsmokers (Stillwell *et al.*, 1991) while a second found no difference between 3-methyladenine concentrations in smokers and nonsmokers (Shuker *et al.*, 1991).

Metals

Large studies in Germany and the USA demonstrated that urinary cadmium increased with age and smoking (Hoffmann *et al*., 2000; Paschal *et al*., 2000). The study in the USA involved 22 162 participants in the Third National Health and Nutrition Examination survey (NHANES III 1988–94), and urine cadmium, expressed either as uncorrected (μg/L) or creatinine corrected (μg/g creatinine), increased with age and smoking (Paschal *et al*., 2000). The German study, involving 4021 adults, found that active cigarette smoking was the predominant factor affecting cadmium concentrations in the blood and urine of adults. Environmental and occupational exposure to cadmium played only a minor role (Hoffmann *et al*., 2000). These results are consistent with those of other studies of cadmium uptake in smokers (IARC, 1993b). The limited data available do not indicate consistent significant differences in levels of urinary nickel (IARC, 1990a), chromium (IARC, 1990b), or lead (IARC, 1980, 1987) between smokers and nonsmokers (Morimoto *et al*., 1977; Schaller & Zober, 1982; Minoia *et al*., 1988; Jin *et al*., 1997; Huang *et al*., 2000).

Conclusion

Representative levels (nmol/24 h) of eight urinary biomarkers discussed here are summarized in Table 4.3. The amounts of these compounds in urine are generally proportional to the levels of their parent compounds in cigarette smoke, with the possible exception of 8-OHdG and 3-ethyladenine, the precursors for which are not known. It should be noted that there are a number of established tobacco smoke carcinogens for which no urinary biomarkers have been validated. Examples include formaldehyde, acetaldehyde, 1,3-butadiene (IARC, 1999f), ethylene oxide and vinyl chloride (IARC, 1979, 1987; Hoffmann *et al*., 2001).

Of the urinary biomarkers discussed here, the following are consistently higher in smokers than in nonsmokers: *tt*-MA, *S*-PMA, 1-naphthol, 2-naphthol, 1-hydroxypyrene, NNAL and NNAL-Gluc, 8-OHdG, 3-ethyladenine and cadmium. For all of these biomarkers, analytical methods with the requisite sensitivity and specificity are available, but only NNAL and NNAL-Gluc have high specificity as biomarkers of exposure to tobacco smoking because sources other than tobacco smoke, including environmental, dietary and occupational exposure, can contribute to the urinary concentration of the other possible biomarkers. Because NNAL and NNAL-Gluc are metabolites of the tobacco-specific nitrosamine NNK, they are not found in the urine of nonsmokers unless they have been exposed to environmental tobacco smoke (see the monograph on involuntary smoking, this volume). It is possible that other sources, such as nicotine replacement products, could, under certain conditions, contribute to the concentrations of urinary NNAL and NNAL-Gluc but this has not been demonstrated to date (Hecht *et al.*, 2000). Levels of NNAL plus NNAL-Gluc of less than 1 pmol/mL of urine have seldom been observed in smokers whereas the highest levels in nonsmokers exposed to environmental tobacco smoke seldom exceed 0.4 pmol/mL (Hecht *et al*., 2001; Hecht, 2002b).

Table 4.3. Representative concentrations of biomarkers in urine of smokers

Biomarker	Amount: nmol/24h[a]	Precursor (see Section 1) [ng/cigarette smoke][a]	Reference
tt-MA	[1100] (153 μg/24 h)	[6000–70 000]; $r = 0.65$[b]	Scherer *et al*. (2001b)
2-Naphthol	[73[c]] (7.03 ng/mL) (8.49 μmol/mol creatinine)	[2000–4000]	Kim *et al*. (1999)
3-Hydroxyphenanthrene	[3.1] (598 ng/24 h)	[85–620]	Jacob *et al*. (1999)
1-Hydroxypyrene	1.6 (0.35 μg/24 h)	[50–270]	Scherer *et al*. (2000); Hecht (2002b)
trans-*anti*-B*a*P-tetraol	[0.0008] (0.5 fmol/mL)	[9]	Simpson *et al*. (2000)
NNAL + NNAL-Gluc	3.2[d]	[100–200]	Hecht *et al*. (1999a)
8-OHdG	25	?	Pilger *et al*. (2001)
3-Ethyladenine	[0.85] (16–139 ng/24 h)	?	Kopplin *et al*. (1995)

[a] [ ], Calculated by the Working Group, on the basis of data given in the cited reference;
[b] *tt*-MA excretion was significantly correlated with the number of cigarettes smoked per day.
[c] Estimate based on 1.5 L urine excreted per day
[d] NNAL/24 h = 944 pmol; NNAL-Gluc/24 h = 2200 pmol; NNAL + NNAL-Gluc = 3144 pmol/24 h = 3.2 nmol/24 h; correlation with nicotine, $r = 0.44$

(ii) *Protein adducts in human tissues (blood)*

Although proteins are not the target molecules for mutagenic events, protein modifications can be useful biomarkers because of the greater abundance of proteins than of DNA and the fact that protein modifications are not subject to enzymatic repair. The rate of turnover of the proteins and/or of the cells that harbour them implies that carcinogen–protein adducts can provide evidence of exposure on a time-scale of up to several months. In theory, haemoglobin, serum albumin, histones and collagen are suitable proteins to study for this purpose (Skipper *et al.*, 1994), but in practice only haemoglobin and albumin have been extensively studied as biomarkers of human exposure to environmental carcinogens.

Protein adducts are generally detected in one of three ways:

— mass spectrometric detection of the carcinogen moiety after its release from protein by mild acid or base hydrolysis, or release and detection of the modified *N*-terminal valine of haemoglobin;
— immunochemical analysis using antibodies raised against protein adducts; and
— HPLC with fluorescence detection of the released carcinogen (Phillips & Farmer, 1995).

The use of protein adducts as biomarkers of human exposure to carcinogens has been extensively reviewed elsewhere (Strickland *et al.*, 1993; Skipper *et al.*, 1994; Wild & Pisani, 1998; Poirier *et al.*, 2000).

The entire literature on smoking-related protein and DNA adducts in human tissues has been produced since the previous IARC evaluation of tobacco smoking (IARC, 1986). These studies are summarized below.

Adducts formed by aromatic amines

In an early study of 22 smokers and 24 nonsmokers, 4-ABP–haemoglobin adducts[1] were measured by GC–MS. The adduct levels of smokers were significantly higher than those of nonsmokers and there was a significant correlation with average number of packs smoked per day. It is noteworthy that the range of values for smokers (75–256 pg/g haemoglobin) did not overlap with that for nonsmokers (7–51 pg/g) (Perera *et al.*, 1987). The absence of overlap was also reported in another study involving 19 smokers (mean, 154 pg/g) and 26 nonsmokers (mean 28 pg/g); the difference between the two groups was highly significant ($p < 0.001$). The finding of detectable levels of adducts in all the non-smokers is consistent with the existence of environmental sources of 4-ABP other than tobacco smoking (Bryant *et al.*, 1987).

In a group of male volunteers from a case–control study of bladder cancer in Turin, Italy (Vineis *et al.*, 1984), haemoglobin adducts of 15 different aromatic amines were measured in nonsmokers and in smokers of blond- or black-tobacco cigarettes. The smokers of blond tobacco ($n = 40$) and black tobacco ($n = 18$), and three subjects who smoked both types, had significantly higher levels of 4-ABP adducts than 25 nonsmokers. Furthermore, adduct levels were significantly higher (40–50%) for smokers of black tobacco (mean, 288 pg/g) than for those of blond tobacco (mean, 176 pg/g). Adduct levels were found to be correlated with amount smoked per day for all smokers ($p = 0.0015$) and this correlation was also significant for smoking blond tobacco only ($p = 0.0074$). Of other aromatic amines, the levels of 3-ABP adducts were also significantly elevated in smokers ($p < 0.0001$) and associated with numbers of cigarettes smoked by the blond tobacco users ($p = 0.02$). The levels of adducts derived from a further five aromatic amines, 2-naphthylamine, *ortho*-toluidine, *para*-toluidine, 2-ethylaniline and 2,4-dimethylaniline, were significantly higher in the smokers, while those of *meta*-toluidine, 2,5-, 2,6-, 2,3-, 3,5- and 3,4-dimethylaniline and 3- and 4-ethylaniline were not (Bryant *et al.*, 1988). In a subsequent analysis, the authors sought explanations for variability observed between individuals. There appeared to be a distinct difference between the levels measured for the binuclear compounds and those obtained with the mononuclear compounds. Correlations between the levels of the three binuclear amines (2-naphthylamine, 4-ABP and 3-ABP) were significant ($p < 0.05$) and 49/54 of the correlations

[1] [Aminobiphenyls in tobacco have been implicated in bladder cancer etiology in smokers. 3- and 4-ABP–haemoglobin adduct levels are considered valid biomarkers of the internal dose of ABP to the bladder (Probst-Hensch *et al.*, 2000).]

between different mononuclear amines were significant, but only 2/33 correlations between a binuclear and a mononuclear amine were significant. These results suggest the existence of two distinct pathways of metabolic activation of aromatic amines and explain a part, but not all, of the interindividual variation in adduct levels observed (Ronco *et al.*, 1990).

As part of a validation exercise in a study of 4- and 3-ABP–haemoglobin adducts in nonsmokers exposed to secondhand smoke (see the monograph on involuntary smoking, this volume), seven smokers who quit were monitored on the day they stopped smoking and again at least 2 months later. The mean levels of 4-ABP adducts fell by 75% from 130.4 pg/g at baseline to 33.3 pg/g and the mean level of 3-ABP fell by at least 80% (from 16.0 pg/g to a baseline of 1.7 pg/g) (in four cases levels of 3-ABP fell below the limit of sensitivity of the assay) (Maclure *et al.*, 1989). A further study of smokers enrolled at a cessation clinic found that the 34 subjects starting the programme had a mean level of 4-ABP–haemoglobin of 120 ± 7 (SE) pg/g which declined to 82 ± 6 pg/g after 3 weeks. In the 15 smokers who remained abstinent after 2 months, the level was 34 ± 5 pg/g. The rate of decline was slightly more rapid than would be expected from the assumption that erythrocytes have a lifespan of 120 days. There was little correlation between plasma cotinine levels and haemoglobin adducts (Maclure *et al.*, 1990). Similar findings were reported from another study of smoking cessation. The mean level of haemoglobin adducts at baseline was four-fold higher than the mean value 8 months later. Depending on the model used, the half-life of the adducts was estimated to be 7–12 weeks (Mooney *et al.*, 1995).

In a study of 50 nonsmokers, 31 smokers of blond tobacco, 16 smokers of black tobacco and three pipe smokers, the relationship between smoking blond or black tobacco and 4-ABP–haemoglobin adduct levels was confirmed ($p = 0.0001$ in both tests). A linear relationship between adduct levels and the numbers of cigarettes smoked in the preceding 24 h was also observed. Furthermore, when the subjects were divided into slow and rapid acetylators (by measuring their urinary excretion of caffeine after administration of a test dose), it was found that the ratio of adduct levels in slow acetylators to that in rapid acetylators was 1.6 for nonsmokers, 1.3 for blond-tobacco smokers and 1.5 for black-tobacco smokers. This approximates to the estimated relative risk of the slow acetylator phenotype for bladder cancer of 1.3 (95% CI, 1.0–1.7) (Evans, 1986; Vineis *et al.*, 1990). A further study of this group, as well as confirming these findings, also found that urinary mutagenicity was associated with the number of cigarettes smoked, but not with the acetylator phenotype (Bartsch *et al.*, 1990). Subsequently, 4-ABP–haemoglobin adduct levels in 21 nonsmokers, 11 blond-tobacco smokers and seven black-tobacco smokers were found to correlate with the total amount of DNA adducts in exfoliated urothelial cells ($p = 0.03$) (Talaska *et al.*, 1991b).

In a case–control study of lung cancer with 53 cases (23 smokers) and 56 controls (18 smokers) (33 with non-cancer pulmonary disease and 23 with non-pulmonary cancer), levels of 4-ABP–haemoglobin adducts were higher in smokers than in nonsmokers and reflected recent exposure to tobacco smoke. There was no association between adduct

levels and lung cancer (Weston *et al.*, 1991). [The control group may have biased the results.] However, in a case–control study of bladder cancer, the mean adduct level in the cases (n = 13, all smokers) was significantly higher than in the controls (n = 13, all smokers) (103 ± 47 [SD] and 65 ± 44 pg/g haemoglobin, respectively; p = 0.04) (Del Santo *et al.*, 1991).

The levels of 4-ABP-haemoglobin adducts were also significantly higher in pregnant women who smoked (n = 15) than in those who did not (n = 40) (183 ± 108 and 22 ± 8 pg/g haemoglobin; $p < 0.001$), respectively, in a study in which levels of the adduct in fetal blood were also measured (see the monograph on involuntary smoking, this volume) (Coghlin *et al.*, 1991). Similarly, a study of 74 nonsmokers and an equal number of smokers measured paired maternal–fetal blood samples. The levels of 4-ABP-haemoglobin adducts were significantly higher in the smokers, and the ratios of adduct levels in maternal and fetal cord blood were found to be similar to those reported in the previous study. There was also a correlation between adduct levels in maternal blood and number of cigarettes smoked per day (Myers *et al.*, 1996).

In another study comparing 27 pregnant women who smoked with 78 who did not, significantly higher levels of haemoglobin adducts of 3-ABP ($p < 0.001$), 4-ABP ($p < 0.001$), *ortho*-toluidine ($p < 0.001$), *para*-toluidine ($p < 0.001$) and 2,4-dimethylaniline ($p < 0.05$) were found in smokers than in nonsmokers (Branner *et al.*, 1998).

A study of smokers and nonsmokers, in which an analysis of the haemoglobin adducts of several aromatic amines was made, revealed significantly higher levels in smokers of those adducts formed by 4-ABP ($p < 0.001$), 3-ABP ($p < 0.001$) and 2,4-dimethylaniline ($p < 0.05$), but not of those formed by aniline, *ortho*-toluidine, *meta*-toluidine, *para*-toluidine, 2-ethylaniline or *ortho*-anisidine (IARC, 1999g). For many of these comparisons, the number of subjects was small (4–22 smokers, 4–16 nonsmokers) (Falter *et al.*, 1994).

Comparisons of 3- and 4-ABP-haemoglobin adducts in three different racial groups (white, black and Asian) led, as expected, to the detection of higher levels of both adducts in 61 smokers than in 72 nonsmokers (these levels were highest in whites, intermediate in blacks and lowest in Asians). There was also a correlation with the numbers of cigarettes smoked per day ($p < 0.0005$). Subjects from all three ethnic groups with the slow acetylator phenotype had higher adduct levels than those in rapid acetylators (2.5-fold higher for 3-ABP, $p < 0.0005$; 1.2-fold higher for 4-ABP, p = 0.19) (Yu *et al.*, 1994).

Differences in the levels of 3- and 4-ABP–haemoglobin adducts between men and women have also been reported. When plotted against number of cigarettes smoked per day, the slopes of the linear regression lines of adduct levels were significantly steeper for women than for men in a cohort of 1514 patients with bladder cancer and 1514 matched controls ($p < 0.001$ and 0.006 for 3-ABP and 4-ABP, respectively) (Castelao *et al.*, 2001).

In a group of 55 smokers and four nonsmokers, the levels of 4-ABP–haemoglobin adducts were related to the number of cigarettes smoked, although saturation of adduct formation was apparent at > 30 cigarettes/day. *GSTM1* and *NAT2* polymorphisms did not affect the levels of haemoglobin adducts (Dallinga *et al.*, 1998). The same authors investigated other genetic polymorphisms in 67 smokers and found no overall effects of poly-

morphisms in *NAT1, NAT2, GSTM1* or *GSTT1* on 4-ABP–haemoglobin adduct levels, except that in smokers of < 25 cigarettes/day, *NAT2* slow acetylators had significantly higher adduct levels than fast acetylators ($p = 0.03$) (Godschalk *et al.*, 2001).

Another study also reported that *NAT2* slow acetylators had significantly higher levels of 4-ABP-haemoglobin adducts than rapid acetylators, but there was no association between the *NAT1*10* genotype and the levels of 3- or 4-ABP–haemoglobin adducts, after adjustment for NAT2 phenotype. As in previous studies, smokers had significantly higher levels of 3- and 4-ABP–haemoglobin adducts than nonsmokers and the levels increased with increasing numbers of cigarettes smoked per day ($p < 0.0001$) (82 smokers, 321 nonsmokers) (Probst-Hensch *et al.*, 2000).

Adducts formed by polycyclic aromatic hydrocarbons

In a study involving 87 mothers and their 87 children in which PAH–albumin adducts in the plasma were investigated as a biomarker of the children's exposure to secondhand smoke from smoking by their mothers (see the monograph on involuntary smoking, this volume), it was also noted that adduct levels were significantly higher in the mothers who smoked than in those who did not (Crawford *et al.*, 1994).

A GC–MS method was used to measure benzo[*a*]pyrene-diol epoxide (BPDE)–globin adducts in 10 smokers and 10 nonsmokers. Subjects were also monitored for formation of globin adducts of chrysene diol epoxide. In both cases the procedure involved measurement of the respective tetrols of PAHs released from globin by acid hydrolysis. Levels of BPDE adducts in smokers were 2.7-fold higher than those in nonsmokers ($p < 0.01$); although the levels of the chrysene diol epoxide adducts were 1.25-fold higher in smokers, this difference was not statistically significant ($p = 0.06$) (Melikian *et al.*, 1997).

BPDE adducts with both haemoglobin and serum albumin were determined by GC–MS of tetrols released by acid hydrolysis in a study of 44 men with incident lung cancer. Individuals who were positive for haemoglobin adducts ($n = 6$) all had detectable albumin adducts, but not vice versa (24 subjects were positive for albumin adducts). Those who were carriers of a *CYP1A1* variant allele were more frequently positive for albumin adducts ($p = 0.03$) and those with two 'slow' *mEH* alleles had a lower frequency of these adducts (Pastorelli *et al.*, 1998).

In another study, 27 smokers were found to have significantly higher levels of BPDE–albumin adducts ($p < 0.05$) and non-significantly higher levels of BPDE–haemoglobin adducts than 42 nonsmokers (Scherer *et al.*, 2000) (see also the monograph on involuntary smoking, this volume).

Adducts formed by tobacco-specific nitrosamines (TSNA)

Treatment of NNK– or NNN–haemoglobin adducts with mild bases releases 4-hydroxy-1-(3-pyridyl)-1-butanone (HPB), which is derivatized to its pentafluorobenzoate, which is detectable by GC–MS after purification. The mean value in 40 smokers was 79.6 ± 189 fmol HPB/g haemoglobin (undetectable in 11 individuals; limit of detection, 5 fmol/g), whereas that in 21 nonsmokers was 29.3 ± 25.9 fmol/g (undetectable

in four individuals) [statistical significance not stated]. The HPB levels in 22 snuff dippers were 517 ± 538 fmol/g, i.e. significantly higher than those in smokers ($p < 0.0001$). No relationship was apparent between HPB levels in smokers and levels of plasma cotinine or number of cigarettes smoked (Carmella *et al.*, 1990).

In a comparison of 20 smokers and 15 nonsmokers, the HPB levels derived from haemoglobin were significantly higher in smokers (69.2 ± 43.9 versus 34.4 ± 16.0 fmol/g haemoglobin; $p < 0.005$) (Falter *et al.*, 1994).

In another study of 18 smokers and former smokers and 52 never-smokers, the levels of HPB–haemoglobin adducts were significantly higher in the smokers (26 ± 12 [SD] fmol HPB/g haemoglobin) than in never-smokers (19 ± 8 fmol/g) ($p = 0.02$). No differences were found between the sexes or between current smokers and former smokers [duration of smoking cessation not stated] (Atawodi *et al.*, 1998).

Significantly higher levels of haemoglobin adducts of TSNA ($p < 0.001$) were found in pregnant women who smoked than in pregnant women who did not smoke (Branner *et al.*, 1998).

Adducts formed by other compounds

Ethylene (IARC, 1994b) is a major gaseous constituent of tobacco smoke that converts, via ethylene oxide, the *N*-terminal valine of haemoglobin to *N*-(2-hydroxyethyl)valine (HOEtVal). The level of this adduct correlates linearly with the alkylating activity occurring in DNA: 10 pmol HOEtVal/g globin corresponds to 0.33 pmol adduct/g DNA (Farmer *et al.*, 1987; Bono *et al.*, 1999). In 11 smokers who smoked more than 20 cigarettes/day, the levels of HOEtVal in haemoglobin were in the range 217–690 pmol/g haemoglobin (mean ± SD, 389 ± 138), whereas in 14 nonsmokers the range was 27–106 pmol/g (58 ± 25). It is noteworthy that there was no overlap in values between the two groups (Törnqvist *et al.*, 1986). In a controlled experiment, two volunteers who were regular smokers (of 29 and 18 cigarettes/day, respectively) abstained from smoking for 7 days and then resumed. From the measurements of levels of HOEtVal before stopping, 7 days after stopping and 7 days after resuming, the investigators calculated that in the smoker of 29 cigarettes/day, each cigarette smoked increased the level of HOEtVal by 0.12 pmol/g globin. For the smoker of 18 cigarettes/day, the increase was 0.08 pmol/g (Granath *et al.*, 1994).

In a study of 26 smokers and 24 nonsmokers, the background levels of HOEtVal in the nonsmokers averaged 49.9 pmol/g haemoglobin (range, 22–106). In the smokers, the levels were significantly higher by an estimated 71 pmol/10 cigarettes/day (Bailey *et al.*, 1988).

As part of a maternal–fetal comparison of HOEtVal in haemoglobin (see the monograph on involuntary smoking, this volume), samples from 10 pregnant women who did not smoke and 13 pregnant women who smoked 15 or more cigarettes/day were analysed. In nonsmokers, 63 ± 20 (mean ± SD) pmol/g haemoglobin were measured, whereas in the smokers, the levels were 361 ± 107 pmol/g ($p < 0.01$) (Tavares *et al.*, 1994).

In a study of 146 adults (82 men and 64 women), 44 smokers were reported to have significantly higher levels of HOEtVal in haemoglobin than did 74 nonsmokers and 29 self-reported passive smokers (mean ± SD: 59.5 ± 53, 17 ± 21 and 17 ± 23 pmol/g haemoglobin, respectively). Linear regression analysis of adduct levels and the number of cigarettes smoked per day showed a highly significant correlation coefficient ($r = 0.63$, $p < 0.0001$). The adduct levels were also significantly higher in men than in women (mean value 2.2-fold higher, $p = 0.00001$) (Bono *et al.*, 1999).

Ethylene oxide is a substrate for GSTT1. To determine whether polymorphisms in *GSTT1* modulate HOEtVal formation, blood samples from 10 women (one smoker) and 17 men (five smokers) were analysed. The median level of the adduct was 5.6-fold higher in smokers than in nonsmokers, but no correlation with daily cigarette consumption was found. *GSTM1* and *GSTT1* genotypes did not influence the adduct levels in the smokers, although the *GSTT1* genotype did influence the adduct levels in nonsmokers (a two-fold higher median HOEtVal value was detected in *GSTT1*-null individuals than in *GSTT1*-positive individuals) (Müller *et al.*, 1998).

The effect of *GSTT1* was also investigated in a study involving 14 nonsmokers, 16 smokers of one pack of cigarettes a day and 13 smokers of two packs a day. HOEtVal levels increased with increasing number of cigarettes smoked, and the differences between the three groups were statistically significant. In addition, levels of *N*-(2-cyanoethyl)valine (CEVal), which is formed from acrylonitrile, were also significantly correlated with increasing smoking in these subjects. HOEtVal and CEVal levels were found to be significantly correlated in smokers ($p = 0.003$). There was no effect of *GSTM1* or *GSTT1* genotypes on the levels of CEVal in any of the groups or of *GSTM1* on HOEtVal levels; however, *GSTT1*-null individuals had higher levels of HOEtVal compared with *GSTT1*-positive individuals (slope of regression line 50% higher) (Fennell *et al.*, 2000).

A study of the effects of exposure to acrylamide and acrylonitrile in laboratory workers (smokers and nonsmokers) included the measurement of ethylene oxide–haemoglobin adducts. The mean levels of adducts from acrylamide, acrylonitrile and ethylene oxide in 10 smokers were 116, 106 and 126 pmol/g, respectively; these levels were significantly higher than those in eight nonsmokers (31, < 2 and 17 pmol/g, respectively). In smokers, the levels of acrylamide, acrylonitrile and ethylene oxide adducts correlated with the number of cigarettes smoked per day (Bergmark, 1997).

Two other studies have reported on acrylonitrile–haemoglobin adducts in smokers. In the first, four smokers had 75–106 pmol CEVal/g haemoglobin (mean, 88) whereas in four nonsmokers the levels were all below the limit of detection of 20 pmol/g (Osterman-Golkar *et al.*, 1994). In the second study, 13 mothers who smoked had adduct levels in the range 92.5–373 pmol/g haemoglobin (mean ± SD: 217 ± 85.1), but the levels in 10 nonsmoking mothers were below the limit of detection (1 pmol/g). In the smokers, there was a linear correlation with number of cigarettes smoked per day ($p = 0.02$) and also with the levels of the adducts in their newborn babies (see the monograph on involuntary smoking, this volume) (Tavares *et al.*, 1996).

A study was conducted in 43 Chinese workers exposed to benzene and 44 unexposed controls. The haemoglobin and albumin adducts of two metabolites, benzene oxide and 1,4-benzoquinone, were measured in these subjects. Tobacco smoking was found to have an additive effect on 1,4-benzoquinone–albumin formation ($p = 0.034$), but not on benzene oxide–albumin formation ($p = 0.23$) (Yeowell-O'Connell *et al.*, 2001).

Human haemoglobin contains relatively high background levels of *N*-methylvaline, which could limit its sensitivity as a biomarker of exposure to environmental carcinogens. However, in a study of 11 pairs of monozygotic twins discordant for tobacco smoking, both HOEtVal and *N*-methylvaline were found to be higher in the smokers than in the nonsmokers. In the smokers the levels of HOEtVal and *N*-methylvaline were 143 ± 24 (mean ± SE) and 268 ± 13 pmol/g haemoglobin, respectively, and in the nonsmokers 15.6 ± 1.9 and 225 ± 11 pmol/g, respectively. Thus, the levels of *N*-methylvaline adduct were significantly different between smokers and nonsmokers ($p = 0.006$) and there was a highly significant correlation with the number of cigarettes smoked per day ($p < 0.001$) (Törnqvist *et al.*, 1992).

Similarly, levels of *N*-methylvaline were found to be higher in a group of 32 smokers than in a group of 37 nonsmokers (mean ± SD: 1546 ± 432 versus 1175 ± 176 pmol/g haemoglobin; $p < 0.001$); for the smokers there was also a linear correlation between adduct levels and the number of cigarettes smoked per day ($p < 0.001$). An increment of 42 pmol/g haemoglobin per cigarette per day was calculated. A significant difference between smokers and nonsmokers in levels of HOEtVal was also observed in this study (Bader *et al.*, 1995).

Because cigarette smoke contains reactive species that can cause oxidative and nitrative damage in cellular macromolecules, samples of plasma protein from 52 lung cancer patients (24 smokers, 28 nonsmokers) and 43 control subjects (18 smokers, 25 never-smokers) were analysed for nitrotyrosine and carbonyl groups as markers of nitration and oxidation, respectively. The quantities of nitrated proteins were significantly higher in the patients than in the controls ($p = 0.003$), but were not related to smoking status. In contrast, the amounts of oxidized proteins were higher in smokers ($p < 0.001$), but were not related to disease status (Pignatelli *et al.*, 2001).

(iii) *DNA adducts and other types of DNA damage in human tissues*

The induction of DNA damage, frequently in the form of chemically stable adduct formation, is an early and essential step in the sequence of events by which genotoxic carcinogens initiate the carcinogenic process. The detection of DNA adducts in human tissues is therefore a useful and appropriate means to assess human exposure to such agents and several different procedures have been used for this.

- ^{32}P-Postlabelling analysis, in which DNA is digested and the resultant carcinogen-modified nucleotides are radiolabelled enzymatically with [^{32}P]*ortho*-phosphate, provides a sensitive method that requires no prior knowledge of the structures of the adducts formed. A common feature of the postlabelled DNA

obtained from cells or tissues exposed to complex mixtures of carcinogens, such as tobacco smoke, is the appearance of a diagonal radioactive zone (DRZ) seen when the material is resolved by two-dimensional thin-layer chromatography. Although the material in the DRZ has not been fully characterized, its properties are compatible with those of a complex mixture of aromatic and/or hydrophobic DNA adducts.

- Another method used to detect DNA adducts in human tissues employs antibodies raised against DNA or nucleotides modified by various carcinogens. Immunohistochemistry allows locating of adducts within a tissue specimen and measurement of the intensity of fluorescent staining permits a semi-quantitative estimate of adduct levels.
- Fluorescence detection of adducts in DNA, or of products released from DNA by hydrolysis, has been used for carcinogens that have strongly fluorescent properties, for example PAHs.
- Mass spectrometry has been used for the chemical-specific detection of certain adducts in DNA samples.
- Electrochemical detection has been used for some smaller DNA lesions, for example 8-OHdG, formed in DNA by oxidative processes.

The uses, strengths and limitations of the various techniques have been extensively described (Beach & Gupta, 1992; Strickland *et al.,* 1993; Weston, 1993; Phillips, 1997; Kriek *et al.*, 1998; Wild & Pisani, 1998; Poirier *et al.*, 2000). Earlier studies of tobacco-related DNA adducts in human tissues have also been reviewed (Phillips, 1996).

Respiratory tract

Lung and bronchus

Many studies have been published comparing the levels and characteristics of DNA adducts in the lung and bronchus of smokers and nonsmokers. These studies are summarized in Table 4.4.

In most of these studies, significantly elevated levels of DNA adducts were detected in the peripheral lung, bronchial epithelium or in cells obtained by bronchial lavage of the smokers. This is the case for total bulky DNA adducts (as detected by the ^{32}P-postlabelling method) and for DNA adducts detected by more chemical-specific methods including HPLC/fluorescence and GC–MS. However, the levels of 4-ABP-DNA adducts in lung did not correlate with smoking status (Culp *et al.*, 1997). In some studies in which smoking status was not known, but was inferred from plasma cotinine levels (indicating smoking habit at the time of death of the subjects), there was a poor correlation with the detection of only one specific type of adduct, such as 7-methyldeoxyriboguanosine (7-MedG) (Kato *et al.*, 1995; Blömeke *et al.*, 1996) or those formed by benzo[*a*]pyrene (Weston & Bowman, 1991; Kato *et al.*, 1995).

Some studies have found a linear correlation between adduct levels and daily or lifetime consumption of cigarettes (Phillips *et al.*, 1988, 1990a; Dunn *et al.*, 1991; Asami *et al.*, 1997) but, in other studies, no such relationship was found (Godschalk *et al.*, 1998;

Table 4.4. Studies of smoking-related DNA adducts in human lung and bronchus. Non-tumorous tissue was analysed except where indicated.

Study	Tissue	Method of analysis	Number of subjects	Outcome
Randerath *et al.* (1986)	Bronchus	^{32}P-Postlabelling	1 smoker 1 nonsmoker	Detection of DRZ from bronchial DNA in smoker only (> 1.5 packs/day for > 20 years, stopped smoking 3 months before his death)
Phillips *et al.* (1988)	Lung	^{32}P-Postlabelling	17 smokers 7 former smokers 5 nonsmokers	Adduct levels significantly higher in smokers. Linear relationship between levels and cigarettes smoked/day
Randerath *et al.* (1989)	Lung, bronchus	^{32}P-Postlabelling	7 smokers 3 former smokers 1 nonsmoker	DRZ detected in smokers' lungs in a dose-dependent manner (2/3 former smokers are tobacco chewers)
Weston *et al.* (1989a)	Lung (tumour and normal tissue)	Synchronous fluorescence spectroscopy	5 lung tumours and 4 matching normal tissues	Only 1/4 normal tissues positive for BPDE–DNA. Lung tumour tissues negative
Phillips *et al.* (1990a)	Bronchus	^{32}P-Postlabelling	37 smokers 8 former smokers 8 nonsmokers	Adduct levels in smokers significantly higher than in former and nonsmokers. Among smokers, correlation found between adduct levels and smoke exposure
Van Schooten *et al.* (1990a)	Lung (tumour and normal tissue)	^{32}P-postlabelling, ELISA	13 smokers 8 former smokers (5 tumorous; 16 non-tumorous tissues)	DRZ detected in all non-tumorous tissue and 4/5 tumours. BPDE–DNA adducts in 3 tumorous and 4 non-tumorous tissues. ELISA positive for 5 non-tumour tissues and 3 tumours. Poor correlation between adduct levels and smoking among current smokers
Dunn *et al.* (1991)	Bronchus	^{32}P-Postlabelling	28 smokers 40 former smokers 10 nonsmokers (biopsies of both tumour tissue and normal tissue available for 4 former smokers and 1 smoker)	DRZ observed in all smokers, 24/40 former smokers and 4/10 nonsmokers. Among smokers, levels correlated with smoke exposure. DRZ generally similar in tumorous and normal tissues except in 2 former smokers out of 5 for whom adduct levels were substantially higher in tumours

Study	Tissue	Method of analysis	Number of subjects	Outcome
Foiles *et al.* (1991)	Lung, tracheo-bronchus	GC–MS for 4-hydroxy-1-(3-pyridyl)-1-butanone after acid hydrolysis	9 smokers, 8 nonsmokers (lung); 4 smokers, 4 nonsmokers (bronchus)	TSNA–DNA adducts measured by HPB levels were higher in smokers for both tissues studied (lung, 11 ± 16 versus 0.9 ± 2.3 fmol/mg DNA, 7/9 positive versus 1/8 in nonsmokers; tracheobronchus, 16 ± 18 versus 0.9 ± 1.7, 2/4 positive versus 1/4).
Geneste *et al.* (1991)	Lung	^{32}P-Postlabelling	19 smokers 4 former smokers	Smokers had significantly higher adduct levels, which correlated with AHH inducibility
Izzotti *et al.* (1991)	Alveolar macrophages	Synchronous fluorescence spectroscopy	16 smokers 4 recent smokers 6 former smokers 13 nonsmokers	BPDE–DNA detected in 84.6% (11/13 pooled from the 16) smokers and 2/4 recent smokers, but not in former or nonsmokers
Weston & Bowman (1991)	Lung	Synchronous fluorescence spectroscopy	20 adults 5 infants	BPDE–DNA adducts detected in 6/25 samples; levels did not correlate with serum cotinine levels.
Alexandrov *et al.* (1992)	Lung	HPLC/fluorescence or ^{32}P-postlabelling	11 smokers 2 former smokers	BPDE–DNA detected in 9/11 smokers and 2/2 former smokers. Linear correlation noted between the 2 adduct methods
Routledge *et al.* (1992)	Lung	^{32}P-Postlabelling	16 smokers 7 former smokers 14 nonsmokers	Adduct levels significantly higher in smokers and former smokers than in nonsmokers
Gallagher *et al.* (1993a)	BAL cells	^{32}P-Postlabelling	5 smokers 11 nonsmokers	Adduct levels 1.7-fold higher in smokers
Mustonen *et al.* (1993)	Bronchus	^{32}P-Postlabelling	13 smokers 7 nonsmokers	7-Methylguanine–DNA adduct levels were significantly higher in smokers than in nonsmokers. For 5 smokers, lung adduct levels correlated with lymphocyte adduct levels.

Table 4.4 (contd)

Study	Tissue	Method of analysis	Number of subjects	Outcome
Schoket *et al.* (1993)	Bronchus	^{32}P-Postlabelling	45 smokers 37 former smokers 16 nonsmokers	Levels in smokers and short-term former smokers were significantly greater than in long-term former smokers and nonsmokers. Weak association found between adduct levels and daily cigarette consumption
Ryberg *et al.* (1994)	Lung	^{32}P-Postlabelling	49 smokers (38 male) 14 nonsmokers (7 male)	Significantly higher levels of adducts in smokers than nonsmokers. Women had higher levels than men after adjusting for smoke exposure. Linear regression analysis showed that adduct levels are inversely related to the number of years of smoking among male lung cancer patients.
Kato *et al.* (1995)	Lung	^{32}P-Postlabelling	90 autopsies	There was no correlation between levels of adducts (7-MedGMP or PAH-dGMP) and serum cotinine levels. Higher 7-MedGMP levels were associated with *CYP2E1* minor alleles ($p = 0.05$) and *CYP2D6* genotype ($p = 0.01$).
Sherman *et al.* (1995)	BAL cells	DNA single-strand breaks by fluor-escence analysis of DNA alkaline unwinding	11 smokers 11 nonsmokers	Alveolar macrophages from smokers had 35 ± 3% double stranded DNA, as against 41 ± 5% for nonsmokers.
Wiencke *et al.* (1995)	Lung	^{32}P-Postlabelling	6 smokers 10 former smokers (≤ 1 year) 15 former smokers (> 1 year)	Correlation with adduct levels in blood mononuclear cells (mean value 2.5-fold higher in lung)

Table 4.4 (contd)

Study	Tissue	Method of analysis	Number of subjects	Outcome
Andreassen *et al.* (1996)	Lung	^{32}P-postlabelling or fluorescence	26 smokers 11 former smokers 2 nonsmokers (tumour and non-tumorous tissues from 39 lung cancer patients)	Heavy smokers (> 20 cigarettes/day) had significantly higher levels of adducts in DRZ than light smokers. Using ^{32}P, DRZ adducts were detected in 37 samples, and 33/37 samples had detectable adducts. Using fluorescence IAC, BPDE–DNA adducts were detected in 11/39 samples.
Blömeke *et al.* (1996)	Lung	^{32}P-Postlabelling	10 autopsies	Levels of 7-MedG adduct did not correlate with smoking exposure at time of death (plasma cotinine levels).
Petruzzelli *et al.* (1996)	BAL cells	^{32}P-Postlabelling	10 smokers 10 former smokers 10 nonsmokers	7-MedG was detected in 7/10 smokers, 2/10 former smokers and 2/10 nonsmokers. Levels of 7-MedG in smokers were significantly different ($p = 0.028$) from former smokers and nonsmokers. Adduct levels did not correlate with number of cigarettes smoked per day.
Asami *et al.* (1997)	Lung	HPLC/ECD	14 smokers 7 former smokers 9 nonsmokers	8-OHdG levels significantly higher in smokers than in nonsmokers; linear correlation with number of cigarettes smoked (daily and cumulative)
Culp *et al.* (1997)	Lung	^{32}P-Postlabelling, ELISA, GC/MS	14 smokers 11 former smokers	Levels of 4-ABP-DNA adducts in lung tissue did not correlate with smoking status.
Ryberg *et al.* (1997)	Lung	^{32}P-Postlabelling	70 smokers	Mean adduct levels increased significantly according to *GSTP1* genotype AA<AG<GG ($n = 25, 35, 10$, respectively; $p = 0.01$, AA versus AG; $p = 0.02$, AA versus GG).
Godschalk *et al.* (1998)	BAL cells	^{32}P-Postlabelling	78 smokers 23 nonsmokers	Adduct levels in BAL cells did not correlate with smoking (pack–years) after correcting for age.

Table 4.4 (contd)

Study	Tissue	Method of analysis	Number of subjects	Outcome
Lodovici *et al.* (1998)	Lung	HPLC/fluorescence	12 smokers 6 former smokers 21 nonsmokers	BPDE–DNA adduct levels in smokers and former smokers significantly higher than in nonsmokers ($p < 0.05$)
Rojas *et al.* (1998)	Lung	HPLC/fluorescence	20 smokers	BPDE DNA adduct levels were higher in 2 individuals with *GSTM1* null and *CYP1A1 Msp*I variant genotypes.
Schoket *et al.* (1998)	Bronchus	^{32}P-Postlabelling	82 smokers 25 short-term former smokers (< 1 year) 20 long-term former smokers (> 1 year) 23 nonsmokers	Adduct levels significantly higher in current and short-term former smokers than in long-term former and nonsmokers. Adduct levels are the same in 66 male and 16 female current smokers. Apparent half-life of adducts ~1.7 years. Adduct levels did not correlate with daily cigarette dose or with *GSTM1* or *CYP1A1 Msp*I genotypes.
Butkiewicz *et al.* (1999)	Lung	^{32}P-Postlabelling	120 smokers 22 former smokers 23 nonsmokers	PAH adduct levels significantly higher in smokers than in former and nonsmokers. High adduct levels (upper quartile) significantly associated with *CYP1A1 Ile-Val* allele carriers in individuals who were *GSTM1 null* ($n = 86$)
Mollerup *et al.* (1999)	Lung	^{32}P-Postlabelling	122 smokers (29 women) 37 nonsmokers (13 women)	Adduct levels significantly higher in women than in men ($p = 0.047$ before adjustment for pack–years, $p = 0.0004$ after adjustment). Lung expression of *CYP1A1* (15 women, 12 men) was significantly higher in women ($p = 0.016$) and in both sexes the correlation between *CYP1A1* expression and adduct levels was significant ($p = 0.009$).

Table 4.4 (contd)

Study	Tissue	Method of analysis	Number of subjects	Outcome
Wiencke *et al.* (1999)	Lung	^{32}P-Postlabelling	57 smokers 79 former smokers 7 nonsmokers	Smokers had significantly higher adduct levels than former smokers. Age of commencing smoking was associated with adduct levels in former smokers, but not in current smokers. Good correlation noted between DNA adduct levels in blood mononuclear cells and lung tissues
Cheng *et al.* (2000)	Lung	^{32}P-Postlabelling	73 cancer cases (32 smokers, 38 nonsmokers) 33 non-cancer controls (11 smokers, 22 nonsmokers)	DNA adduct levels were significantly higher in cases than in controls, but not higher in smokers than in nonsmokers. Adduct levels not influenced by *CYP1A1 MspI* or *GSTM1* genotypes.
Piipari *et al.* (2000)	BAL cells	^{32}P-Postlabelling	31 smokers 16 nonsmokers	PAH–DNA adduct levels 3-fold higher in smokers than in nonsmokers ($p < 0.001$) and correlated with number of cigarettes smoked daily. Smokers with high levels of *CYP3A* expression had higher adduct levels ($p < 0.002$).
Schoket *et al.* (2001)	Bronchus	^{32}P-Postlabelling	94 smokers and short-term former smokers (≤ 1year)	Evidence for a weak influence of some combinations of *CYP* and *GST* genotypes on adduct levels

DRZ, diagonal radioactive zone; BPDE, benzo[*a*]pyrene diol epoxide; ELISA, enzyme-linked immunoassay; AHH, aryl hydrocarbon hydroxylase; GC–MS, gas chromatography/mass spectrometry; TSNA, tobacco-specific nitrosamines; HPB, 4-hydroxy-1-(3-pyridyl)-1-butanone; HPLC, high-performance liquid chromatography; BAL, bronchio-alveolar lavage; 7-MedGMP, 7-methyl-2′-deoxyriboguanosine-3′-monophosphate; PAH, polycyclic aromatic hydrocarbons; IAC, immunoaffinity chromatography; 7-MedG, 7-methyl-2′-deoxyriboguanosine; 4-ABP, 4-aminobiphenyl; ECD, electrochemical detection; 8-OHdG, 8-hydroxydeoxyguanosine

Schoket *et al.*, 1998). In one study in a group of male smokers with lung cancer, a linear regression analysis showed that adduct levels were inversely related to the number of years of smoking (Ryberg *et al.*, 1994). Mean levels of adducts in former smokers (usually with an interval of at least 1 year since smoking cessation) were generally found to be intermediate between the levels found in smokers and in life-long nonsmokers. From these comparisons, the half-life of adducts in the lung is estimated to be 1.7 years in bronchial tissue from former smokers (Schoket *et al.*, 1998). This is somewhat longer than would be estimated from a consideration of the biochemical processes of DNA repair and the rate of cell turnover, and may be a consequence of the slow clearance of carcinogen-containing tar and particulate deposits from the lung, resulting in continued metabolic activation of tobacco carcinogens after smoking cessation.

In a study in Norway, adduct levels were higher in the lungs of women smokers than in those of men, a difference that was greater after adjustment for intensity of smoking (Ryberg *et al.*, 1994; Mollerup *et al.*, 1999). However, in a study in Hungary, adduct levels in male and female smokers with lung cancer were found to be the same (Schoket *et al.*, 1998).

Larynx

^{32}P-Postlabelling analysis of DNA from larynx mucosa revealed the presence of hydrophobic adducts (DRZ) in 21 smokers but not in four nonsmokers. The ability of both the nuclease P_1 digestion and the butanol extraction procedures to detect these adducts suggested that they were formed primarily by PAHs rather than aromatic amines. Adduct levels correlated with levels of P4501A1, 2C and 3A4, but not with levels of P4502E1 and 2A6 (Degawa *et al.*, 1994).

Another study compared adduct levels in laryngeal tumours with those in non-tumour tissue from 43 patients, 38 of whom were smokers. Adduct levels, as determined by ^{32}P-postlabelling, were higher in tumour tissue than in normal tissue, and the few non- or former smokers had lower levels than the smokers (differences were not significant) (Szyfter *et al.*, 1994). In a subsequent study, ^{32}P-postlabelling analysis was used to measure levels of 7-alkylguanine in DNA from laryngeal biopsies. In larynx tumour tissues, the levels reported in heavy smokers (> 40 cigarettes/day) were 2.5-fold higher than those in moderate smokers (~20 cigarettes/day) and 5.5-fold higher than in nonsmokers and former smokers. There was a significant correlation between 7-alkylguanine levels and aromatic/hydrophobic adduct levels in these tissue samples (Szyfter *et al.*, 1996).

An immunohistochemical study of laryngeal biopsies from 38 patients, using antibodies against 4-ABP–DNA adducts, included analyses of tumours (9), polyps (28) and surrounding tissue (1). The investigators noted a significantly higher staining intensity of polyps and surrounding tissue from smokers than of that from nonsmokers, but the differences between tumour tissue from smokers and nonsmokers were not significant [limited number of samples]. The study showed that 4-ABP–DNA adducts, related to smoking exposure, are formed in the larynx (Flamini *et al.*, 1998).

An analysis of laryngeal tumour biopsies from 33 patients was carried out by ^{32}P-post-labelling. DNA from tumour tissue, non-tumour tissue and the interarytenoid area was analysed separately. Large interindividual differences in adduct levels were reported, with highest levels in the interarytenoid area. Adduct levels were reported to be correlated with age (the highest levels in all tissues were noted in the 50–60-year and 60–70-year age groups), sex (28 of the patients were men, five were women; adduct levels were higher in the men), cigarette smoking (all patients were smokers, 19 smoked 20 cigarettes/day, 14 smoked 30–40) and stage of tumour progression (*p* values were not reported) (Banaszewski *et al.*, 2000).

Sputum

DNA isolated from sputum, induced by inhalation of nebulized saline solution, was compared in a group of 20 smokers and 24 nonsmokers using the nuclease P_1 digestion method of ^{32}P-postlabelling analysis. All smokers, but only one nonsmoker, showed a DRZ in their adduct patterns, and adduct levels were significantly higher in smokers than in nonsmokers (3.1 ± 1.4 versus $0.6 \pm 0.8/10^8$ nucleotides; $p = 0.0007$) (Besarati Nia *et al.*, 2000a). The same authors also found that the adduct levels in the induced sputum of nine smokers (monitored on three occasions) were significantly higher than those in nine non-smokers (monitored once) (Besarati Nia *et al.*, 2000b). When immunohistochemical analysis of induced sputum was carried out, the cells of 20 smokers were found to have significantly greater intensity of staining when using antibodies against 4-ABP–DNA than the cells of 24 nonsmokers ($p = 0.001$), but not when BPDE–DNA antibodies were used ($p = 0.07$) (Besarati Nia *et al.*, 2000c).

Oral and nasal cavities

In two early ^{32}P-postlabelling studies of DNA from oral mucosal cells, varying amounts of a variety of aromatic and/or hydrophobic adducts were seen in smokers and nonsmokers, but none of them were specific to exposure to tobacco smoke (Dunn & Stich, 1986; Chacko & Gupta, 1988).

DNA from clinically normal oral tissue (mucosa) from patients undergoing surgery for intraoral squamous-cell carcinoma was analysed by ^{32}P-postlabelling using both nuclease P_1 digestion and butanol extraction enhancement methods. Both the range and levels of adducts measured were greater with the latter method, and the mean level of adducts in the smokers ($n = 19 + 1$ pipe smoker) was statistically significantly higher than that in the four former smokers and nine nonsmokers combined (Jones *et al.*, 1993). A comparison between DNA obtained from oral biopsies and from buccal mucosa from the same individuals showed that there was a good correlation between adduct levels from the two sources, with a significantly higher level of adducts in DNA from 20 smokers than that from 10 nonsmokers (Stone *et al.*, 1995).

In a small study of nasal mucosal DNA from nine smokers, two former smokers and 10 nonsmokers, ^{32}P-postlabelling analysis detected the DRZ in eight of the smokers, one of the former smokers and one of the nonsmokers. The mean adduct level in smokers was

significantly higher than that in the nonsmokers ($p < 0.01$; 4.8 versus $1.4/10^8$ nucleotides using the nuclease P_1 digestion) and a linear relationship between adduct levels and daily cigarette consumption was observed among the smokers (Peluso *et al.*, 1997). In another study, the levels of DNA adducts detected by ^{32}P-postlabelling analysis in nasal cells from six smokers were also significantly higher than the levels in cells of 14 nonsmokers (mean value, 17.0 versus $6.8/10^8$ nucleotides) (Zhao *et al.*, 1997).

Using a ^{32}P-postlabelling method to detect cyclic adducts such as 1,N^2-propanodeoxyguanosine, possible products of the reaction of tobacco smoke constituents such as acrolein (A) and crotonaldehyde (C) with DNA, significantly higher levels of each of three such adducts (AdG, CdG1 and CdG2) were detected in the DNA of gingival tissue of 11 smokers than in that of 12 nonsmokers; the total levels of the adducts were 4.4-fold higher in smokers than in nonsmokers (Nath *et al.*, 1998).

Using the alkaline comet (single-cell gel electrophoresis) assay to detect DNA strand breaks in exfoliated buccal cells, significantly higher DNA migration was found to occur in the cells of 11 smokers than in those of nine nonsmokers (Rojas *et al.*, 1996).

A study of exfoliated oral cells from healthy volunteers used an immunohistochemical technique to stain cells with antibodies raised against BPDE–DNA adducts. The intensity of staining was significantly greater in cells from 33 smokers than in those from 64 nonsmokers, and increased intensity of staining was observed with increasing number of cigarettes smoked per day by the smokers (Romano *et al.*, 1999a). Similar results were obtained in another study that used this technique. Both buccal cavity and mouth floor cells were investigated; staining intensity in both cell types was found to be significantly higher in 26 smokers than in 22 nonsmokers (Besarati Nia *et al.*, 2000d). When antibodies to 4-ABP–DNA adducts were used, staining intensity was also found to be significantly higher in the exfoliated oral cells of 12 smokers than in those of 12 nonsmokers (Romano *et al.*, 1997).

Immunohistochemical staining of human oral mucosal cells, using antibodies against BPDE–DNA adducts, revealed significantly higher intensities of staining in 16 smokers than in 16 matched nonsmokers (Zhang *et al.*, 1995). A second study, using antibodies against BPDE–DNA adducts or against 4-ABP-modified DNA in exfoliated oral cells, showed significantly higher levels of DNA damage in 20 smokers than in 20 matched nonsmokers for both DNA adducts (Hsu *et al.*, 1997). Subsequently, an analogous analysis using antibodies to malonaldehyde–DNA adducts has demonstrated higher levels of this adduct, derived from lipid peroxidation, in the oral mucosal cells of 25 smokers than in 25 matched nonsmokers (Zhang *et al.*, 2002).

Urogenital tissues

Bladder

Investigations of the presence of smoking-related DNA adducts in bladder cells have made use of autopsy and biopsy specimens and of exfoliated epithelial cells excreted in urine.

When the levels of DNA adducts were determined in bladder biopsy samples using ^{32}P-postlabelling with both butanol extraction and nuclease P_1 enhancement procedures, the mean levels of several specific adducts were higher in 13 smokers than in 20 former smokers and nine never-smokers; some adducts were present at similar levels in all groups and thus were not smoking-related. One of the smoking-related adducts was chromatographically identical to the major adduct formed in DNA by 4-ABP (Talaska *et al.*, 1991a).

Exfoliated urothelial cells recovered from the urine of 39 of 73 individuals yielded sufficient DNA for ^{32}P-postlabelling analysis (21 from nonsmokers, 18 from current smokers). The DNA was found to contain several DNA adducts, of which at least four were present in the DNA of smokers at levels 2–20 times higher than those in the DNA of nonsmokers. One of these corresponded chromatographically to *N*-(deoxyguanosin-8-yl)-4-ABP (Talaska *et al.*, 1991b). In a further study of the same subjects, two DNA adducts detected in exfoliated uroepithelial cells were found to be specifically associated with smoking and with the levels of 4-ABP–haemoglobin adducts (Vineis *et al.*, 1996).

In a study of bladder biopsies of 20 bladder cancer patients and of exfoliated bladder cells of 36 healthy individuals, a dose–response relationship between smoking levels and adduct levels was found for both groups [statistics not given and the sizes of the groups studied were small]. The levels of adducts were not higher in the cases than in the controls (Talaska *et al.*, 1994).

Bladder tissue samples taken at autopsy from 56 individuals were analysed by ^{32}P-postlabelling of DNA. A positive but weak association ($p = 0.09$) between adduct levels and tobacco smoking was found, and there was a correlation between the levels of adducts in lung and bladder ($p < 0.01$, Spearman rank correlation test) (Routledge *et al.*, 1992) (see also Table 4.4).

A comparison of the adducts detected by ^{32}P-postlabelling in bladder biopsies from 30 smokers with those from 24 nonsmokers revealed that, overall, adduct levels were not significantly different between the two groups; 3–5-fold higher levels of adducts were detected by the butanol extraction procedure than by nuclease P_1 digestion, implying a preponderance of aromatic amine-like adducts over those formed by PAHs. In a more detailed analysis, however, the level of one minor DNA adduct was found to be twice as high in samples analysed from 17 smokers than in those from eight nonsmokers ($p < 0.005$, one-tailed) (Phillips & Hewer, 1993).

Biopsy samples from human bladder were subjected to immunohistochemical analysis with antibodies to 4-ABP–DNA adducts to determine the relationship between smoking history and intensity of staining. The adduct levels were significantly higher in 24 current smokers than in 22 nonsmokers ($p < 0.0001$). There was also a linear relationship between mean levels of adduct staining and number of cigarettes smoked per day (Curigliano *et al.*, 1996). In another study using the same technique, higher levels of 4-ABP–DNA adducts were also observed in bladder specimens from 30 smokers than in those from 41 former smokers and 24 nonsmokers, but the statistical significance of this difference was borderline ($p = 0.07$) (Romano *et al.*, 1999b).

Immunohistochemical staining of human exfoliated urothelial cells from urine, using antibodies to BPDE–DNA adducts or to 4-ABP–DNA adducts, revealed significantly higher ($p < 0.0005$) intensities of staining in 20 smokers than in 20 matched nonsmokers in both cases (Hsu *et al.*, 1997).

The presence of 3-alkyladenines in human urine was determined in two smokers who underwent a period of voluntary abstinence from smoking. In one subject, the excretion of 3-ethyladenine was significantly lower on nonsmoking days ($p < 0.01$). Smoking-dependent differences in levels of 3-methyladenine were apparent only when volunteers consumed a diet low in 3-alkyladenines during the study period. Thus, although both adducts are produced by alkylating agents in tobacco smoke, natural dietary levels of 3-methyladenine make this an insensitive biomarker of smoking (Prévost & Shuker, 1996).

In a study of depurinated adducts of benzo[*a*]pyrene in urine, detectable levels of BaP-6-N7 Ade[1] were found in the urine of three of seven smokers (not quantifiable but detectable up to 0.1–0.6 fmol/mg creatinine), but not in the urine from any of 13 nonsmokers (Casale *et al.*, 2001).

The comet assay was used to analyse urinary bladder cells for DNA damage. A significant increase in comet tail moments for 18 smokers and former smokers was found as compared with 12 nonsmokers ($p < 0.03$) (Gontijo *et al.*, 2001).

In a study of oxidative DNA damage measured by 8-OHdG excretion in urine, 30 smokers were reported to have levels of the nucleoside that were 50% higher (corrected for body weight) than 53 nonsmokers (Loft *et al.*, 1992).

Taken together, the studies analysing DNA adducts in bladder tissue or exfoliated urothelial cells demonstrate that smoking-related formation of DNA adducts is detectable, but that some of the adducts present derive from other sources of environmental carcinogens.

Cervix

A pilot study of DNA isolated from cervical scrapes of 22 women and analysed by the butanol extraction enrichment procedure of ^{32}P-postlabelling showed the presence of the DRZ and higher levels of adducts in three of nine smokers than in 13 nonsmokers (Phillips *et al.*, 1990b). In a subsequent study, sufficient DNA was isolated from 33 of 38 cervical smear samples and subjected to ^{32}P-postlabelling analysis. Adduct levels were significantly higher in the DNA from 18 smokers than in that from 15 nonsmokers (Simons *et al.*, 1995).

Using DNA isolated from cervical biopsies, ^{32}P-postlabelling analysis with butanol extraction was carried out on samples from 39 women (11 smokers, seven former smokers and 21 never-smokers). Adduct levels were significantly higher in the smokers and former smokers than in the nonsmokers ($p = 0.048$). Exclusion of those women whose urinary cotinine levels did not confirm their self-reported nonsmoking status ($n = 7$) increased the differences in levels of adducts between smokers and nonsmokers ($p = 0.03$) (Simons *et al.*, 1993).

[1] N7-(benzo[*a*]pyrene-6-yl) adenine

A study of cervical biopsy samples from 35 women (19 smokers, five former smokers and 11 nonsmokers) found that DNA adduct levels, determined by ^{32}P-postlabelling analysis with the butanol extraction procedure, were significantly higher in the smokers than in the nonsmokers (p = 0.002), and an intermediate mean value was obtained for the former smokers (Phillips & Ni She, 1993). This study population was subsequently increased to 22 smokers, four former smokers and 14 nonsmokers and analysed by both butanol extraction and nuclease P_1 digestion procedures of ^{32}P-postlabelling. Adduct levels were significantly higher in smokers when the former procedure was used (p = 0.005), but not with the latter (Phillips & Ni She, 1994). The lack of a difference between smokers and nonsmokers using nuclease P_1 digestion was also reported in another small study in women not using oral contraceptives (15 smokers, eight nonsmokers) (King *et al.*, 1994). However, in another larger study, ^{32}P-postlabelling analysis using nuclease P_1 digestion found significantly higher levels (p = 0.07) in DNA from histologically normal cervical biopsy tissue from 48 current smokers than in that from 48 non-current smokers (non-current smokers included nonsmokers, former smokers and passive smokers) (Ali *et al.*, 1994).

Immunohistochemical analysis of human cervical cells, using antibodies against BPDE–DNA adducts, demonstrated significantly higher staining intensity (p = 0.04) in smears from 16 smokers than in smears from 16 nonsmokers (Mancini *et al.*, 1999).

GC–MS analysis of BPDE–DNA adducts in cervical epithelial cells found that the level of adducts was approximately twofold higher in seven smokers than in seven nonsmokers and this difference was statistically significant (p = 0.02) (Melikian *et al.*, 1999).

Other tissues

Breast

In a pilot study, a total of 31 samples of human breast tissue were analysed by ^{32}P-postlabelling using nuclease P_1 digestion to determine the levels of aromatic/hydrophobic DNA adducts. The breast tissues included samples from tumours and from tissues adjacent to tumours from 15 women with breast cancer and four samples from women who had had reduction mammoplasties. The characteristic DRZ was detected in tumorous and non-tumorous tissues from five of 15 cancer patients, all of whom were current smokers. None of the eight former smokers and nonsmokers displayed this pattern (p < 0.01) (Perera *et al.*, 1995).

Another ^{32}P-postlabelling study using nuclease P_1 digestion of aromatic DNA adducts was conducted on normal (non-tumour) breast tissue from 87 breast cancer patients undergoing mastectomy and from 29 women who did not have cancer (controls) undergoing reduction mammoplasty. The characteristic DRZ was detected in 29 of 87 normal tissues from breast cancer patients (17/17 smokers, 5/8 former smokers, 4/52 nonsmokers, 3/10 with unknown smoking status), and in two of 10 control tissues. In addition, a benzo[*a*]-pyrene-like DNA adduct was observed in 36 normal adjacent breast tissue samples (27 of them from nonsmokers) from cancer patients and its presence was not significantly associated with smoking (Li *et al.*, 1996).

Higher levels ($p = 0.0001$) of DNA adducts putatively derived from malonaldehyde and detected by ^{32}P-postlabelling using nuclease P_1 digestion were determined in tissue adjacent to tumours from 51 breast cancer patients than in tissue from 28 controls (undergoing reduction mammoplasty). The levels of these adducts were also associated with the previously detected benzo[*a*]pyrene-like DNA adduct (see above), but were significantly lower in smokers than in former smokers and in nonsmokers (Wang *et al.*, 1996).

Immunohistochemical staining intensity of breast tumour tissue using antibodies against BPDE-DNA adducts was not significantly different between 35 smokers, 72 former smokers who had smoked one cigarette or more per day for 6 months or longer and 75 nonsmokers. However, among smokers and former smokers, there was a trend towards higher intensities of staining with greater levels of exposure or earlier age at starting smoking (Santella *et al.*, 2000). Positive staining using antibodies against BPDE–DNA adducts was also obtained with tissue samples from 48 patients with breast tumours and tissue samples from 30 patients with benign disease (with higher adduct levels being found in tissues from patients with benign breast disease than in cancer tissues). This study was carried out on inhabitants of Upper Silesia, a region of Poland that has been subject to high levels of environmental pollution. However, in neither group of patients were staining intensities higher in smokers than in nonsmokers (Motykiewicz *et al.*, 2001).

In a study of PAH–DNA adducts in breast tumour tissue from 119 cancer patients and from 108 patients with benign breast disease, immunohistochemical analysis indicated a significant association between adduct levels and breast cancer, but there was no relationship between smoking status, stage or tumour size and adduct levels (Rundle *et al.*, 2000).

Pancreas

^{32}P-Postlabelling analysis of 20 pancreatic tumours and 13 samples of normal tissue adjacent to the tumour, using nuclease P_1 digestion, led to the detection of significantly higher levels of DNA adducts in the normal tissues surrounding the tumour than in either the tumour tissue or in normal pancreatic tissue from five patients with non-pancreatic cancer and 19 previously healthy organ donors who served as controls. Two novel clusters of adducts were observed: 11/13 in adjacent normal tissues from pancreatic cancer patients, 12/20 in tumour tissues and 2/24 in normal pancreatic tissues from controls. The presence of these adducts was positively correlated with smoking status (Wang *et al.*, 1998).

Another study that used fluorescence spectral analysis for the presence of BPDE–DNA adducts in pancreatic samples revealed no detectable levels in any of 11 samples (six from smokers) (Alexandrov *et al.*, 1996).

Colon

Fluorescence spectral analysis of samples of colon mucosa for the presence of BPDE–DNA adducts resulted in their detection in three of four samples from smokers and

one of three samples from nonsmokers. Adduct levels were estimated to be in the range 0.2–1.0 adducts/10^8 nucleotides (Alexandrov *et al.*, 1996).

Stomach

Tumour DNA from 26 patients (18 smokers) with gastric cancer was analysed for DNA adducts using ^{32}P-postlabelling with butanol extraction. In men only, the numbers of DNA adducts were found to be significantly higher in the samples from 14 smokers than in that from four nonsmokers (Dyke *et al.*, 1992). [The Working Group noted that the number of nonsmokers was small.]

Placenta and fetal tissue

In the first study of placental DNA for the presence of DNA adducts, ^{32}P-postlabelling analysis and ELISA with antibodies against BPDE–DNA adducts were used. The use of the ELISA found a small but non-significant increase in adducts in placental tissue from smokers when compared with the numbers found in nonsmokers. Using ^{32}P-postlabelling analysis, one particular DNA adduct was found to be present in the DNA from 16 of 17 smokers, but in only three of 14 nonsmokers (Everson *et al.*, 1986). In a subsequent study using ^{32}P-postlabelling, up to seven different adducts were detected in 53 specimens of human placental tissue, three of these adducts were found 'almost exclusively' in smokers (Everson *et al.*, 1988).

The combined use of immunological, fluorescence spectroscopic and mass spectrometric methods has led to the detection and characterization of BPDE–DNA adducts in human placental DNA and also provided evidence for the presence of adducts formed by other PAHs (Weston *et al.*, 1989b; Manchester *et al.*, 1990). Synchronous fluorescence spectroscopy for the detection of BPDE–DNA adducts gave positive results in 10 of 28 human placental samples, but there was no correlation with smoking status (Manchester *et al.*, 1988). In a subsequent study, five of seven placentas from smokers and three of nine from nonsmokers gave positive results when analysed for these adducts (Manchester *et al.*, 1992).

Placental DNA from five smokers was found to contain adduct levels, detected as a DRZ by ^{32}P-postlabelling, 1.8-fold higher than that in placental DNA from five nonsmokers (4.3 ± 1.7 versus 2.3 ± 0.4 adducts/10^8 nucleotides) (Gallagher *et al.*, 1993a) [statistical significance not stated].

Using ^{32}P-postlabelling with nuclease P_1 digestion, DNA adducts were detected in DNA from placenta and umbilical cord regardless of whether or not the mothers were smokers. Adduct levels were significantly higher in maternal than in fetal tissue (and were higher in placenta than in umbilical cord) and, combining data for all tissues, total levels of DNA adducts were significantly higher in eight smokers than in 11 nonsmokers. Although individual tissues showed a trend towards increased levels of adducts in smokers, the differences were not statistically significant (Hansen *et al.*, 1992, 1993). DNA adducts derived from PAHs were detected by a competitive ELISA in six of 14 placentas and in five of 12 matched fetal lung samples from spontaneous abortions. None

of the samples were from women who reported smoking during pregnancy; thus smoking was not a likely source of the adducts (Hatch *et al.*, 1990). However, in another study using ELISA with antibodies against BPDE–DNA adducts, a linear correlation was found between levels of adducts and levels of urinary cotinine for both placental DNA and umbilical cord DNA, the former tissue having the higher adduct levels. Overall, adducts were detected in 13 of 15 placental samples and 12 of 15 samples of umbilical cord blood from smokers and three of 10 placental samples and one of 10 samples of umbilical cord from nonsmokers (Arnould *et al.*, 1997).

When placental DNA was analysed both for bulky DNA adducts by ^{32}P-postlabelling with nuclease P_1 digestion and for 8-OHdG by electrochemical detection, neither method showed a difference between 11 smokers, 10 nonsmokers and nine nonsmokers who were exposed to secondhand smoke (Daube *et al.*, 1997).

Thus, although some studies indicate the presence of smoking-related DNA adducts in human placenta, overall the association between smoking status and adduct levels, determined by a variety of different methods, is weak. The results appear to indicate that there are significant sources of environmental carcinogens other than tobacco smoke that result in DNA adducts being formed in this tissue.

Sperm

In a study in which sperm DNA from 12 heavy smokers (> 20 cigarettes/day), 12 moderate smokers (1–19 cigarettes/day) and 12 nonsmokers was subjected to ^{32}P-postlabelling analysis, no discernible differences were observed between the patterns or levels of DNA adducts between the three groups of subjects (Gallagher *et al.*, 1993b).

However, immunohistochemical analysis of sperm, with antibodies against BPDE–DNA adducts showed significantly higher intensity of staining in the sperm of 11 smokers than in the sperm of 12 nonsmokers (Zenzes *et al.*, 1999a). Furthermore, in-vitro fertilization experiments using sperm from smokers and oocytes from nonsmoking partners suggested that there was transmission of benzo[*a*]pyrene-modified DNA to the embryos (Zenzes *et al.*, 1999b). In related studies, granulosa-lutein cells from women undergoing in-vitro fertilization were analysed. Immunostaining for BPDE–DNA adducts was confined to the nucleus and was significantly greater in cells from 14 smokers than in those from seven passive smokers and 11 nonsmokers (Zenzes *et al.*, 1998) (see also the monograph on involuntary smoking, this volume).

The sperm DNA of 28 smokers contained levels of 8-OHdG about 1.5 times higher than that of 32 age-matched nonsmokers, a difference that was statistically significant (6.19 ± 1.71 versus 3.93 ± 1.33 8-OHdG/10^5 dG, $p < 0.001$) (Shen *et al.*, 1997). The same authors reported a correlation between sperm defects and levels of 8-OHdG in sperm DNA, indicating that this lesion is useful for assessing sperm quality and male fertility (Shen *et al.*, 1999).

In another study, the sperm DNA of smokers ($n = 35$) was found to be more sensitive to acid-induced denaturation ($p < 0.02$) and to possess higher levels of DNA strand breaks ($p < 0.05$) than that of nonsmokers ($n = 35$) (Potts *et al.*, 1999).

Cardiovascular tissues

In a pilot study investigating the presence of DNA adducts by ^{32}P-postlabelling in a number of human tissues at autopsy, the DRZ characteristic of smoking-related DNA damage was observed in heart tissue from two smokers, but not in that of a nonsmoker who chewed tobacco. Moreover, of all the tissues examined, which included lung and bronchus, the levels of adducts were highest in heart tissue (Randerath *et al.*, 1989). A study comparing ^{32}P-postlabelling, HPLC-fluorescence detection of BPDE–DNA adduct hydrolysis products and synchronous fluorescence spectroscopy (SFS) detection of the same products demonstrated that all three methods were capable of detecting DNA adducts in atherosclerotic lesions in smooth muscle of human abdominal aorta. However, because of the limited number of samples investigated (four from smokers, three from former smokers), no conclusion could be drawn regarding the origins of the adducts detected (Izzotti *et al.*, 1995a). Another study measured DNA adducts by ^{32}P-postlabelling with nuclease P_1 digestion in the thoracic aorta of 133 victims of sudden or accidental death. Those with significant atherosclerotic changes and for whom atherosclerosis was classified as the main cause of death were designated as 76 cases, those with few atherosclerotic changes as 57 controls. Smoking status was determined by measuring cotinine levels in plasma. Levels of bulky aromatic DNA adducts were significantly higher in the cases than in the controls, but when smokers and nonsmokers were compared, significant differences were observed in the controls, but not in the cases (Binková *et al.*, 2001).

Immunohistochemical staining of endothelial and smooth muscle cells of blood vessels using antibodies against BPDE–DNA adducts resulted in higher intensity of the endothelial cells. However, the correlation with smoking habits among the 33 subjects studied (samples from nine of 11 smokers showed positive staining, compared with 12 of 22 nonsmokers) was not statistically significant (Zhang *et al.*, 1998).

In a study of DNA from the right atrial appendage of 41 patients undergoing open heart surgery, the levels of aromatic DNA adducts detected by ^{32}P-postlabelling with nuclease P_1 digestion were significantly higher in 15 smokers than in 15 former smokers ($p < 0.01$) and in 11 nonsmokers ($p < 0.001$). A significant linear relationship between adduct levels and daily cigarette smoking was observed in the smokers (Van Schooten *et al.*, 1998).

Blood cells

Although nucleated peripheral blood cells are not generally considered to be target cells for tobacco-induced tumorigenesis, the relative ease with which they can be obtained from human subjects, when compared with many target organs, has led to a large number of studies exploring the differences between cells from smokers and nonsmokers. The studies in which smoking-related DNA adducts have been determined in blood cells are summarized in Table 4.5.

The picture that emerges from these many studies is an inconsistent one. Measurements made in the longer-lived cells (lymphocytes and monocytes) are more likely to reveal significant differences between smokers and nonsmokers than measurements made

Table 4.5. Studies of smoking-related DNA adducts in human blood cells

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Perera *et al.* (1987)	WBC	ELISA	22 smokers 24 nonsmokers	BPDE–DNA adducts detected in 5/22 smokers and 7/24 nonsmokers
Perera *et al.* (1989)	WBC	ELISA	81 lung cancer cases (38 smokers, 43 former and nonsmokers) 67 controls (19 smokers, 48 former and nonsmokers)	For cases, 19/38 smokers and 21/43 former and nonsmokers were positive for PAH–DNA adducts; for controls, 9/19 smokers and 27/48 former and nonsmokers were positive. Current smokers who were cases had higher (0.35) adduct levels than controls who smoked (0.14). But PAH–DNA adduct formation was unrelated to number of cigarettes smoked.
Holz *et al.* (1990)	Monocytes	^{32}P-Postlabelling + nuclease P_1 enhancement	5 smokers	In a controlled experiment, smoking caused the formation of DNA adducts. Not all adducts observed were smoking-related.
Jahnke *et al.* (1990)	Lymphocytes	^{32}P-Postlabelling	11 smokers 15 nonsmokers	Differences in distribution of lipophilic DNA adducts between smokers and nonsmokers not significant
Kiyosawa *et al.* (1990)	WBC	HPLC/ECD	10 smokers	10 minutes after smoking 2 cigarettes, 8-OHdG adduct levels in volunteers were increased 1.5-fold ($p < 0.05$).
Phillips *et al.* (1990a)	WBC	^{32}P-Postlabelling	31 smokers 20 nonsmokers	Adduct levels not significantly different in smokers and nonsmokers
Van Schooten *et al.* (1990b)	WBC	ELISA	44 controls	30% of controls had detectable BPDE–DNA adducts. Smokers had significantly higher adduct levels than nonsmokers (11/28 versus 2/16).
Savela & Hemminki (1991)	Lymphocytes, granulocytes	^{32}P-Postlabelling with nuclease P_1 enhancement	11 smokers 10 nonsmokers	DNA adducts in lymphocytes of smokers significantly higher ($p < 0.05$) than in those of nonsmokers. Differences in granulocytes not significant

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Mustonen & Hemminki (1992)	WBC, lymphocytes, granulocytes	^{32}P-Postlabelling	10 smokers 10 nonsmokers	DNA adduct levels as 7-methylguanine residues were significantly higher in smokers in all 3 cell populations. Adduct levels highest in lymphocytes and lowest in granulocytes
Santella *et al.* (1992)	Mononuclear[b] cells	ELISA	63 smokers 27 nonsmokers (all males)	BPDE–DNA adduct levels were higher in smokers (70%) than in nonsmokers (22%). DNA adduct levels in smokers did not correlate with number of cigarettes/day or pack–years.
Van Schooten *et al.* (1992)	WBC	^{32}P-Postlabelling, ELISA	39 lung cancer patients	Adduct levels were not significantly associated with smoking status, or with adduct levels in lung tissue (matching tissue for 20 subjects).
Gallagher *et al.* (1993a)	WBC, lymphocytes	^{32}P-Postlabelling	23 smokers 16 nonsmokers	Adduct levels 2.5-fold higher in smokers for both cell types ($p < 0.01$)
Holz *et al.* (1993)	Lymphocytes	Nick translation to detect DNA single strand breaks	5 smokers	Under controlled conditions, single-strand breaks increased in 4/5 smokers who smoked 24 cigarettes in 8 h, having refrained from smoking for 12 h prior to the test.
Mustonen *et al.* (1993)	Lymphocytes	^{32}P-Postlabelling	13 smokers 7 nonsmokers	7-Methylguanine DNA adduct levels significantly higher in smokers than in nonsmokers. In 5 smokers, lung adduct levels correlated with lymphocyte adduct levels.
Popp *et al.* (1993)	Lymphocytes	^{32}P-Postlabelling and alkaline elution	23 oral cancer patients 15 hospital controls 21 healthy nonsmokers	Significant correlation between smoking and DNA elution rates, but not DNA adduct levels

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Grinberg-Funes *et al.* (1994)	Mononuclear[b] cells	ELISA	63 male smokers	No relationship between smoking and PAH–DNA adduct levels observed previously (Santella *et al.*, 1992), but significant association of serum vitamin E and C observed among *GSTM1* null individuals with adduct levels
Ichiba *et al.* (1994)	WBC	^{32}P-Postlabelling + nuclear P1 digestion	26 chimney sweeps 14 controls	Smokers had 48% higher levels of aromatic DNA adducts than nonsmokers (statistically significant).
Rojas *et al.* (1994)	WBC	HPLC/fluorescence, ^{32}P-postlabelling + nuclease P_1 enrichment and ELISA	7 lung cancer patients (6 smokers); 3 controls (2 nonsmokers)	BPDE–DNA adducts detected in the 6 patients who smoked at substantially higher levels than in the controls who did not smoke. A good correlation was obtained with results from fluorometry and ^{32}P-postlabelling, but not from fluorometry and ELISA.
Binková *et al.* (1995)	WBC	^{32}P-Postlabelling with butanol enrichment	9 smokers 21 nonsmokers	In a study designed to investigate exposure of women working outdoors to PAH, no effect of smoking on adduct levels was observed.
Mooney *et al.* (1995)	WBC	ELISA	40 smokers	In a smoking cessation study, a 50–75% reduction in PAH–DNA adduct levels was observed 8 months after cessation, with similar reductions in 4-ABP–haemoglobin adduct levels.
Rojas *et al.* (1995)	Mononuclear[b] cells	HPLC/fluorescence	39 coke-oven workers 39 controls	Workers had higher levels of BPDE–DNA adducts than controls. In both groups, mean level in smokers was higher, but differences not statistically significant (large interindividual variation).

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Schell *et al.* (1995)	WBC, lymphocytes	^{32}P-Postlabelling	103 smokers 107 nonsmokers	In a study of several populations occupationally exposed to PAH and controls, no influence of smoking on adduct levels in WBC was evident, and only a weak trend in lymphocytes.
Tang *et al.* (1995)	WBC	ELISA	119 lung cancer cases (52 smokers, 58 former smokers, 9 nonsmokers) 98 controls (25 smokers, 34 former smokers, 39 nonsmokers)	Adduct levels were significantly higher in cases than in controls ($p < 0.01$) and higher in smokers and former smokers in both groups ($p < 0.05$). Adducts increased with number of cigarettes smoked in cases who were current smokers ($n = 51$), but not in control smokers. Adducts in WBC correlated with adducts in lung tumour tissue ($p < 0.05$, $n = 34$).
Wiencke *et al.* (1995)	Mononuclear cells	^{32}P-Postlabelling	6 smokers 10 former smokers (< 1 year) 15 former smokers (> 1 year)	Correlation of adduct levels in mononuclear cells with adduct levels in lung (value 2.6-fold higher in lung than in mononuclear cells)
Asami *et al.* (1996)	WBC	HPLC/ECD	10 smokers 10 former smokers 10 nonsmokers	Levels of 8-OH-guanine in DNA 1.88-fold higher in smokers than in nonsmokers ($p = 0.013$)
Mooney *et al.* (1997)	WBC	ELISA	159 smokers enrolled in a smoking cessation programme	PAH–DNA adduct levels 2-fold higher ($p < 0.03$) in individuals with *CYP1A1* exon 7 Val allele[d] ($n = 10$). Association between plasma levels of β-carotene and adducts seen only in *GSTM1* null subjects

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Van Schooten *et al.* (1997)	Lymphocytes	^{32}P-Postlabelling	54 smokers 21 nonsmokers	Aromatic DNA adduct levels significantly related to daily exposure to cigarette tar, with evidence of saturation at > 29 cigarettes/day. No significant correlation with adduct levels in BAL cells
Wang *et al.* (1997)	Lymphocytes	^{32}P-Postlabelling	94 smokers 98 nonsmokers	DNA adduct levels in smokers not significantly different from levels in nonsmokers. Plasma levels of β-carotene and α-tocopherol did not influence adduct levels significantly, nor did *CYP1A1* or *GSTM1* genotype.
Zhao *et al.* (1997)	WBC	^{32}P-Postlabelling	6 smokers 14 nonsmokers	Difference in adduct levels between smokers and nonsmokers of borderline significance ($p = 0.051$). No correlation between adducts and daily cigarette consumption
Arnould *et al.* (1998)	WBC	ELISA	58 smokers 20 nonsmokers	BPDE–DNA adducts not detected in nonsmokers. Adduct levels in smokers correlated with tobacco consumption ($p < 0.001$)
Dallinga *et al.* (1998)	Lymphocytes	^{32}P-Postlabelling	55 smokers 4 nonsmokers	DNA adduct levels correlated with cigarette and tar consumption, with evidence of saturation at higher smoking levels. No effect of *GSTM1* genotype. Slow acetylators (*NAT2*) had significantly higher adduct levels ($p < 0.05$).

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Godschalk *et al.* (1998)	Lymphocytes, monocytes, granulocytes	^{32}P-Postlabelling	86 smokers 23 nonsmokers	Aromatic DNA-adduct levels significantly higher in lymphocytes and monocytes of smokers, but not granulocytes. Adduct levels in monocytes + lymphocytes of smokers (n = 78) linearly related to daily exposure to 'cigarette tar' but not cigarette consumption or pack–years
Pastorelli *et al.* (1998)	Lymphocytes	GC–MS	44 male lung cancer patients, all smokers	Significant correlation between levels of BPDE–DNA adducts and numbers of cigarettes smoked daily (p = 0.02) and pack–years (p = 0.05). No effect of *CYP1A1, mEH* or *GSTM1* genotypes on levels of adducts
Rojas *et al.* (1998)	WBC	HPLC/fluorescence	20 smokers (coke-oven workers)	BPDE–DNA adduct levels higher in 1 individual with *GSTM1* null and *CYP1A1* 2A/2A variant genotypes
Hou *et al.* (1999)	Lymphocytes	^{32}P-Postlabelling	179 lung cancer cases (36 smokers, 29 recent former smokers, 27 long-term former smokers, 87 never-smokers) 161 controls (46 smokers, 12 recent former smokers, 24 long-term former smokers, 79 never-smokers)	Aromatic DNA adduct levels significantly higher in smokers (cases + controls) than in long-term former smokers (> 2 years) and nonsmokers (p = 0.0003). No significant differences between cases and controls for any of the smoking categories
Pavanello *et al.* (1999)	Mononuclear cells	HPLC/fluorescence	130 subjects	Subjects were exposed to PAH from a variety of occupational and iatrogenic sources. Smoking did not influence BPDE–DNA adduct levels.

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Poli *et al.* (1999)	WBC	Comet assay	50 smokers 50 nonsmokers	Significant differences in DNA migration[c] between smokers and nonsmokers ($p < 0.001$)
Shinozaki *et al*. (1999)	Lymphocytes	Flow cytometry	40 smokers 35 nonsmokers	Mean level of BPDE–DNA adducts in smokers significantly higher than in nonsmokers. In smokers, adduct levels correlated with age, years of smoking and pack–years, but not with number of cigarettes/day.
Wiencke *et al.* (1999)	Mononuclear cells	^{32}P-Postlabelling	54 lung cancer patients	A significant correlation was observed between adduct levels in blood mononuclear cells and in lung ($r = 0.77$, $p < 0.001$)
van Zeeland *et al.* (1999)	WBC leukocytes	HPLC/ECD	57 smokers 16 former smokers 29 nonsmokers	Levels of 8-OHdG in DNA significantly lower in smokers than in nonsmokers ($p < 0.05$)
Besarati Nia *et al.* (2000b)	Lymphocytes	^{32}P-Postlabelling	9 smokers 9 nonsmokers	Lipophilic DNA adduct levels significantly higher in smokers than in nonsmokers ($p = 0.0001$). Levels of adducts in induced sputum higher than those in lymphocytes with adducts
Duell *et al.* (2000)	Mononuclear cells	^{32}P-Postlabelling	11 smokers 38 former smokers 11 nonsmokers	Polyphenol–DNA adducts showed a weak positive trend with the presence of *XRCC1* allele 399Gln. No association found with smoking. No effect of *ERCC2* polymorphism observed
Georgiadis *et al.* (2000)	Peripheral and cord WBC	Competitive repair assay	28 smokers 5 smokers	O^6-Methylguanine levels in DNA not influenced by smoking status
Jacobson *et al.* (2000)	Mononuclear[b] cells	ELISA	121 smokers	PAH–DNA and 8-OHdG adduct levels in smokers reduced by vitamin supplements, but differences from placebo group not significant

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Peluso *et al.* (2000)	WBC	^{32}P-Postlabelling	162 bladder cancer cases 104 hospital-based controls	No relationship between smoking and adduct levels found, although there was a strong association with case/control status. Adduct levels significantly reduced in subjects with higher fruit and vegetable consumption. Adduct levels influenced by *NAT2* genotype, but not by *GSTM1, GSTT1, GSTP1, COMT* or *NQO1* genotypes
Rojas *et al.* (2000)	WBC	HPLC/fluorescence	89 coke oven workers (35 smokers, 36 former smokers, 18 nonsmokers) 44 controls (all smokers)	BPDE–DNA adducts increased in smokers. *GSTM1* genotype also influenced adduct levels, as did combinations of *GSTM1* and *CYP1A1* genotypes, but *GSTT1* genotype did not.
Vulimiri *et al.* (2000)	Lymphocytes	^{32}P-Postlabelling	55 lung cancer cases (46 smokers, 6 former smokers, 3 nonsmokers) 58 controls (39 smokers, 6 former smokers, 13 nonsmokers)	Lung cancer cases had higher levels of aromatic adducts and 8-OHdG than controls regardless of smoking status; and among smokers, only higher levels of bulky adducts. No correlation was seen between levels of the two adduct types.
Besarati Nia *et al.* (2001)	Lymphocytes	HPLC/ECD for 8-OHdG; comet assay for oxidized pyrimidines	21 smokers 24 nonsmokers	Smokers had lower levels of 8-OHdG adduct than nonsmokers (38.6 versus 50.9 10^6 dG, $p = 0.05$). Levels of oxidized pyrimidines were lower (not statistically significant) than in nonsmokers.

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Godschalk *et al.* (2001)	Mononuclear cells[b]	^{32}P-Postlabelling + nuclease P_1 enrichment	67 smokers	A positive correlation was found between self-reported numbers of cigarettes smoked daily and aromatic-DNA adduct levels ($p = 0.04$). DNA adduct levels correlated with 4-ABP–haemoglobin adduct levels. Individuals with some combinations of *GSTT1* or *GSTM1* genotypes with *NAT1* and *NAT2* genotypes had significantly different adduct levels.
Hou *et al.* (2001)	Lymphocytes	^{32}P-Postlabelling + nuclease P_1 treatment	170 lung cancer cases 144 controls (113 smokers and recent former smokers, 201 long-term former smokers and nonsmokers)	Aromatic DNA adduct levels higher in smokers than in nonsmokers, especially in controls. Controls with the *NAT2* slow genotype had higher adduct levels than controls with the rapid phenotype.
Matullo *et al.* (2001)	WBC	^{32}P-Postlabelling	81 smokers 92 former smokers 131 nonsmokers	No effect of smoking on adduct levels apparent, but within each group, polymorphisms in *XRCC3* were associated with higher adduct levels. *XRCC1* and *XPD* genotype affected adduct levels in nonsmokers only.
Tang *et al.* (2001)	WBC	^{32}P-Postlabelling	89 lung cancer cases (36 smokers, 36 former smokers, 16 nonsmokers) 173 controls (67 smokers, 72 former smokers, 32 nonsmokers)	In this prospective study, among current smokers, the mean level of adducts among cases was double that among the controls ($p = 0.03$). Smokers had higher levels of adducts than former and nonsmokers, but differences not significant.
van Delft *et al.* (2001)	Lymphocytes	^{32}P-Postlabelling TLC and HPLC	37 controls (18 smokers, 19 nonsmokers)	PAH–DNA adduct levels significantly higher in smokers by TLC method

Table 4.5 (contd)

Study	Blood cells[a]	Method of analysis	Number of subjects	Outcome
Whyatt *et al.* (2001)	WBC	^{32}P-Postlabelling, ELISA	160 mother/newborn infant pairs (16 smokers, 38 former smokers, 106 nonsmokers)	Cord blood of infants had higher aromatic DNA adduct levels than maternal WBC. When analysed by ELISA, PAH–DNA adduct levels were higher in 7/10 smoking mothers than in their infants ($p = 0.05$). Among mother/newborn pairs where blood samples were obtained concurrently ($n = 61$), aromatic DNA adducts were higher in the WBC of newborns than in the parental WBC in all groups except current smokers.
Hou *et al.* (2002)	Lymphocytes	^{32}P-Postlabelling	185 lung cancer cases (97 smokers, 88 never-smokers) 162 controls (83 smokers, 79 never-smokers)	Adduct levels similar in cases and controls, but increased in smokers and recent former smokers (statistically significant). Adduct levels significantly increased with increasing number of variant alleles in *XPD* exon 10 or exon 23

WBC, white blood cells; ELISA, enzyme-linked immunosorbent assay; BPDE, benzo[*a*]pyrene diol epoxide; PAH, polycyclic aromatic hydrocarbons; HPLC, high-performance liquid chromatography; ECD, electrochemical detection; 8-OHdG, 8-hydroxy-2′-deoxyguanosine; 4-ABP, 4-aminobiphenyl; BAL, bronchoalveolar lavage; GC–MS, gas chromatography–mass spectrometry; dG, deoxyguanosine; TLC, thin-layer chromatography

[d] Val allele = valine polymorphism

in whole white blood cell preparations (see Table 4.5). However, a study of adduct levels in smokers following cessation of the habit did show a decline over time (Mooney *et al.*, 1995). It is clear from studies of populations occupationally exposed to agents such as PAHs that there are many sources of exposure that result in DNA adducts in blood cells and whether or not the influence of tobacco smoking is discernible probably depends on the extent of the contribution of other occupational or environmental sources in particular study populations. There have also been reports of the influence of nutritional factors on levels of DNA adducts in blood cells in some studies (Grinberg-Funes *et al.*, 1994; Mooney *et al.*, 1997; Jacobson *et al.*, 2000), but not in others (Wang *et al.*, 1997). The modulating effects of genetic polymorphisms in xenobiotic metabolizing genes and DNA repair genes have been implicated in several studies. In general, these observations have been made on rather small numbers of subjects and the magnitude of the effects noted was not large. Confirmation of the findings from larger studies is required.

A few reports have suggested that the levels of adducts in the blood of smokers correlate with the levels of adducts in the lung (Tang *et al.*, 1995; Wiencke *et al.*, 1995, 1999). However, there are also conflicting studies in which no association was found between levels of blood BPDE–DNA adducts and levels of adducts in lung (Van Schooten *et al.*, 1992) or in cells obtained by bronchio-alveolar lavage (Van Schooten *et al.*, 1997).

A number of studies in lymphocytes have reported an increase in oxidative damage in the DNA of smokers (Kiyosawa *et al.*, 1990; Asami *et al.*, 1996). The magnitude of this increase, although significant, is generally small (less than twofold) and its biological significance is unclear. In contrast, there have been two reports in which smokers had lower levels of this lesion in DNA from their leukocytes or lymphocytes (van Zeeland *et al.*, 1999; Besarati Nia *et al.*, 2001).

Several studies that have compared smokers with cancer with smokers who are free of the disease have reported an approximately twofold higher level of lymphocyte adducts in the cases. This has been observed in two case–control studies of lung cancer (Perera *et al.*, 1989; Vulimiri *et al.*, 2000) and in one prospective study (Tang *et al.*, 2001), but not in another case–control study (Hou *et al.*, 1999). The effect was also observed in a case–control study of bladder cancer (Peluso *et al.*, 2000). These findings suggest that DNA adducts can be considered as biomarkers of risk in some populations, although the magnitude of the changes in levels is small when seen against a background of wide inter-individual variation, making the assessment of risk on an individual basis problematic.

Another approach to monitoring human exposure to carcinogens has been to detect the antigenic response to BPDE-DNA adducts in blood cells. Serum antibodies to these adducts have been detected in a number of groups of occupationally exposed workers, but in a study of smokers only four of 50 heavy smokers initially tested positive for the antibodies. Paradoxically, the frequency of positivity increased during a cessation programme in which 28 subjects quit smoking and 22 reduced cigarette consumption by 75% (Pulera *et al.*, 1997). Nevertheless, in a larger population study of 1345 individuals tested for the presence of detectable BPDE–DNA antibodies in serum, there was a positive association with smoking in 17.8% of nonsmokers, 21.5% of former smokers and 25.7% of smokers.

There was also a synergism between smoking and family history of lung cancer in determining the prevalence of antibodies ($p = 0.02$) (Petruzzelli *et al.*, 1998).

(iv) *Blood compounds*

Tobacco use is associated with increased levels of several carcinogens in blood. These compounds may prove useful as biomarkers of exposure to tobacco smoke when blood samples are collected in epidemiological studies.

Tobacco is a major source of exposure to cadmium in the general population and blood cadmium concentrations correlate positively with current tobacco smoking habits (WHO, 1992). Cadmium levels increase with the number of cigarettes smoked per day (Hoffmann *et al.*, 2000). Current smokers have, on average, levels of cadmium that are four to five times higher than those of never-smokers (Ellingsen *et al.*, 1997; Hoffmann *et al.*, 2000). Cigarette smoking or both sheesha (tobacco–fruit mixture cooked) and cigarette smoking lead to significantly higher blood cadmium levels than those observed in nonsmokers or in smokers of only sheesha (Al-Saleh *et al.*, 2000). Although smoking has less effect on lead levels than on those of cadmium, slightly higher levels of lead in blood have generally been reported for smokers than for nonsmokers or former smokers (Brockhaus *et al*., 1983; Al-Saleh, 1995; Ellingsen *et al*., 1997).

Many studies have shown that the levels of certain volatile organic compounds in blood were significantly higher in smokers than in nonsmokers (Ashley *et al.*, 1996). The mean levels of benzene and styrene in blood were significantly higher among smokers than nonsmokers. The concentrations of benzene in blood were significantly associated with the number of cigarettes smoked per day (Ashley *et al.*, 1995). The difference in the levels of benzene in blood persisted when comparisons between smokers and nonsmokers in the general public and in occupationally exposed groups were made (Brugnone *et al.*, 1999).

The levels of NNAL (a metabolite of NNK) has been measured in the blood (unhydrolysed plasma) of smokers (Hecht *et al.*, 1999a). NNAL and its detoxification product, NNAL-glucuronide, can be detected in the blood plasma for up to 2 days after quitting tobacco use. Levels of NNAL and NNAL-glucuronide in blood are 18.8% and [4.1%] of those in urine, respectively (Hecht *et al.*, 2002).

(v) *Breath compounds*

Exhaled carbon monoxide

The measurement of exhaled carbon monoxide (CO) has often been used as a tool for validation of self-reported cigarette consumption and smoking histories and to distinguish smokers from nonsmokers (Robertson *et al.*, 1987; Muranaka *et al.*, 1988; Morabia *et al.*, 2001).

The concentration of CO in exhaled air was significantly correlated with the self-reported number of cigarettes smoked per day. The average concentration of expired CO was 4.9 ppm (v/v) ($n = 20$) in nonsmokers and 18.5 ppm in smokers ($n = 20$; $p < 0.001$).

The concentration of expired CO in male smokers (n = 12) was 22.7 ppm and in female smokers was 12.0 ppm (n = 8; $p < 0.05$) (Muranaka *et al.*, 1988).

Various measures of exhaled CO as a marker of exposure to cigarette smoke were compared between 400 current regular male and female smokers. Cigarette consumption was categorized as moderate (< 15 cigarettes/day for at least 5 days per week for the last 2 years) or heavy (> 15 cigarettes/day for at least 2 years). Individuals with genetic variants of the *CYP2A6* gene (*CYP2A6*2* and *CYP2A6*A* genes) were not included in the analysis (n = 25). No difference was found in the number of cigarettes per day or levels of exhaled CO between the sexes among Caucasian smokers. Women smoked 19.3 cigarettes per day and exhaled 19.6 ppm (v/v) CO, whereas men smoked 19.8 cigarettes/day and exhaled 20.6 ppm CO. The ratio of nicotine:CO was determined using plasma nicotine levels. Women had significantly lower levels of nicotine in the blood than men (17.3 versus 20.9 ng/mL; $p < 0.01$). Although no significant difference was found in levels of CO in breath, women tended to smoke cigarettes with a lower nicotine content and their nicotine:CO ratios were lower than those measured in male smokers. Among other ethnic groups, there were no statistically significant gender differences in the number of cigarettes smoked per day, but men had higher concentrations of CO in exhaled air and higher concentrations of blood nicotine and cotinine ($p < 0.01$) than women (Zeman *et al.*, 2002).

The CO level measured in exhaled breath condensate was significantly higher in smokers (12.5 ppm) than in nonsmokers (3.4 ppm) and increased significantly to 19.6 ppm 30 min after exposure to tobacco smoke (Balint *et al.*, 2001).

At the time of delivery, pregnant women who smoked exhaled 8.42 ppm (v/v) CO corrected for inhaled air as opposed to 1.33 ppm exhaled by pregnant women who did not smoke ($p < 0.0001$) (Seidman *et al.*, 1999). The concentration of exhaled CO in mothers who smoked was strongly correlated with the number of cigarettes smoked per day ($p < 0.000001$). Within hours of delivery, the newborns of women smokers exhaled 10 ppm CO, whereas 1.74 ppm CO was exhaled by newborns of nonsmoking mothers ($p < 0.0001$). Maternal exhaled CO correlated strongly ($p < 0.000001$) with neonatal exhaled CO.

No differences in concentrations of exhaled CO were found between smokers of either three mentholated or three non-mentholated cigarettes with different nicotine content (the three cigarettes were smoked 45 min apart, in a single session) (Pickworth *et al.*, 2002). According to Clark *et al.* (1996), African American smokers had significantly higher levels of cotinine and CO per cigarette smoked and per millimetre of tobacco rod smoked than white American smokers ($p < 0.001$). After adjustment for race, number of cigarettes smoked per day and mean length of each cigarette smoked, the presence of menthol was associated with higher concentrations of cotinine ($p = 0.03$) and CO ($p = 0.02$).

A preliminary evaluation of a novel smoking system that employs electrical heating of tobacco (600 °C) instead of combustion (900 °C) (Accord®) was carried out by enrolling 10 smokers of 'light' cigarettes (≥ 10 cigarettes/day). The novel system limited

users to eight puffs per cigarette instead of their usual 10–11 puffs. The levels of expired CO were lower in subjects using the novel system than when normal cigarettes were smoked (Buchhalter & Eissenberg, 2000).

Eclipse® is a novel nicotine delivery device that primarily heats, rather than burns, tobacco. In a cross-over study, the number of cigarettes smoked per day decreased from 19 at baseline to 2.1 after two weeks of using Eclipse® ($p < 0.001$), but exhaled CO concentrations increased from 21 ppm to 33 ppm ($p < 0.001$). During use of Eclipse®, the concentration of nicotine in blood remained fairly stable although it increased slightly from 16.8 ng/mL to 18.0 ng/mL (Fagerström *et al.*, 2000).

Smoking fewer cigarettes may reduce exposure to toxins even if the smoker adopts a more intensive smoking behaviour to compensate for the reduced number of cigarettes. If consumption is reduced from an average of 37 cigarettes/day to an average of five cigarettes/day, the intake of tobacco toxins per cigarette increased roughly threefold and daily exposure to tar and CO declined by only 50% (Benowitz *et al.*, 1986). The reduction of cigarette consumption from 40 cigarettes/day to 20 cigarettes/day was not followed by any consistent reduction in the levels of biomarkers of exposure to tobacco carcinogens (Hurt *et al.*, 2000).

Exhaled nitric oxide

Nitric oxide (NO) is formed from L-arginine by the enzyme NO synthase (NOS). NO is a highly reactive molecule that can be oxidized or complexed with other biomolecules depending on the microenvironment. The stable oxidation products of NO metabolism are nitrite and nitrate. Cigarette smoking is associated with an increased risk for respiratory tract infection, chronic airway disease and cardiovascular diseases, all of which may be modulated by endogenous NO (which acts as an endogenous vasodilator). Cigarette smoking reduces the levels of NO exhaled by healthy subjects, but the mechanism for this is unclear (Schilling *et al.*, 1994; Yates *et al.*, 2001). In the study by Yates *et al.* (2001), the amount exhaled by active smokers was significantly less than the amounts of NO exhaled by subjects who were exposed to sham and passive smoking for the same length of time (49 ppb (v/v) after 15 min of active smoking, a 30.3% decrease from the baseline level of 71 ppb versus 115 ppb in subjects exposed to sham smoking and 102 ppb in subjects exposed to passive smoking). Schilling *et al.* (1994) reported the same trend, with concentrations of exhaled NO being lower in smokers than in nonsmokers exposed to secondhand smoke (mean, 16 ppb in women who smoked versus 21 ppb in women who did not smoke and 15 ppb in men who smoked versus 19 ppb in men who did not smoke). However, the absolute values were much lower than those reported by Yates *et al.* (2001). In a single-breath analysis, smokers exhaled about 20 ppb NO, healthy controls, 40 ppb and asthmatic patients, 60 ppb (Persson *et al.*, 1994). Kharitonov *et al.* (1995) reported that smokers exhaled 42 ppb NO, whereas the concentration exhaled by nonsmokers was 88 ppb ($p < 0.01$). There was a significant relationship between the amount of exhaled NO and cigarette consumption ($r = –0.77$, $p < 0.001$).

Measurement of exhaled NO may yield information about the mechanisms underlying cigarette-induced lung damage. Balint *et al.* (2001) found that there was no difference between smokers and nonsmokers in the levels of nitrite, nitrite + nitrate, *S*-nitrosothiols and nitrotyrosine in the exhaled breath condensate at the baseline visit. Thirty minutes after smoking two cigarettes, the levels of nitrite + nitrate were significantly increased (from 20.2 to 29.8 μM, $p < 0.05$) and returned to the baseline within 90 min. There was no significant change in the levels of exhaled NO, nitrite, *S*-nitrosothiols or nitrotyrosine 30 and 90 min after smoking two cigarettes. There was no correlation between levels of exhaled NO and NO metabolites in breath condensate before and after smoking.

Benzene

Breath analysis under controlled conditions has been used to measure the exposure to benzene associated with active smoking (Jo & Pack, 2000)**.** The mean benzene concentrations in exhaled breath measured 1 min after smoking 5.0 cm of a cigarette (to a remaining butt length of 3.3 cm) ranged from 58.1 to 81.3 μg/m^3, depending on the commercial cigarette brand, whereas benzene concentrations measured prior to smoking ranged from 15.9 to 19.2 μg/m^3. These post-exposure concentrations of benzene in breath were much higher than the mean concentrations of benzene in breath reported in some previous studies (e.g. 16 μg/m^3 among smokers versus 2.5 μg/m^3 among nonsmokers; $p < 0.001$) (Wallace & Pellizzari, 1986) in which the exposure conditions and post-sampling times were not controlled. The concentration of benzene in breath increases with the number of cigarettes smoked: from 9.4 μg/m^3 (no cigarettes) to 47 μg/m^3 (> 50 cigarettes/day). The increase in concentrations of benzene in breath after active smoking is due to benzene being absorbed through the lung while an individual is smoking. From direct measurements of benzene in mainstream smoke, it was calculated that a typical smoker (30 cigarettes/day) inhales 2 mg benzene daily, whereas a nonsmoker inhales 0.2 mg/day (Wallace *et al.*, 1987).

Volatile organic compounds

Volatile organic compounds (VOC) other than benzene are often measured in expired breath to determine the exposure to cigarette smoke. Among 20 VOC analysed by Wallace and Pellizzari (1986), the levels of *meta* + *para*-xylene, ethylbenzene, *ortho*-xylene, styrene and octane were found to be statistically significantly higher ($p < 0.05$) in smokers ($n = 198$) than in nonsmokers ($n = 322$). Significant increases in the concentration in breath with number of cigarettes smoked were noted for styrene, ethylbenzene and *meta* + *para*-xylene (Wallace *et al.*, 1987).

Gordon (1990) analysed VOC in the exhaled breath of 26 smokers and 43 nonsmokers to identify possible biochemical markers of exposure to cigarette smoke. Among 230 GC–MS peaks, 2,5-dimethylfuran was found to have sufficient discriminatory power to allow almost complete distinction to be made between smokers and nonsmokers. Several other compounds could also be used to distinguish between the two groups with

a high level of accuracy. However, the half-lives of these compounds must be determined before they can be exploited as practical indicators of exposure to smoking.

Ethane, often used routinely as a marker of lipid peroxidation, has the potential to be a non-invasive marker of free-radical activity. Ethane levels in exhaled air were found to be higher in active smokers than in former smokers and nonsmokers (2.9 pmol/min/kg versus 1.55 and 1.11 pmol/min/kg, respectively), reflecting the presence of ethane in cigarette smoke (Habib *et al.*, 1995).

The levels of isoprene in exhaled breath increased on average by 70% after smoking one cigarette. The concentration of acetone increased by 22%, whereas that of ethanol decreased by 28% after smoking one cigarette (Senthilmohan *et al.*, 2001).

(vi) *Other*

Polycyclic aromatic hydrocarbons

Several studies have quantified PAHs in lung tissue (Tomingas *et al*., 1976; Seto *et al*., 1993; Tokiwa *et al*., 1993; Lodovici *et al*., 1998). In a recent investigation, the quantities of 11 PAHs were measured in 70 lung tissue samples from 37 smokers and 33 nonsmokers (defined by serum cotinine concentration). The sum of PAH concentrations was higher in smokers and there was a dose–response relationship for smoking characterized by increasing serum cotinine (Goldman *et al*., 2001).

Benzo[*a*]pyrene

Benzo[*a*]pyrene and several of its metabolites were detected in the cervical mucus of both smokers and nonsmokers (Melikian *et al*., 1999).

***N*-Nitrosamines**

The tobacco-specific nitrosamine, NNK, was detected in 16 samples of cervical mucus from 15 women who were smokers at concentrations of 11.9–115 ng/g (mucus) (two samples were collected from one smoker at different times) and in nine of 10 samples from nonsmokers at concentrations of 4.1–30.8 ng/g (mucus), but the concentrations of NNK in specimens from cigarette smokers were significantly higher than in those obtained from nonsmokers (Prokopczyk *et al*., 1997). Further studies demonstrated that human cervical tissue can metabolize NNK by both α-hydroxylation and carbonyl reduction (Prokopczyk *et al*., 2001).

NNK was detected in 15 of 18 samples of pancreatic juice from smokers at concentrations of 1.4–604 ng/mL and in six of nine samples from nonsmokers (range of concentrations, 1.13–97 ng/mL), and the levels were significantly higher in smokers than in nonsmokers. NNAL was present in 11 of 17 samples from smokers and in 3/9 from nonsmokers. NNN was found in two of 17 samples from smokers (68 and 242 ng/mL) (Prokopczyk *et al*., 2002).

Particulate matter (tar)

A problem in the analysis of exposure to tobacco smoke is that there is no direct marker for tar uptake (exposure). The biomarkers most frequently used for measuring the uptake of tobacco smoke (nicotine and cotinine) reflect the exposure to particulate-phase constituents.

Russel *et al.* (1986) and Woodward and Tunstall-Pedoe (1992) used an indirect measure, based on the assumption that the intake of different smoke components relative to one another is proportional to their concentration in the smoke, to evaluate the exposure of smokers in large population studies. Two tar indices were calculated:

- tar index (CO) = eCO × tar yield/CO yield; and
- tar index(cot) = serum cotinine × tar yield/nicotine yield

where the 'yields' were the values obtained by standard machine-smoking methods and expired CO (eCO) and serum cotinine were the individual's values. An average tar index was calculated as a weighted mean of the two indices for each individual, using the inverse standard deviations as the weights. This approach was validated by testing its ability to predict the levels of one marker by use of another. For example, using blood carboxyhaemoglobin (COHb) concentrations and CO:nicotine yield ratio of the cigarettes, the mean concentration of nicotine in the blood of smokers of low-tar cigarettes was predicted to be 31.9 ng/mL, whereas the measured mean was 31.8 ng/mL. Based on the measurements of the concentrations of cotinine, nicotine and COHb in blood and the calculated tar indices for 392 smokers (255 women and 137 men) of 'middle-tar' (17–22 mg), 'low-to-middle' (11–16 mg) and 'low-tar' (< 11 mg) cigarettes, Russell *et al*. (1986) concluded that despite substantial compensatory increases in inhalation, the low-tar smokers took in about 25% less tar, 15% less nicotine and 10% less CO than smokers of middle- and low-to-middle tar cigarettes. Similar outcomes were reported by Woodward and Tunstall-Pedoe (1992). They evaluated the exposure of 1133 male and 1621 female smokers of the three groups of cigarettes (low tar [< 13 mg/cigarette], middle tar [14–15 mg] and high tar [> 15 mg]) in the Scottish Heart Health Study by measuring the expired CO, serum thiocyanate and serum cotinine and calculating the indices of tar consumption. Expired CO and cotinine were found to peak in the middle-tar group. Tar consumption increased with tar yield of the cigarette smoked, but the increase in consumption was much lower than would be expected. This finding led to the conclusion that the tar yield of a cigarette is not an accurate guide to the amount of smoke components consumed by the smoker.

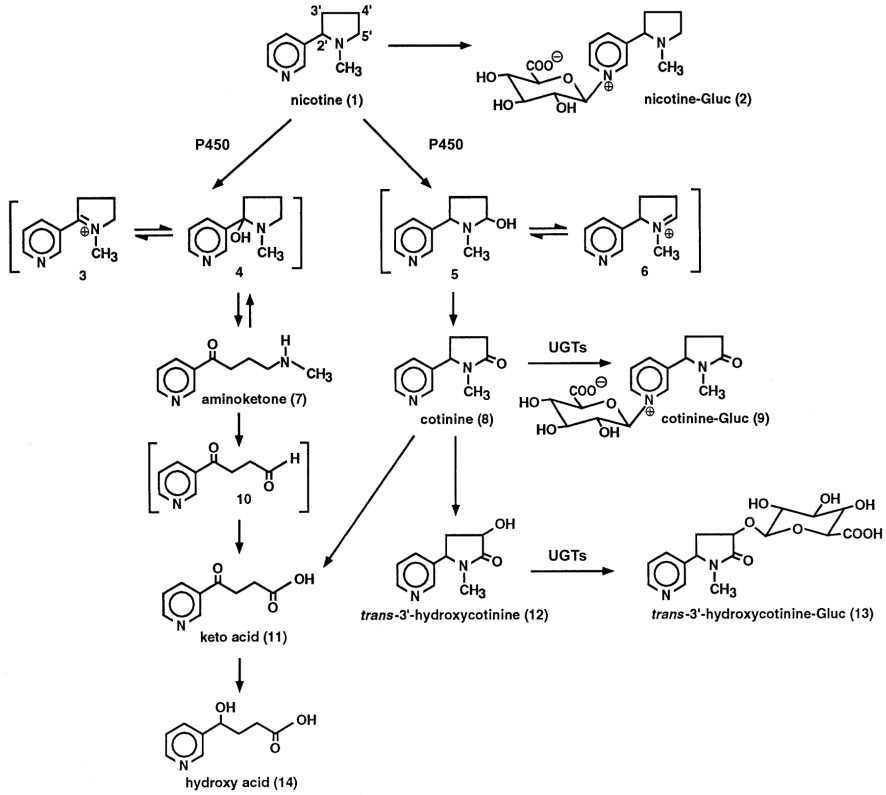
The atherogenic potential of mainstream smoke is associated with the particulate and vapour-phase components and not with CO. The thrombogenic potential is also associated with the particulate matter and vapour phase (Smith & Fisher, 2001).

Nicotine and its metabolites as markers of exposure to tobacco smoke

Nicotine is the principal alkaloid present in tobacco. Nicotine is also the main addictive constituent of tobacco products. It also has other pharmacological activities and toxic effects (Domino, 1999). Manufactured cigarettes contain 1–7% nicotine by weight

(6–12 mg nicotine/cigarette) and, of this, 15–25% enters the mainstream smoke while 75% is emitted into the air as sidestream smoke (Benowitz, 1999a). Nicotine is also found in exhaled smoke (Curvall & Enzell, 1986; IARC, 1986; California Environmental Protection Agency, 1997) (see Section 1).

An overview of the pathways of nicotine metabolism is presented in Figure 4.4. Nicotine is hydroxylated at the 5′-position by cytochromes P450 to yield an unstable intermediate, 5′-hydroxynicotine (**5**; see Figure 4.4), which exists in equilibrium with $\Delta^{1'(5')}$ iminium ion (**6**). 5′-Hydroxynicotine is oxidized by aldehyde oxidase to cotinine (**8**). Cotinine, in turn, is metabolized further to cotinine–glucuronide (cotinine–Gluc, **9**), *trans*-3′-hydroxycotinine (**12**) and *trans*-3′-hydroxycotinine–glucuronide (*trans*-3′-hydroxycotinine–Gluc, **13**) (Gorrod & Schepers, 1999). 2′-Hydroxylation of nicotine, mediated by cytochromes P450, gives 2′-hydroxynicotine (**4**), which spontaneously yields $\Delta^{1'(2')}$ iminium ion (**3**) and 4-(methylamino)-1-(3-pyridyl)-1-butanone (aminoketone, **7**), also known as pseudooxynicotine. Aminoketone (**7**) is then converted to 4-oxo-4-(3-pyridyl)butyric acid (keto acid, **11**) and 4-hydroxy-4-(3-pyridyl)butyric acid (hydroxy acid, **14**) (Hecht *et al*., 2000).



The major urinary metabolite of nicotine in smokers is *trans*-3′-hydroxycotinine (**12**) (about 40% of total urinary nicotine and metabolites). This is followed by cotinine (**8**) and cotinine–Gluc (**9**) (12–15% of each), *trans*-3′-hydroxycotinine–Gluc (**13**) (10%), hydroxy acid (**14**) (8%) and keto acid (**11**) (2%). Unchanged nicotine (8% of total urinary nicotine plus metabolites) and nicotine–Gluc (**2**) (2–3%) also occur (Byrd *et al*., 1992; Benowitz *et al*., 1994; Hecht *et al*., 1999b).

Since the mid-1980s, studies that have measured exposure to tobacco smoke and its biological effects have predominantly used nicotine and its metabolite cotinine determined in blood, urine or saliva as biological markers of exposure and uptake of tobacco smoke (IARC, 1986; National Research Council, 1986; US Department of Health and Human Services, 1986; Environmental Protection Agency, 1993; California Environmental Protection Agency, 1997). The main advantage of using nicotine and, consequently that of cotinine, as a marker compound over other markers is their specificity for tobacco and tobacco smoke. The measurements of all the metabolites in Figure 4.4 provides a more complete assessment of nicotine uptake.

The half-life of nicotine in the body is short, approximately 2 h in nonsmokers (IARC, 1986; Benowitz, 1996; Benowitz & Jacob, 1997; Benowitz, 1999b). Nicotine concentration can therefore reflect only acute exposure. This limits its use as a biomarker (IARC, 1986; US Environmental Protection Agency, 1993; Benowitz, 1996). The concentrations of nicotine in blood or plasma are higher in smokers than in nonsmokers, but vary considerably, mainly depending on the number of cigarettes smoked recently. Other variables, such as the tar content, yield of nicotine, average number of cigarettes smoked per day or type of filter, have been found to be poor predictors of nicotine concentrations in the blood (IARC, 1986).

The concentrations of cotinine can be measured in blood, urine or saliva samples. Because of its specificity and the availability of sensitive methods for reliable measure-

Figure 4.4. Pathways of mammalian nicotine metabolism initiated by 5′-hydroxylation and 2′-hydroxylation

Other pathways not shown include *N*-oxidation, *N*-demethylation and *N*-methylation.

Adapted from Hecht *et al.* (2000)

ments, cotinine, regardless of the body fluid, is currently the most widely used biomarker for measuring tobacco smoke uptake (reviewed in IARC, 1986; National Research Council, 1986; Jarvis *et al*., 1987; Muranaka *et al.*, 1988; Etzel, 1990; US Environmental Protection Agency, 1993; Benowitz, 1996, 1999b). It has a sensitivity of 96–97% and a specificity of 99–100% (Jarvis *et al*., 1987). The half-life of cotinine in smokers is longer than that of nicotine, on average about 16–20 h, with a range of approximately 10–40 h (US Environmental Protection Agency, 1993; Benowitz & Jacob, 1994; Benowitz, 1996; Pérez-Stable *et al*., 1998; Benowitz, 1999a,b). Cotinine concentrations are a good measure of average daily exposure to tobacco smoke and reflect the exposure to tobacco smoke over the past 2–3 days (IARC, 1986; National Research Council, 1986; US Environmental Protection Agency, 1993). Cotinine concentration, however, is not suitable for measuring more long-term exposure, although it may serve as a surrogate measure for that purpose.

The main determinant of cotinine levels in smokers and nonsmokers, like that of nicotine, is exposure to tobacco smoke (reviewed in IARC, 1986; National Research Council, 1986; US Environmental Protection Agency, 1993; Benowitz, 1996, 1999a) and also exposure from use of products designed for nicotine replacement therapy (Leyden *et al*., 1999). However, some variability due to individual differences in uptake, metabolism, distribution and elimination occurs (Benowitz *et al*., 1982; Benowitz, 1996; Benowitz & Jacob, 1997; Benowitz *et al*., 1999, 2002). The amount of nicotine converted to cotinine in humans varies, and this variability is attributable to dietary, environmental and genetic factors (Benowitz *et al.*, 1996; Benowitz & Jacob, 1997; Benowitz, 1999a; Hecht *et al*., 1999b; Sellers *et al*., 2000). Differences in the metabolism of nicotine and cotinine have been reported to occur between various racial and ethnic groups (Wagenknecht *et al*., 1993; Caraballo *et al*., 1998; Pérez-Stable *et al*., 1998; Benowitz *et al*., 1999; Kwon *et al*., 2001). These differences have been associated with slower metabolism and lower uptake of nicotine in some populations (Benowitz *et al*., 1999, 2002), whereas in others uptake may be higher (Caraballo *et al*., 1998).

Many studies have demonstrated that cotinine levels are clearly higher in smokers than in nonsmokers, leading to increased levels of cotinine being detected in the urine, serum and/or saliva of smokers. Generally, urinary cotinine concentrations are more than one hundred times greater in smokers than those in nonsmokers (e.g. IARC, 1986; National Research Council, 1986; US Department of Health and Human Services, 1986; Jarvis *et al*., 1987; Etzel, 1990; Tunstall-Pedoe *et al*., 1991; Environmental Protection Agency, 1993; Pirkle *et al*., 1996; Jarvis *et al.*, 2001). The large studies have been consistent in showing a positive correlation between cotinine levels and number of cigarettes smoked per day regardless of the body fluid in which cotinine was measured; however, the magnitude of the correlation varies to some extent (IARC, 1986; National Research Council, 1986; US Department of Health and Human Services, 1986; US Environmental Protection Agency, 1993; Law *et al*., 1997a; Etter *et al*., 2000).

Carboxyhaemoglobin and thiocyanate

The uptake of tobacco smoke constituents from the gaseous and particulate phases of mainstream smoke, inhaled by smokers, and of secondhand smoke, breathed in by nonsmokers, was investigated by Scherer *et al.* (1990). Tobacco smoke uptake was quantified by measuring COHb in erythrocytes and measuring nicotine and cotinine in plasma and urine, and the data obtained were correlated with urinary excretion of thioethers (biomarkers of electrophilic mainstream smoke carbonyls such as acrolein) and with mutagenic activity. An increase in all biochemical parameters was observed in smokers who inhaled the whole smoke of 24 cigarettes over a period of 8 h, whereas, after smoking the gas phase of mainstream smoke under the same conditions, only an increase of COHb and, to a minor degree, in urinary thioethers was found.

Serum thiocyanate has often been used for the validation of smoking histories as well as for the assessment of passive exposure to cigarette smoke. There was a significant increase ($p < 0.01$) in serum thiocyanate with increased smoking. The concentrations of

serum thiocyanate in plasma were positively associated with moderate and heavy smoking, but could not distinguish between nonsmokers, light smokers and passive smokers. Fourteen smokers enrolled in this study had serum thiocyanate concentrations higher than 70 μM. The complementary assay of exhaled CO was helpful in confirming nonsmoking status. Using a combination of serum thiocyanate and exhaled CO levels, nonsmoking status was confirmed in 98% of the cases (Robertson *et al.*, 1987).

Genetic factors affecting the metabolism of nicotine to cotinine

Genetic factors are among the major determinants of the variation in the metabolism of nicotine to cotinine. Poor metabolism of nicotine with lack of cotinine formation has been seen and shown to have a genetic basis (Benowitz *et al*., 1995). Many P450 enzymes are involved in the oxidative metabolism of nicotine; they include P4502A6, P4502B6, P4502D6, P4502E1, P4501A2, P4503A4 and P4501A1 (Yamazaki *et al*., 1999), but, in contrast to the findings reported from earlier studies, P4502D6 probably plays only a minor role (Benowitz *et al.*, 1996; Nakajima *et al.*, 1996; Yamazaki *et al*., 1999). According to present data, the most important and rate-limiting gene in 5′-hydroxylation [c-oxydation] of nicotine to cotinine is P4502A6 (Nakajima *et al*., 1996; Messina *et al*., 1997; Yamazaki *et al*., 1999). In addition, there are data indicating that P4502A6 is involved in 2′-hydroxylation of nicotine potentially leading to endogenous formation of NNK. This was reported to occur in human liver microsomes incubated with nicotine at a rate of about 6% of that of cotinine formation (Hecht *et al*., 2000).

P4502A6 enzyme activity can be lost as a result of a genetic polymorphism that can give rise to homozygosity for the inactive alleles of *CYP2A6*. In addition, individuals who are carriers of alleles with an inactivating mutation in a heterozygous condition and/or carry defective alleles of decreased enzyme activity are deficient in metabolizing nicotine to cotinine. Subjects with low P4502A6 enzyme activity have significantly lower levels of cotinine, as seen in smokers and in those administered nicotine via another route (Fernandez-Salguero *et al*., 1995; Oscarson *et al*., 1998; Kitagawa *et al.*, 1999; Nunoya *et al*., 1999; Oscarson *et al*., 1999; Nakajima *et al*., 2000; Kwon *et al*., 2001; Nakajima *et al.*, 2001; Yang *et al*., 2001; Xu *et al*., 2002). The prevalence of the homozygous genotypes with two inactive alleles varies in different populations. They are very rare among Caucasians and Japanese populations, but have been reported to be somewhat more common in the Chinese population (Yokoi & Kamataki, 1998; Kitagawa *et al*., 1999; Oscarson *et al*., 1999). More than 95% of members of Caucasian populations who show the *CYP2D6* poor-metabolizer phenotype can be diagnosed by gene analysis, whereas about 20–30% of poor metabolizers can be diagnosed by the known mutant alleles in the Japanese population. Subsequently to this finding, a new mutation, *CYP2D6* J9 was found in the Japanese population (Yokoi & Kamataki, 1998). In addition, a gene duplication genotype associated with increased plasma cotinine has recently been reported to occur at a low frequency in Caucasians (Rao *et al*., 2000). It has been proposed that *CYP2A6* polymorphism may be a major determinant of an individual's smoking behaviour and may lead to less desire to smoke (Pianezza *et al.*, 1998; Sellers *et al.*, 2000).

In addition to the individual and racial variation that occurs in the oxidative metabolism of nicotine, variation in the glucuronide conjugation of nicotine and cotinine also exists (Benowitz *et al*., 1999). Both nicotine and cotinine are metabolized by *N*-glucuronidation catalysed by uridine-5′-diphosphate-glucuronosyltransferase (UGT) enzymes (see Figure 4.4; Byrd *et al*., 1992; Benowitz *et al*., 1994). Although the specific UGTs involved in these metabolic steps are so far not known, it has been observed that *N*-glucuronidation of nicotine and cotinine is polymorphic, with evidence of slow and fast *N*-glucuronidation (Benowitz *et al*., 1999). Environmental factors may influence *N*-glucuronidation, but with current data indicating that many of the genes encoding UGTs are polymorphic (Burchell *et al*., 2000; Mackenzie *et al*., 2000), genetic polymorphism may also be involved. Distribution of slow and fast glucuronidation has been found to vary according to ethnicity; the extent of *N*-glucuronidation is generally less in blacks than in whites (Benowitz *et al*., 1999).

4.1.2 *Experimental systems*

(*a*) *Effects of tobacco smoke on enzyme activities*

In-vivo studies

Most investigations of the effects of tobacco smoke on enzyme activities in animals have measured changes in levels of phase I, phase II and antioxidant enzymes in the lung and liver of mice and rats (Table 4.6). Some studies have also measured its effects on enzyme activities in other organs such as the kidney, stomach, heart and brain.

Enzyme effects

The induction of several phase I enzymes, including P4501A1 (aryl hydrocarbon hydroxylase), P4501A2, P4502B, P4502C, P4502D and P4502E1 by tobacco smoke in mouse lung and liver has been reported (Table 4.6). An increase of at least twofold in the activity of most of these enzymes is induced within a few days after initial exposure of the mice to tobacco smoke, and the enzyme levels usually remain elevated throughout exposure. It is probable that the induction of these enzymes can be attributed to the presence of many carcinogens and toxins in tobacco smoke. P4502E1 appears to be induced to a greater extent (5–13-fold) than other phase I enzymes both in the lungs and liver of mice (Villard *et al.*, 1994, 1998a,b). Similarly, P4502E1 is strongly induced by tobacco smoke in mouse kidney (Seree *et al.*, 1996). To investigate the role of nicotine in the induction of CYP2E1, rats were treated once daily with saline or nicotine bitartrate (0.1, 0.3 and 1.0 mg/kg bw, subcutaneously) for 7 days. After nicotine administration, immunostaining for CYP2E1 was increased in the centrilobular region of the liver. Western-blot analyses revealed that hepatic levels of CYP2E1 were increased 1.3–1.7-fold by nicotine. In-vitro analysis of the metabolism of chlorzoxazone (i.e. 6-hydroxylation) showed that V_{max} values were higher than those measured in saline-treated rats when hepatic microsomes from nicotine-treated rats were used (2.35 ± 0.04 versus 1.32 ± 0.55 nmol/mg/min, $p < 0.005$), with no change in affinity. The magnitude of the

enhancement of metabolism by microsomes from nicotine-treated animals is consistent with the observed increase in CYP2E1 protein as measured by immunoblot analysis. The data suggest that nicotine may increase CYP2E1-induced toxicity (Howard *et al*., 2001). Although not detectable in mouse lung, P4503A is induced by tobacco smoke in mouse liver (Villard *et al.*, 1994). Some investigations have reported conflicting results on the extent of phase I enzyme induction by tobacco smoke. For example, in one study, P4501A1 was induced in the liver of NMRI mice exposed to tobacco smoke (Villard *et al.*, 1994) whereas, in another study in the same laboratory, P4501A1 activity was either reduced or not detected in the liver of NMRI mice (Villard *et al.*, 1998b). These opposing results might be explained by the length of the exposure period: P4501A1 was induced in mice exposed to tobacco smoke for 4 or 8 days, and was reduced in mice exposed for 30 days. In one report on the effects of tobacco smoke on phase II enzyme activity in the tissues of mice exposed to tobacco smoke, UGT was induced in the lung and liver, but not in the kidney (Villard *et al.*, 1998a).

The induction of phase I and phase II enzymes in rats has been thoroughly investigated (Table 4.6). An early study demonstrated a three- to fourfold induction of Ahh in lung microsomes of Sprague-Dawley rats exposed daily to either mainstream or sidestream whole smoke for 16 weeks (Gairola, 1987). The magnitude of Ahh induction in animals exposed to mainstream and sidestream smoke was similar, although the dose of smoke particulates received from rats exposed to sidestream smoke was significantly less than the amount inhaled by the corresponding group exposed to mainstream smoke. In another study, Ahh was induced in both the lung and liver of Sprague-Dawley rats given intraperitoneal injections of condensates of mainstream and sidestream smoke. The induction of the enzyme in the lung exceeded that in the liver, and the sidestream-smoke condensate was a more effective inducer than the mainstream-smoke condensate. The activity of lung and liver NDMA demethylase was unaffected by treatment with either condensate (Pasquini *et al.*, 1987). Ethoxyresorufin *O*-deethylase (associated with P4501A1/2) activity was induced to a similar extent in both the lung and liver of Wistar rats after a single, short exposure to cigarette smoke (Godden *et al.*, 1987). In another study, Sprague-Dawley rats were exposed to mainstream smoke produced by a commercial filter-tipped cigarette for 8 consecutive days, amounting to a cumulative exposure to 75 cigarettes. The most pronounced changes in enzyme expression consisted of a 2.6-fold induction of Ahh in the lung and an eightfold induction of ethoxyresorufin *O*-deethylase in the liver (Bagnasco *et al.*, 1992). In addition to Ahh and ethoxyresorufin *O*-deethylase, other phase I enzymes that were induced by tobacco smoke in either the lung or liver of rats included aniline 4-hydroxylase, *para*-nitroanisole *O*-demethylase, and aminopyrine *N*-demethylase (Eke *et al.*, 1996). With the exception of aniline 4-hydroxylase, the inducibility of these enzymes in the lung and liver was similar in rats ranging in age from 20 days to 360 days. Aniline 4-hydroxylase was induced in the lung and liver of 20-day-old rats, but not in 360-day-old rats (Eke *et al.*, 1997). A more recent study in Fischer 344 rats reported on the inducibility by tobacco smoke of P4501A1, P4501A2 and P4502B1/2 in the nasal mucosa, lung and liver. Rats were exposed to mainstream cigarette smoke or

to filtered air for 2 or 8 weeks. The inducibility of the three enzymes varied significantly: P4501A1 levels were increased in all three tissues; P4501A2 was increased slightly in nasal mucosa and liver and decreased in lung; and P4502B1/2 was increased in liver and decreased in nasal mucosa and lung (Wardlaw *et al.*, 1998). These and other data suggest that the regulation of xenobiotic-metabolizing enzymes varies from one rodent tissue to another.

In a study of the effects of tobacco smoke on the activity of phase II enzymes in rat tissues, liver glutathione *S*-transferase (GST) activity with regard to ethacrynic acid was increased by tobacco smoke whereas that with regard to 1,2-epoxy-3-(*para*-nitrophenoxy)-propane was decreased (Eke *et al.*, 1996). Hepatic GST activities against 1-chloro-2,4-dinitrobenzene or 1,2-dichloro-4-nitrobenzene were unaltered. In the lung, however, the activity of GST against all substrates was decreased by tobacco smoke. These results indicate that the regulation of hepatic and pulmonary GSTs is differentially influenced by tobacco smoke. Cigarette smoke has the potential to depress severely the detoxification capacity of the lung.

The effects of tobacco smoke on the activities of the antioxidant enzymes catalase, superoxide dismutase, glutathione peroxidase and glutathione reductase in rat tissues have been investigated (Table 4.6). In one study in which Sprague-Dawley rats were exposed to mainstream cigarette smoke for 65 weeks, oxidative stress was increased whereas the activities of catalase and glutathione peroxidase in the lung were not significantly altered by exposure to smoke (Wurzel *et al.*, 1995). In another study, the activities of glutathione reductase and catalase were reported to be decreased in the kidney of rats exposed to tobacco smoke for 3 months, whereas the activity of glutathione peroxidase and lipid peroxide levels were increased. The excretion of glutathione and lipid peroxides in urine was also increased. The authors concluded that the reduced activity of glutathione reductase and the increased activity of glutathione peroxidase may perturb the ratio of reduced glutathione:oxidized glutathione, which in turn could lead to the increased levels of lipid peroxide in the kidney and urine seen in chronic exposure to tobacco smoke (Anand *et al.*, 1996). In a more recent study, the activities of catalase, superoxide dismutase and glutathione peroxidase were increased in the lung, liver and kidney of albino rats exposed to tobacco smoke for 2 × 15 min per day for 30 days. The activity of GST was also increased in the lung, liver and kidney. Interestingly, the activities of the antioxidant enzymes were unchanged in the brain and heart of the animals, but GST was increased in the brain. The authors concluded that tobacco smoke induces lipid peroxidation in the lung, liver and kidney, and the levels of the antioxidant enzymes are enhanced to protect these tissues against the deleterious effects of oxygen-derived free radicals (Baskaran *et al.*, 1999).

Nitric oxide synthase (Nos) catalyses the production of NO which, through its conversion to peroxynitrite, can cause damage to cellular macromolecules. The effects of tobacco smoke on *Nos* gene expression and protein production have been examined in the lung of rats exposed to tobacco smoke either once only or daily and killed after 1, 2, 7 or 28 days of exposure. *Nos1*, *Nos2* (inducible Nos (iNos)) and *Nos3* mRNAs in whole lung

were quantified using reverse transcription polymerase chain reaction, and Nos protein levels were determined by Western blotting. Neither *Nos1* gene expression nor protein levels were altered by exposure to tobacco smoke. Levels of *Nos2* expression were more than doubled in animals exposed to smoke on day 1 and had decreased to control values by 28 days, whereas protein levels did not change. *Nos3* expression was increased by approximately 35% after 2 days of exposure and remained at this level to 28 days, whereas protein levels were increased by approximately 60% at day 7 and remained elevated to 28 days. In-situ hybridization showed that *Nos2* was diffusely expressed in the lung parenchyma, airways and vessels, and that *Nos3* was strongly expressed in vascular endothelium. The authors concluded that tobacco smoke could directly and rapidly affect *Nos* expression, and thus potentially affect the function of the pulmonary vasculature (Wright *et al.*, 1999). In another study, the expression of Nos2, NF-κB, the mitogen-activated protein kinases Mek1 (mitogen-activated extracellular kinase 1) and Erk2 (extracellular signal-regulated kinase 2), phosphotyrosine protein and c-Fos was increased in the terminal bronchioles of rats exposed to gas-phase tobacco smoke in association with an increase in lipid peroxidation. In contrast, the levels of protein kinase C, Mekk1, Jnk, p38, c-Jun and c-Myc in the terminal bronchioles were unchanged. The authors concluded that exposure to tobacco smoke results in oxidative stress (NOx and ROS) that leads to the induction of Nos2 (iNos) and c-Fos together with the induction of transduction signalling proteins, protein tyrosine phosphorylation and Mek1/Erk2 which, in turn, may promote lung pathogenesis (Chang *et al.*, 2001).

The effects of tobacco smoke on enzyme activities have also been investigated to a limited extent in guinea-pigs. In contrast to the results obtained in mice and rats, daily exposure of Hartley strain guinea-pigs to either mainstream or sidestream tobacco smoke for 16 weeks did not result in an increase in Ahh activity in the lung (Gairola, 1987). In another study, however, tobacco smoke-induced emphysema in the lungs of guinea-pigs was associated with an increase in the activity of a proteolitic enzyme–collagenase activity in the alveolar walls and interstitium (Selman *et al.*, 1996).

(*b*) *Biomarkers of tobacco smoke carcinogens*

(i) *Urinary compounds*

Urinary compounds are useful markers of the uptake of tobacco smoke constituents (Hecht, 2002b). Most, if not all, of the compounds detected in the urine of human smokers have also been found in the urine of animals exposed to mainstream tobacco smoke. Since 1985, however, there have been relatively few reports of the identification and quantitation of urinary compounds in animals exposed to tobacco smoke (Table 4.7). Rats exposed to four dilutions of cigarette smoke over a period of 4 weeks had a lower output of hydroxyproline (relative to creatinine) for all dilutions of smoke and showed a negative dose–response relationship (Read & Thornton, 1985). *cis*-3′-Hydroxycotinine was detected as a nicotine metabolite in the urine of human smokers as well as in the urine of rats and hamsters dosed with nicotine. This was the first report of the identification of *cis*-

3′-hydroxycotinine as a urinary metabolite of nicotine (Voncken *et al.*, 1990). The compound 4-(methylnitrosamino)-4-(3-pyridyl)-butyric acid (*iso*-NNAC) was identified in the urine of rats exposed to tobacco smoke and in the urine of human smokers (Pachinger *et al.*, 1993).

(ii) *DNA adducts in animal tissues*

Mouse

There have been several reports of the detection of DNA adducts in tissues of mice exposed to tobacco smoke (Table 4.7). Synchronous fluorescence spectrophotometry was used to investigate the formation of the BPDE–DNA adducts in the lung and liver of genetically responsive C57BL/6 and non-responsive DBA/2 mice exposed to cigarette smoke for 3–16 days. Interestingly, BPDE–DNA adducts were not detected in the lung and liver of either mouse strain, although Ahh activity, an indicator of benzo[*a*]pyrene metabolism, was clearly induced in the lungs of C57BL/6 mice. Thus, there appeared to be no clear correlation between Ahh activity and the formation of BPDE–DNA adducts (Bjelogrlic *et al.*, 1989).

The effect of tobacco smoke on the formation of promutagenic O^6-methyldesoxyguanosine (O^6-MeG) adducts from the TSNA NNK, in the lungs and liver of A/J mice has been investigated. Mice were exposed to smoke generated from Kentucky 1R4F reference cigarettes at 0, 0.4, 0.6 or 0.8 mg wet total particulate matter per litre of air for 2 h, and a single intraperitoneal injection of NNK (0, 3.75 or 7.5 μmol/mouse) was administered midway through the exposure. Tobacco smoke alone did not yield detectable levels of O^6-MeG but NNK did form this adduct. The number of O^6-MeG adducts following intraperitoneal injection of NNK during cigarette smoke exposure was significantly ($p < 0.05$) reduced in both lung and liver. The same effect was seen in mice co-exposed to NNK and cotinine. The authors hypothesized that the reduction of O^6-MeG in liver and lung results from competitive inhibition by cotinine of the cytochrome P450 enzyme system for NNK activation (Brown *et al.*, 1999). The effect of exposure to tobacco smoke on the formation of DNA adducts in the lungs and heart of $B6C3F_1$ mice was determined using the ^{32}P-postlabelling assay. Mice were exposed for 1 h per day, 5 days per week for a period of 4 weeks to mainstream smoke at concentrations of 0, 0.16, 0.32 and 0.64 mg total particulate matter per litre of air. There was an exposure-dependent increase in the numbers of DNA adducts in lung and heart at all three concentrations; increases found in the mid- and high-exposure groups were significant ($p < 0.05$) (Brown *et al.*, 1997).

Mainstream-smoke condensate and sidestream-smoke condensate were applied topically to mouse skin, and DNA adducts were quantified in skin, lung, kidney, liver and bladder tissues by ^{32}P-postlabelling. Mainstream-smoke condensate produced higher levels of DNA adducts in mouse heart and bladder than sidestream-smoke condensate (but the difference was not statistically significant). However, sidestream-smoke condensate produced higher adduct levels in mouse skin, lung and kidney than mainstream smoke (Carmichael *et al.*, 1993).

Rat

The effect of mainstream tobacco smoke on the formation of DNA adducts in various tissues of rats has been investigated extensively by use of ^{32}P-postlabelling and SFS (Table 4.7). The formation of DNA adducts in the nasal cavity, lung and liver of Sprague-

Dawley rats exposed daily to fresh smoke from a University of Kentucky reference cigarette (2R1) for up to 40 weeks was examined by ^{32}P-postlabelling (Gupta *et al.*, 1989). The amount of total particulate matter inhaled with the smoke was 5–5.5 mg per animal per day. The average concentration of COHb in blood was 5.5%. Mainstream smoke induced at least four new DNA adducts in the nasal mucosa of rats and the amount of these adducts increased with length of exposure. In the lung, smoke induced an accumulation of one DNA adduct, which upon cessation of exposure for 19 weeks was reduced by about 75%. Smoke-related adducts were not detected in the liver. Selective chromatography and butanol extractability suggested that the DNA adducts in all tissues examined were aromatic and/or lipophilic. In a more recent study, Gupta *et al.* (1999) reported increases in the levels of DNA adducts in various tissues of Sprague-Dawley rats exposed to both mainstream and sidestream tobacco smoke, but not in liver. Mean total adduct levels in the various tissues ranked from heart > lung > trachea > larynx > bladder. Izzotti *et al.* (1995b) employed ^{32}P-postlabelling analysis to evaluate the effect of *N*-acetyl-L-cysteine (NAC) on the formation of carcinogen–DNA adducts in tracheal epithelial cells of Sprague-Dawley rats exposed (whole-body) to mainstream tobacco smoke for either 40 or 100 consecutive days. DNA adducts were observed after 40 days of exposure and no further increase was noted after 100 days. NAC, given by gavage in the 40-day study and in the drinking-water in the 100-day study, reduced the formation of smoke-related carcinogen–DNA adducts in the tracheal epithelium to the levels seen in sham-exposed control rats. These results indicate the considerable efficacy of oral NAC, a chemopreventive agent, in inhibiting the formation of smoke-related carcinogen–DNA adducts (Izzotti *et al.*, 1995b).

^{32}P-Postlabelling was also used to investigate the effects of exposure mode, sex and time (adduct persistence) on the level of DNA adducts in tissues of Fischer 344 rats (Bond *et al.*, 1989). Rats were exposed to tobacco smoke for 6 h per day, 5 days per week for 22 days by intermittent nose-only, continuous nose-only or continuous whole-body exposure. The animals were killed at either 18 h or 3 weeks after the 22-day exposure period and DNA adducts in lung tissues were quantified. Significant ($p < 0.05$) increases in the levels of DNA adducts were observed in both male and female rats exposed to tobacco smoke. No significant effects of exposure mode or sex on the induction of lung DNA adducts were observed. Significantly fewer clearly resolved DNA adducts were found in the lungs of rats killed 3 weeks after exposure, suggesting that smoke-induced adducts were repaired by DNA repair mechanisms. A single unidentified adduct accounted for about 20% of the total resolved lung DNA adducts and occurred at levels nine- to 14-fold higher than those in control animals (Bond *et al.*, 1989). It is not certain whether this adduct is the same one as that described in the lung of Sprague-Dawley rats by Gupta *et al.* (1989) or in the skin of mice by Randerath *et al.* (1986). Izzotti *et al.* (1998) used ^{32}P-postlabelling to investigate the effects of tobacco smoke and alcohol consumption on DNA adduct levels in the oesophagus, lung, liver and heart of BD6 rats. Groups of female rats were exposed to ethanol (5% in drinking-water for 8 consecutive months) and/or whole-body to mainstream tobacco smoke (1 h per day, 5 days per week for 8 months). As

expected, ingestion of alcohol alone did not affect the levels of DNA adducts in any of the four organs studied. Exposure to tobacco smoke induced formation of DNA adducts in the lung and heart, but not in the oesophagus or liver. Combined exposure to alcohol and smoke, however, resulted in the significant formation of smoke-related DNA adducts in the oesophagus and in a further increase in the number of adducts in the heart. Therefore, a likely interpretation is that ethanol may solubilize water-insoluble smoke components in the upper aerodigestive tract, thereby determining a first-pass effect in the oesophagus (Izzotti *et al.*, 1998). Another important mechanism may be the induction by ethanol of CYP2E1-dependent microsomal monooxygenases that catalyse the metabolism of a variety of xenobiotics (Tsutsumi *et al.*, 1993; Gonzalez & Gelboin, 1994).

The formation of smoke-related DNA adducts and their chemoprevention were investigated in tissues of Sprague-Dawley rats by SFS which, as mentioned above, can detect BPDE–DNA adducts (Izzotti *et al.*, 1992). Animals were exposed (whole-body) to mainstream cigarette smoke once daily for up to 40 consecutive days. No adduct was detected in liver DNA, whereas smoke-related DNA adducts were detectable in the lung from the day 8 of exposure and continued to increase until the study ended at day 40. The levels of adducts in heart DNA were even higher than those found in the lung. The daily administration of NAC by gavage significantly inhibited the occurrence of the same adducts in both heart and lung DNA, as measured by ^{32}P-postlabelling of DNA adducts in tracheal epithelial cells (Izzotti *et al.*, 1995b).

It is currently not clear why rats exposed to cigarette smoke form lung DNA adducts when previous studies have not demonstrated smoke-induced pulmonary carcinogenesis in rats. However, it is possible that the previous studies failed to demonstrate smoke-induced cancer because:

— a smaller dose of particulate matter was delivered per gram of lung tissue than in human heavy smokers;
— less than lifetime exposures were used; and
— the experimental groups used were too small in number (Bond *et al.*, 1989).

Interspecies comparison

^{32}P-Postlabelling has also been used to detect and quantify DNA adducts in the lung of guinea-pigs and mice exposed to mainstream and sidestream tobacco smoke. DNA adducts were identified in lung, but less DNA-adduct formation was seen in guinea-pigs than in either mice or rats at the same level of exposure to tobacco smoke (Gupta *et al.*, 1999).

(iii) *DNA damage in cultured human lung cells*

In cultured human lung cells, bubbling cigarette smoke through phosphate-buffered saline was found to induce DNA single-strand breaks and formation of 8-OHdG in DNA. Evidence was presented that this was mediated, in part, by the formation of reactive oxygen species (Leanderson, 1993). It was shown that cigarette tar promotes neutrophil-

induced DNA damage in cultured human lung cells and that this activity is further enhanced by iron and inhibited by catalase (Leanderson & Tagesson, 1994).

Treatment of human fetal lung cells with the TSNAs NNN and NNK caused single-strand breaks in DNA. Inhibition of this effect by oxygen radical scavengers suggested that the hydroxyl radical was an important intermediate in the process (Weitberg & Corvese, 1993).

DNA damage, as measured by the alkaline single-cell gel microelectrophoresis (Comet) assay, has also been shown to be induced in human embryo lung cells treated with water-soluble compounds from cigarette smoke (Wang, Q. *et al.*, 2000).

Treatment of tracheobronchial epithelial cells with gas-phase cigarette smoke caused DNA strand breakage that was accompanied by increases in the levels of a number of DNA lesions, including 8-OHdG, xanthine and hypoxanthine. These latter lesions can arise from the deamination of guanine and adenine by a mechanism involving reactive nitrogen species. Thus, DNA damage induced by cigarette smoking may be mediated by both reactive oxygen species and reactive nitrogen species (Spencer *et al.*, 1995).

(*c*) *Other data*

(i) *Effects on particle clearance*

Cigarette smoking induces a variety of carcinogenic and non-carcinogenic effects in humans and laboratory animals. An issue of concern is the extent to which smoking might influence pulmonary responses to other inhaled toxic materials. This influence can take the form of a direct alteration of the deposition or clearance of another inhaled agent. For example, it has been reported that cigarette smoking delays the pulmonary clearance of inhaled, insoluble particles in humans (Bohning *et al.*, 1982) and in laboratory animals (Mauderly *et al.*, 1989).

Finch *et al.* (1995) investigated the influence of cigarette smoke exposure of Fischer 344 rats on the pulmonary clearance of inhaled, relatively insoluble radioactive tracer particles. Following 13 weeks of whole-body exposure to air or mainstream tobacco smoke for 6 h per day, 5 days per week at concentrations of 0, 100 or 250 mg/m^3 total particulate matter, rats were acutely exposed pernasally to ^{85}Sr-labelled fused aluminosilicate (^{85}Sr-FAP) tracer particles; exposure to air or smoke was then resumed. A decreased clearance of ^{85}Sr-FAP from the lungs, which was smoke concentration-dependent, was observed. By 180 days after exposure to the tracer aerosol, about 14, 20 and 40% of the initial activity of the tracer was detected in the control, 100-mg/m^3 and 250-mg/m^3 groups, respectively. Exposure to mainstream smoke produced lung lesions that contained increased numbers of pigmented alveolar macrophages throughout the parenchyma, and focal collections of enlarged alveolar macrophages with concomitant alveolar hyperplasia. The severity of lesions increased with duration of exposure. These data confirm previous findings that exposure to cigarette smoke decreases the ability of the lung to clear inhaled materials. In a subsequent publication, Finch *et al.* (1998) reported that chronic exposure to cigarette smoke containing 100 or 250 mg/m^3 total particulate matter increased the pulmonary

retention and radiation dose of ^{239}plutonium inhaled as $^{239}PuO_2$ in two groups of Fischer 344 rats. Assuming a linear dose–response relationship between radiation dose and the incidence of lung neoplasms, the exposure to $^{239}PuO_2$ was predicted to increase the incidence of lung tumours relative to that in controls by 20% or 80%, depending upon the concentration of total particulate matter in smoke.

(ii) *Carboxyhaemoglobin*

There have been several reports on the relationship between levels of exposure to carbon monoxide from tobacco smoke and levels of COHb adducts in the blood of animals. For example, Attolini *et al.* (1996) exposed male NMRI mice to tobacco smoke for 2, 4, 8 or 31 days. The levels of COHb in blood increased significantly after 4 or 8 days of exposure and decreased after 31 days to a level which remained higher than the level of the controls. Two hypotheses were proposed to explain the decrease in COHb levels at 31 days.

(1) The mice may develop a state of tolerance against compounds in tobacco smoke: the increase in respiratory rhythm leads to hyperventilation and to a concomitant decrease in the quantity of CO fixed to haemoglobin.

(2) Chronic exposure to tobacco smoke increases the thickness of the airway epithelium and alveolar septae, as well as mucus hypersecretion and ciliostasis, which increases the barrier to smoke constituents, reducing their accessibility to the blood circulation and therefore decreasing the level of CO fixed to haemoglobin.

Loennechen *et al.* (1999) exposed Sprague-Dawley rats to CO at 100 ppm for 1 week or to 100 ppm CO for 1 week followed by 200 ppm for 1 week. The formation of COHb was found to be dependent upon the amount of CO exposure; COHb was approximately 13% in the group exposed to the low level of CO and 23% in the group exposed to the higher level. Exposure to a high level of CO increased the expression of endothelin-1 mRNA by more than 50% in both the left and right ventricles of the heart. The authors concluded that chronic exposure to CO leading to COHb levels similar to those observed in smokers increases endothelin-1 gene expression and induces myocardial hypertrophy in the rat.

4.2 Toxic effects

4.2.1 *Humans*

(*a*) *Nicotine addiction*

Cigarette smoking is the single largest avoidable cause of premature death and disability. Many smokers express a desire to stop smoking, and many have made one or more unsuccessful attempts to quit, supporting the evidence that tobacco smoking is addictive. Research has been focused on nicotine because it is the most addictive constituent of tobacco products (see also Section 4.1.1(*c*)(vi)). Therefore, cigarette smoking should be understood as a manifestation of nicotine addiction. This topic has been extensively

reviewed (Benowitz, 1988; US Department of Health and Human Services, 1988; Moxham, 2000).

Nicotine is an addictive drug and smoking of tobacco rapidly delivers a dose of nicotine to receptors in the brain. The effects on the central nervous system are more important than those on the peripheral nervous system (Le Houezec & Benowitz, 1991). With repeated experience, consolidation into physiological and psychological addiction is reinforced by pronounced withdrawal symptoms.

To achieve a psychoactive impact, nicotine must be delivered rapidly to the brain which is best achieved by inhalation of tobacco smoke. The speed of nicotine delivery is a fundamental difference between cigarettes and products aimed at nicotine replacement. The nicotine-replacement products deliver nicotine at lower, subaddictive rates and are only effective in reducing cravings and withdrawal symptoms from tobacco-delivered nicotine dependence.

It is far from clear that the benefits attributed to nicotine use, such as stress relief, improved mood and enhanced cognitive performance, are real. Many of the perceived benefits are actually attributable to the relief of nicotine withdrawal symptoms (Le Houezec & Benowitz, 1991).

The addictive properties of nicotine imply that analytical measurements of tar and nicotine yields from cigarettes do not reflect the true exposure to tar and nicotine experienced by smokers. Smokers adjust the way they smoke in order to self-administer a satisfactory dose of nicotine (Benowitz, 1995).

(*b*) *Health effects other than cancer*

Besides its carcinogenic effects, tobacco smoke has a number of other pathogenic properties. Causal associations have been established between active smoking and a number of specific diseases.

(i) *Effects on the cardiovascular system*

Cigarette smoking is a major independent risk factor for coronary heart disease and the most important risk factor for atherosclerotic peripheral vascular disease. There is a dose–response relationship between cigarette smoking and cardiovascular disease: the risk increases with the number of cigarettes smoked daily, the total number of years for which a person has smoked, the degree of inhalation and earlier age of initiation of the smoking habit. Cigarette smoking has been found to elevate significantly the risk for sudden death (US Department of Health and Human Services, 1983, 1989). Cigarette smoking accounts for about half of deaths from coronary disease in women during middle age. It has been shown that premenopausal women have lower rates of heart disease than postmenopausal women. This protection is presumed to be provided by the presence of circulating estrogens, but it is unknown whether estrogens have the same protective effect in women who smoke (Villablanca *et al.*, 2000). A synergistic effect between smoking and the use of oral contraceptives has also been reported (US Department of Health and Human Services, 1983). In female smokers who take oral contraceptives, particularly

those over the age of 35 years, there is a well-established increase in risk of myocardial infarction and cerebrovascular disease (Villablanca *et al.*, 2000).

Cigarettes that nominally deliver less tar or nicotine have not consistently been shown to reduce the risk of cardiovascular disease (reviewed by Burns *et al.*, 2001).

(ii) *Effects on the cerebrovascular system*

Cigarette smoking is a major cause of cerebrovascular disease (ischaemic stroke). It is estimated that as many as 25% of all strokes can be attributed to smoking. The relative risk of stroke is similar in male and female smokers and is maximal near middle age (Hankey, 1999). Although nicotine has strong and potentially harmful effects on cerebral and peripheral vascular tissues, it is not certain whether and how these effects are related to stroke (Hawkins *et al.*, 2002).

(iii) *Effects on the respiratory system*

Cigarette smoking is the most important cause of cough, sputum production, chronic bronchitis and asthma (Hargreave & Leigh, 1999; Maestrelli *et al.*, 2001; Ulrik & Lange, 2001). It increases the risk for dying from chronic bronchitis and pulmonary emphysema (US Department of Health and Human Services, 1984; Aubry *et al.*, 2000; Seagrave, 2000; Fraig *et al.*, 2002).

(iv) *Gastrointestinal effects*

Smoking increases the risk for peptic ulcer and mortality from this disease (Ma *et al.*, 1998). It delays peptic ulcer healing and increases the risk of recurrence after healing (Ashley, 1997). Nicotine has been shown to potentiate aggressive gastric factors and to attenuate defensive ones; it also increases acid and pepsin secretions, gastric motility, duodenogastric reflux of bile salts, the risk of *Helicobacter pylori* infection, levels of free radicals and platelet-activating factor, endothelium generation and vasopressin secretion (Endoh & Leung, 1994). Although the mechanisms by which smoking or nicotine adversely affect the gastric mucosa have not been fully elucidated, the available evidence supports the hypothesis that nicotine is harmful to the gastric mucosa (Endoh & Leung, 1994). Smoking is also a risk factor for Crohn disease in both men and women, but the excess risk is higher among female smokers. There is growing evidence that smoking is inversely related to ulcerative colitis (Westman *et al.*, 1995; Rubin & Hanauer, 2000) and some evidence that it is a risk factor for gallstones (Ashley, 1997).

(v) *Neurological disorders*

The relationship between smoking and some neurological diseases has been controversial. A number of epidemiological studies have found a significant, negative association between cigarette smoking and Parkinson or Alzheimer disease, the risk among nonsmokers being approximately twice that of smokers (Fratiglioni & Wang, 2000). However, whereas a community-based longitudinal study of elderly people found a higher risk of Alzheimer disease in smokers than in nonsmokers (Merchant *et al.*, 1999),

an analysis based on a comparison of persons with Alzheimer dementia with their unaffected siblings suggests that smoking does not decrease the risk for the disease (Debanne *et al.*, 2000). Both retrospective and prospective epidemiological studies have demonstrated an inverse association between cigarette smoking and Parkinson disease, leading to theories that smoking and nicotine may be neuroprotective. Coffee and caffeine consumption have been reported to have a similar effect (Ross & Petrovitch, 2001; Hernan *et al.*, 2002).

(vi) *Other inverse associations of smoking with health effects*

Some studies suggest that there may be inverse associations of smoking with uterine fibroids and endometriosis, and protective effects against hypertensive disorders and vomiting during pregnancy are likely. Inverse associations of smoking with venous thrombosis after myocardial infarction are probably not causal, but indications of positive effects with regard to recurrent aphthous ulcers and control of body weight may reflect a genuine benefit. A variety of mechanisms for the potentially beneficial effects of smoking have been proposed; of these three predominate:

— the anti-estrogenic effect of smoking;
— alterations in prostaglandin production; and
— stimulation of nicotinic cholinergic receptors in the central nervous system.

It should be noted that even established inverse associations cannot be used as a rationale to encourage cigarette smoking because overall effects on health and mortality are clearly negative (Baron, 1996).

4.2.2 *Animals*

(*a*) *Nicotine addiction/dependence*

(i) *Studies with animal models*

Various animal models have been described that mimic nicotine dependence and withdrawal syndromes. In one such model, dependence is induced in rats by continuous subcutaneous infusion of nicotine (3 or 9 mg/kg bw per day as nicotine hydrogen tartrate) over 7 days by the use of implanted osmotic minipumps. The nicotine is absorbed quickly and almost completely. Abstinence is initiated through termination of infusion or by injection of nicotine antagonists. The resulting abstinence syndrome involves a pattern of behaviour somewhat resembling opiate abstinence, with weight gain and reduced locomotor activity. The model has been replicated in a number of laboratories. It is sensitive to various abstinence-alleviating therapeutic approaches, such as nicotine replacement and the administration of nitric oxide synthase inhibitors and serotonergic compounds. A strong reduction of abstinence symptoms was seen with bupropion and acetyl-L-carnitine, both of which are used clinically as part of smoking cessation regimens (Malin, 2001).

Nicotine has also been given orally to experimental animals either in liquid diets or in drinking fluids, or by forced oral administration (rats show an aversion to the taste of nicotine). When nicotine is given orally, it is absorbed slowly by the gastrointestinal tract and

the concentrations in blood remain considerably lower than those observed after subcutaneous infusion (Le Houezec *et al.*, 1989).

In another experimental model, mice were given drinking-water containing gradually increasing concentrations (50–500 μg/mL) of nicotine for 7 weeks. After replacement of the nicotine solutions with tap-water, a significantly higher fluid intake was seen in the nicotine-treated mice than in control animals, but this effect disappeared within 1 week. Plasma nicotine concentrations in the treated mice were found to be similar to those reported in heavy smokers. The results of a pharmacological study with this mouse model suggested that the effects of nicotine in striatal dopamine metabolism are critical for its stimulating and reinforcing effects (Pietilä & Ahtee, 2000).

(ii) *Studies with genetically modified mice*

Numerous studies have shown that nicotine is likely to be responsible for the addictive properties of tobacco. In addition, nicotine has effects on locomotion, cognition, affect and sensitivity to pain. In recent studies with transgenic mice, molecular biology has been combined with pharmacology, electrophysiology and behavioural analysis to elucidate the specific role of nicotine in these phenomena. The physiological effects of nicotine are mediated by binding to and activation of nicotine acetylcholine receptors. These receptors are pentamers made up of subunits with distinct expression patterns in different neurons. More than 10 different neuronal receptor subunits have been identified, and for seven of these subunits, knock-out mice lacking one receptor subunit have been constructed. These mice are being used in studies to identify the receptor subtypes responsible for the different effects of nicotine. As an example, nicotine self-administration is abolished in mice lacking the β2 subunit of the receptor, which implies that this subunit is a component of the receptor that mediates nicotine reinforcement (Marubio & Changeux, 2000; Picciotto *et al.*, 2000).

(*b*) *Other effects in experimental animals*

(i) *Effects on the cardiovascular system*

To determine whether chronic exposure to tobacco smoke for less than 2 months alters cardiovascular regulation, male Sprague-Dawley rats were exposed to tobacco smoke from low-nicotine cigarettes (1 mg/cigarette) for 4–6 weeks, and a second group served as sham controls receiving only puffs of room air. Reflex adjustments in mean arterial blood pressure after bilateral common carotid occlusion were compared between the two groups. In the anaesthetized control state, there was no significant difference between the cardiovascular parameters measured in the two groups. However, the increase in mean arterial blood pressure after carotid occlusion was significantly greater in the smoke-treated than in the control animals ($p < 0.05$). In addition, the time required to reach maximum arterial blood pressure after carotid occlusion was significantly less ($p < 0.05$) for the smoke-treated animals (8.5 ± 0.2 s) than in the controls (11.2 ± 0.3 s). The results show that chronic exposure to tobacco smoke in experimental animals for periods

as short as 4–6 weeks alters the reflex regulation of the cardiovascular system (Bennett & Richardson, 1990).

To determine whether exposure to sidestream cigarette smoke promotes atherogenesis in a mouse model of human atherosclerosis, female ApoE-deficient mice, fed a western diet, were exposed to sidestream smoke in a whole-body exposure chamber for a total of 6 h/day, 5 days per week, for 7, 10 and 14 weeks. Animals exposed to filtered ambient air served as controls. Elevated concentrations of blood COHb and pulmonary CYP1A1 were indicative of effective exposure. There were no consistent changes in serum concentrations of cholesterol between control and exposed mice. Morphometric assessment of grossly discernible lesions covering the intimal area of the aorta showed remarkable increases in exposed mice, at all three durations of exposure studied. Increases in the area of the lesion were accompanied by higher levels of esterified and unesterified cholesterol in the aortic tissues of exposed mice. The results clearly demonstrate promotion of the development of atherosclerotic lesions by tobacco smoke in an atherosclerosis-susceptible mouse model (Gairola *et al*., 2001).

(ii) *Effects on the cerebrovascular system*

Initial investigations with a rat model of nicotine exposure in adolescents have demonstrated that the vulnerable developmental period for nicotine-induced brain cell damage extends into adolescence. The effect of nicotine on cholinergic systems in adolescent male and female rats was investigated with a nicotine-infusion protocol designed to produce nicotine plasma concentrations similar to those measured in human smokers or in users of transdermal nicotine patches. Choline acetyltransferase activity (ChAT), a static marker that closely reflects the density of cholinergic innervation, and binding of [^{3}H]hemicholinium-3 (HC-3), which labels the presynaptic high-affinity choline transporter, were monitored in the midbrain (the region most closely involved in reward and addiction pathways), as well as in the cerebral cortex and hippocampus. During nicotine treatment and for 1 month after termination of treatment, ChAT activity was significantly reduced and HC-3 binding was significantly increased in the midbrain, but not in the other regions. The levels returned to normal immediately after cessation of nicotine exposure and subsequently showed a transient suppression of activity. Although the cerebral cortex showed little or no change in HC-3 binding during or after nicotine administration, activity was persistently reduced in the hippocampus. The regionally selective effects of nicotine treatment of adolescent rats on cholinergic systems support the concept that adolescence is a vulnerable developmental period for determining ultimate effects on behaviour (Trauth *et al*., 2000).

(iii) *Effects on the respiratory system*

To study the role of transforming growth factor-β1 (TGF-β1) in the pathogenesis of chronic bronchitis and emphysema, an animal model was used in which hamsters were exposed by chronic inhalation of cigarette smoke. The expression of TGF-β1 mRNA and protein in the pulmonary tissue was measured. In a parallel experiment, bronchial epi-

thelium was stimulated with cigarette smoke extract *in vitro* and the expression of TGF-β1 was determined. After 3 months of exposure, the animals developed chronic bronchitis and emphysema. The increase in TGF-β1 immunoreactivity in the pulmonary tissue and in the cultured bronchial epithelial cells was significantly higher than in the controls ($p = 0.001$). The expression of TGF-β1 mRNA was also increased in the pulmonary tissue of exposed animals. The results indicate that exposure to cigarette smoke can induce over-expression of TGF-β1 in bronchial epithelia; this may be one of the mechanisms for smoking-induced chronic bronchitis and emphysema (Li *et al*., 2002).

To assess induction of emphysema in the rodent lung, $B6C3F_1$ mice and Fischer 344 rats were exposed, whole-body, to cigarette smoke at a concentration of 250 mg/m^3 total particulate matter for 6 h per day, 5 days per week, for either 7 or 13 months. Morphometry included measurements of parenchymal air-space enlargement and tissue loss. In addition, centriacinar intra-alveolar inflammatory cells were counted to assess species differences in the type of inflammatory response associated with the exposure. In mice, significant differences in many of the morphometric parameters indicating emphysema were noted between smoke-exposed and control animals. In rats exposed to cigarette smoke, only some of the parameters differed significantly from control values. Morphological evidence of tissue destruction in the mice included alveoli that were irregular in size and shape and alveoli with multiple foci of septal discontinuities and isolated septal fragments. There were more morphometric anomalies in the mice at 13 months than at 7 months, suggesting a progression of the disease. Inflammatory lesions in the lungs of mice contained significantly more neutrophils than these lesions in rats. These results suggest that $B6C3F_1$ mice are more susceptible than Fischer 344 rats to the induction of emphysema by this exposure regimen and that the emphysema may be progressive in mice. Furthermore, the type of inflammatory response may be a determining factor for species differences in susceptibility to the induction of emphysema by exposure to cigarette smoke (March *et al.*, 1999).

The hypothesis was tested that variations in α1-antitrypsin expression modulate the pattern of emphysema and functional consequences in mice exposed to cigarette smoke. The effects of cigarette smoke were investigated in C57BL/6J (C57) mice and in low-α1-antitrypsin, C57BL/6J pa^+/pa^+ (pallid) mice. After 4 months of exposure, a significant increase in the extent of emphysema was seen in pallid mice, but not in C57 mice. After 6 months, mechanical properties of lung, the extent and type of emphysema, and the cellular inflammatory response were measured. C57 mice and pallid mice had similar degrees of emphysema, whereas pallid mice, but not C57 mice, had developed a T-cell inflammation in the alveolar wall ($p < 0.01$). Although lung compliance was not changed in C57 mice after exposure to smoke, it increased significantly in pallid mice over the 6 months of exposure ($p < 0.0082$). In summary, exposure to cigarette smoke induced emphysema in C57 and pallid mice, but the emphysema, inflammatory infiltrate and the resulting physiological abnormalities were substantially different in the two strains, with the C57 and pallid mice exhibiting features similar to centrilobular and panlobular emphysema, respectively (Takubo *et al*., 2002).

To determine whether smoking affects the clearance of asbestos fibres, guinea-pigs were given amosite asbestos by intratracheal instillation. They were divided into groups that received (a) no further treatment, (b) were exposed to tobacco smoke after asbestos instillation, or (c) were exposed to smoke both before and after asbestos instillation. The numbers and sizes of the asbestos fibres were measured in respiratory tract tissue and in lavage samples at 1 week and 1 month after exposure. During this time, the asbestos burden in the first group decreased sixfold on average, whereas no significant decrease was seen in either of the smoke-exposed groups. The mean length of retained fibres increased in the first group (asbestos only), but decreased in both the smoke-exposed groups. This phenomenon was seen in tissue samples and lavage samples, although the fibres in the lavage fluid were consistently shorter than those in tissue. The authors concluded that, in this model, cigarette smoking impeded asbestos clearance, largely by increasing retention of short fibres. This increased pulmonary fibre burden may be important in the increased rate of parenchymal fibrosis and carcinoma of the lung seen in asbestos workers who smoke (McFadden *et al*., 1986).

(iv) *Neurological disorders*

In view of the suggested inverse relationship in humans between cigarette smoking and the risk for Parkinson and Alzheimer disease, which are both characterized by enhanced oxidative stress, the antioxidant potential of nicotine was investigated in rats. Initial chromatographic studies suggested that nicotine can affect the formation of the neurotoxin 6-hydroxydopamine resulting from the addition of dopamine to Fenton's reagent (i.e. Fe^{2+} and hydrogen peroxide). Under certain circumstances, nicotine can strongly affect the course of the Fenton reaction. In in-vivo studies, adult male rats treated with nicotine showed greater memory retention than controls in a water-maze task. However, neurochemical analysis of neocortex, hippocampus and neostriatum from these animals revealed that nicotine had no effect on the formation of reactive oxygen species or on lipid peroxidation in any brain region studied. In an in-vitro study with rat neocortical homogenates, there were no differences in lipid peroxidation between nicotine-treated rats and controls. The results of these studies suggest that the beneficial/protective effects of nicotine in both Parkinson disease and Alzheimer disease may result, at least partly, from antioxidant mechanisms (Linert *et al*., 1999).

The effects of nicotine on the central nervous system are mediated by the activation of neuronal heteromeric acetylcholine-gated ion channel receptors (also termed nicotinic acetylcholine receptors). The neuroprotective effects of nicotine were studied in two animal models of parkinsonism: diethyldithiocarbamate-induced enhancement of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine toxicity in mice and methamphetamine-induced neurotoxicity in rats and mice. The neuroprotective effect of nicotine was very similar to that of the non-competitive *N*-methyl-D-aspartate receptor antagonist, MK-801. In parallel experiments, nicotine was shown to induce the basic fibroblast growth factor-2 (FGF-2) and the brain-derived neurotrophic factor in rat striatum. The effect on the induction of FGF-2 was prevented by the nicotinic acetylcholine receptor antagonist,

mecamylamine, whereas MK-801 induced FGF-2 in the striatum. As trophic factors have been reported to be neuroprotective for dopaminergic cells, these data suggest that the increase in neurotrophic factors is a possible mechanism by which nicotine provides protection from experimental parkinsonism (Maggio *et al*., 1998).

(v) *Effects on the immune system*

Five groups of 2-month-old male Syrian golden hamsters were exposed to cigarette smoke for three 10-min periods per day, on 5 days per week, for the duration of their lives. Three of the groups were also chronically exposed to aerosols of chrysotile asbestos, cobalt oxide or nickel oxides. The fourth group was exposed to smoke and sham dust and was compared with the control group exposed to sham smoke and sham dust. The fifth group received 12 weekly injections of 0.25 mg of *N*-nitrosodiethylamine. Each cigarette smoke-exposed group was compared with the group exposed to sham smoke and the respective aerosol treatment. The cigarette smoke-exposed groups lived significantly ($p < 0.01$) longer than the sham-exposed groups and the untreated controls. Their mean body weights were significantly ($p < 0.01$) lower than those of the sham-exposed groups. The delayed onset of amyloidosis and the lower body weight in the smoke-exposed hamsters may have been responsible for their increased lifespans. The results suggest that cigarette smoke affects the immune system of the animals, resulting in retardation of amyloidosis, a frequent cause of death in hamsters (Wehner *et al*., 1976).

In rats, chronic inhalation of cigarette smoke preferentially inhibited the plaque-forming cell response of lung-associated lymph nodes (LALN) to sheep erythrocytes rather than anatomically distant lymph nodes. Inhibition of the antibody response in LALN of smoke-exposed animals was first detected after 21 weeks of smoke inhalation and was well established by the 27th week of exposure to smoke. After prolonged exposure (> 34 weeks) to cigarette smoke, similar changes in the plaque-forming cell response were also observed in other lymphoid tissues. Cigarette smoke affected the response of LALN cells to sheep erythrocytes, a T cell-dependent antigen, but did not alter the relative percentages of W3/13-positive (T cells) or Ig-positive (B cells) cells, or those of T-cell subsets as scored by their surface phenotypes, i.e. T helper ($W3/25^+$) or T suppressor/cytotoxic ($OX\text{-}8^+$) cells. The percentage of phagocytic cells and the accessory cell functions of macrophages remained comparable between sham-exposed and smoke-exposed animals. Exposure to cigarette smoke did not significantly alter the response of LALN cells to T-cell mitogens (concanavalin A and phytohaemagglutinin). However, response to trinitrophenyl *Brucella abortus*, a T-cell-independent antigen, was also significantly reduced. The results show that exposure to cigarette smoke results in a decreased antibody response in the rat, primarily affecting the B-cell function (Sopori *et al.*, 1989).

Chronic exposure of mice and rats to cigarette smoke affects T-cell responsiveness which may account for the decreased T-cell proliferative and T-dependent antibody responses in humans and animals exposed to cigarette smoke. However, the mechanism by which cigarette smoke affects the T-cell function is not clearly understood. Chronic exposure of rats to nicotine has been shown to inhibit the antibody-forming cell response,

to impair the antigen-mediated signalling in T cells and to induce T-cell anergy. To study cigarette smoke-induced immunosuppression and to compare it with the effects of chronic nicotine exposure, rats were exposed to diluted, mainstream cigarette smoke for up to 30 months or to nicotine (1 mg/kg bw per day) by osmotic minipumps for 4 weeks, and were evaluated for immunological function *in vivo* and *in vitro*. The T cells from rats subjected to long-term exposure to cigarette smoke showed decreased antigen-mediated proliferation and constitutive activation of protein tyrosine kinase and phospholipase C-γ1 activities. Moreover, spleen cells from smoke-exposed and nicotine-treated animals had depleted inositol-1,4,5-trisphosphate-sensitive Ca^{2+} stores and a decreased ability to raise intracellular Ca^{2+} concentrations in response to T-cell antigen receptor ligation. The results suggest that chronic smoking causes T-cell anergy by impairing the antigen receptor-mediated signal transduction pathways and depleting the inositol-1,4,5-trisphosphate-sensitive Ca^{2+} stores. Moreover, nicotine may be responsible for or contribute to the immunosuppressive properties of cigarette smoke (Kalra *et al*., 2000).

(vi) *Toxic effects of kreteks*

Kreteks are a type of small cigarette containing approximately 60% tobacco and 40% ground clove buds (Stratton *et al.*, 2001). The typical chemical composition of mainstream smoke per kretek is total particulate matter, 52.3 mg; nicotine, 2.4 mg; and CO, 23.7 mg. In the several inhalation studies that have looked specifically at exposure of rats and hamsters to kreteks smoke, few signs of toxicity (focal alveolitis, bronchiolar epithelial hyperplasia, alveolar haemorrhage) were observed after 1 or 14 days' exposure (LaVoie *et al.*, 1986; Clark, 1989, 1990), but the routes and methods of exposure used do not replicate human exposure (Guidotti, 1989).

4.3 Reproductive and hormonal effects

4.3.1 *Humans*

(*a*) *Reproductive effects*

Cigarette smoking has clearly been associated with a wide range of adverse effects on reproduction, some of which may have implications for cancer risk.

(i) *Effects on female fertility*

Women who smoke cigarettes have an increased risk for both primary and secondary infertility, with an odds ratio of 1.6 (95% CI, 1.3–1.9) (Augood *et al.*, 1998 (meta-analysis of 12 studies); US Department of Health and Human Services, 2001). The resulting decrease in parity could have implications for risk for cancers of the breast, endometrium and ovary. There is also evidence that women who smoke cigarettes are more likely to be subfertile, and to take longer to get pregnant than women who do not smoke (Baird, 1992; Hughes & Brennan, 1996; Jensen *et al.*, 1998, Hull *et al.*, 2000; US Department of Health and Human Services, 2001).

(ii) *Effects on pregnancy*

The use of tobacco products by pregnant women is associated with placenta praevia, placental abruption, premature rupture of membranes, pre-term birth, intrauterine growth restriction and sudden infant death syndrome (Castles *et al.*, 1999; Andres & Day, 2000; US Department of Health and Human Services, 2001). The association between smoking and pre-term delivery appears to be more pronounced for older women (US Department of Health and Human Services, 2001). There is also a relatively modest increase in the risk for spontaneous abortion and stillbirth among women who smoke during pregnancy (Windham *et al.*, 1999). Smoking may be responsible for 15% of all pre-term births, 20–30% of all infants of low birth weight, and for a 1.5-fold increase in overall perinatal mortality (Andres & Day, 2000).

Women who smoke cigarettes during pregnancy have been observed to have a decreased risk for various pregnancy-related disorders, including hypertension of pregnancy and pre-eclampsia, even after control for relevant covariates (Castles *et al.*, 1999; US Department of Health and Human Services, 2001).

Pre-eclampsia is caused by damage to the placenta and develops in the second half of pregnancy, usually in the last few weeks, or immediately after delivery. Initially, the main symptoms are raised blood pressure and the presence of protein in the urine of the mother, and a slower-than-normal growth of the unborn child. In rare cases, women can go on to develop fits, known in pregnancy as eclampsia. Cigarette smoking has been associated with a lower rate of pre-eclampsia among women who were pregnant for the first time, independent of other maternal factors (Newman *et al.*, 2001). For pre-eclampsia, however, dose–response relationships have not regularly been found (US Department of Health and Human Services, 2001). The limited data available regarding the association between cigarette smoking and the risk of eclampsia are mixed (US Department of Health and Human Services, 2001).

(iii) *Effects on menopause*

Cigarette smoking has repeatedly been found to be associated with an earlier menopause. Current female smokers are about twice as likely to reach menopause at an earlier age as nonsmokers; the relative risk increases with the average number of cigarettes smoked. When the effect is expressed as a difference in the median (or mean) age at menopause, women who smoke reach menopause about 0.8 to 1.7 years earlier than never-smokers, again with a greater effect among heavier smokers. Women who have stopped smoking reach menopause at an age similar to that of never-smokers, or somewhat later (Midgette & Baron, 1990; US Department of Health and Human Services, 2001).

The association between smoking and earlier age-at-menopause has been very consistently found in studies from Asia (Kato *et al.*, 1988), northern Europe (Andersen *et al.*, 1982; Luoto *et al.*, 1994; Torgerson *et al.*, 1994), southern Europe (Parazzini *et al.*, 1992; Meschia *et al.*, 2000) and the USA (Jick *et al.*, 1977). Studies using various designs have reported this association, including cross-sectional surveys of patient populations (Jick

et al., 1977), population-based surveys (Andersen *et al.*, 1982; McKinlay *et al.*, 1985; Luoto *et al.*, 1994; Gold *et al.*, 2001), retrospective cohort studies (Kaufman *et al.*, 1980) or prospective cohort studies (Willett *et al.*, 1983; Bromberger *et al.*, 1997; Kato *et al.*, 1998). In a study from Nigeria, the effect of smoking on age-at-menopause could not be demonstrated because of the small numbers of female smokers in that country, where smoking by women is a social taboo (Okonofua *et al.*, 1990).

The mechanisms underlying this association are not entirely clear. However, at least in animals, the PAHs contained in cigarette smoke are toxic to ovarian follicles (Mattison & Thorgeirsson, 1978) and the human ovary probably contains the microsomal mono-oxygenases required to convert toxic chemicals into reactive species that affect oocytes. Smoking has been implicated in the increased rate of follicular atresia in women (Matisson, 1982). The higher concentrations of follicle-stimulating hormone in premenopausal smokers than in premenopausal nonsmokers are consistent with ovarian toxicity (Velasco *et al.*, 1990; Cooper *et al.*, 1995; Cooper & Thorp, 1999; Cramer *et al.*, 2002). The occurrence of a diminished ovarian reserve is significantly higher among women who smoke, as was shown in studies of infertile women undergoing assisted reproduction (Sharara *et al.*, 1994; El-Nemr *et al.*, 1998). Premenopausal women who smoke may have fewer ovarian follicles than nonsmokers (Westhoff *et al.*, 2000), although the data are conflicting. One study reported that smoking is associated with smaller ovarian volume (Syrop *et al.*, 1995), whereas another failed to demonstrate this association (Flaws *et al.*, 2000).

(iv) *Effects on male reproductive potential*

Cigarette smoking has repeatedly been associated with modest reductions in sperm density, motility and morphology (Vine *et al.*, 1994; Wong *et al.*, 2000). It has also been associated with increases in the levels of estrone, estradiol, testosterone and free testosterone in serum (Vine, 1996; Trummer *et al.*, 2002). This effect may be mediated in part by constituents of seminal plasma. In one study, exposure of spermatozoa from nonsmokers to seminal plasma from smokers was associated with decreased viability. On the other hand, when spermatozoa from smokers were incubated in seminal plasma from nonsmokers, an improvement in the quality of semen was seen (Zavos *et al.*, 1998). Despite the relatively clear effects of smoking on sperm parameters and the possible delay in conception, smoking by the male partner has not been found to have a consistent impact on fertility (Bolumar *et al.*, 1996; Curtis *et al.*, 1997; Hull *et al.*, 2000).

(*b*) *Hormonal effects*

(i) *Sex hormones*

Estrogens

Smoking is thought to exert an ‘antiestrogenic’ effect in women (Baron *et al.*, 1990; US Department of Health and Human Services, 2001). This is based on the observation that smoking increases the risk for estrogen-deficiency disorders, and decreases the risk

for many disorders associated with estrogen-excess. Generally, this effect seems more pronounced in postmenopausal women. Of the estrogen-deficiency disorders, smoking has been found to be associated with an increased risk for hip fracture (Law & Hackshaw, 1997; Law *et al.*, 1997; US Department of Health and Human Services, 2001). Of the estrogen-excess disorders, smoking has been found to be inversely associated with endometrial cancer, uterine fibroids, endometriosis, vomiting during pregnancy and hypertensive disorders of pregnancy (Baron *et al.*, 1990; US Department of Health and Human Services, 2001).

Cigarette smoking does not seem to affect endogenous levels of the major estrogens in either premenopausal (Lucero *et al.*, 2001; Manson *et al.*, 2001) or postmenopausal women (Baron *et al.*, 1990; Law *et al.*, 1997; Verkasalo *et al.*, 2001) although there are reasons for predicting such effects: nicotine or smoke-associated PAHs may inhibit aromatase, an enzyme that is required for estrogen production, in granulosa cells (Barbieri *et al.*, 1986). This lack of effect indicates that smoking alters estrogen-related processes in women in ways other than through direct modulation of endogenous estrogen levels. Nevertheless, among postmenopausal women who take oral estrogens, cigarette smoking has been shown to reduce circulating levels of estradiol (Jensen *et al.*, 1985; Jensen & Christiansen, 1988; Bjarnason & Christiansen, 2000), unbound estradiol (not bound to sex hormone-binding globulin) (Cassidenti *et al.*, 1990) and estrone (Jensen *et al.*, 1985; Jensen & Christiansen, 1988; Geisler *et al.*, 1999). During oral estrogen therapy, estrone sulfate accounts for a higher proportion of circulating total estrogens in smokers than in nonsmokers (Geisler *et al.*, 1999; Cassidenti *et al.*, 1990). With lower-dose regimens, smokers seem to have higher levels of follicle-stimulating hormone than nonsmokers (Bjarnason & Christiansen, 2000).

On the other hand, smoking does not affect the estradiol or estrone levels in plasma of women treated with parenteral (transdermal) estrogens (Jensen & Christiansen, 1988), at least in the dose-range studied. However, plasma levels of estrone sulfate may be reduced during parenteral estrogen therapy, although not significantly (Geisler *et al.*, 1999). This difference from the findings after oral treatment suggests that cigarette smoking induces the hepatic enzymes that affect hormone metabolism in a 'first pass' manner.

The biological mechanisms that may explain an anti-estrogenic effect of smoking are not clear. Changes in body weight and age at menopause caused by smoking do not seem sufficient by themselves to provide an explanation. Some of the potentially anti-estrogenic effects occur in premenopausal women and adjustment for body weight and age at menopause does not greatly affect the observed associations. Smoking-related changes in adrenal androgens are also insufficient to explain the effects observed (Thomas *et al.*, 1993) (see below). A smoking-induced shift in estrogen metabolism towards 2-hydroestrogens and catechol estrogens with weak estrogenic potency may play a role (Michnovicz *et al.*, 1986, 1988). A recently described molecular mechanism may also be relevant. Cigarette smoking is a rich source of PAHs and other ligands for the aryl hydrocarbon receptor. The ligand–receptor complex has the capacity to bind to response ele-

ments in the promoter region of estrogen-regulated genes, thereby serving as a transcription repressor. This inhibition of estrogen may explain the lack of estrogen stimulation in women with normal estradiol and estrone levels (Safe *et al.*, 1998, 2001; Safe & McDougal, 2002).

Androgens

In women, the most potent circulating androgen, testosterone, derives both from the ovary (predominantly in premenopausal women) and the adrenal gland. Androstenedione and dihydroepiandrosterone, which have an adrenal origin, are much less potent as androgens, but may serve as precursors for other, more potent hormones, such as dihydroepiandrosterone sulfate (DHEAS). Circulating levels of testosterone, androstenedione and perhaps DHEAS have been associated with cancers of the breast and endometrium (Dorgan *et al.*, 1997; Zeleniuch-Jacquotte *et al.*, 1997; Akhmedkhanov *et al.*, 2001; Endogenous Sex Hormones and Breast Cancer Collaborative Group, 2002).

In postmenopausal women, cigarette smoking clearly increases serum concentrations of the adrenal androgens, androstenedione and DHEAS (Law *et al.*, 1997). In premenopausal women who smoke, DHEAS levels are significantly increased (Manson *et al.*, 2001); for androstenedione, findings are consistent with an increase, but the relevant studies are small and the results of individual studies are not statistically significant (Longcope & Johnston, 1988; Ruiz *et al.*, 1992; Thomas *et al.*, 1993).

The levels of the major circulating androgen, testosterone, seem unaffected by smoking in women. For example, Law *et al.* (1997) found that testosterone concentrations in postmenopausal women seem not to be substantially affected. Studies in premenopausal women have generally been small and have yielded conflicting results. Nevertheless, one larger investigation (of > 600 women) reported higher testosterone concentrations in the serum of female smokers than in nonsmokers (Sowers *et al.*, 2001), whereas an earlier study had reported a decreased free testosterone index (Ortego-Centeno *et al.*, 1994).

(ii) *Diabetes mellitus and insulin resistance*

Diabetes mellitus is a risk factor for endometrial and breast cancers and possibly also for colorectal cancer (Giovannucci, 2001; Gupta *et al.*, 2002). Epidemiological data on type 2 diabetes suggest that cigarette smoking is a risk factor for this common disease. Type 2 diabetes, generally incident among children or young adults, has strong immunological and genetic determinants, and has essentially not been studied with respect to possible associations with tobacco use.

Recent cohort studies have shown a modest association of smoking with risk for incident type 2 diabetes mellitus, though typically the increased risks were found only in the heaviest smokers and in those who start smoking at a younger age (Feskens & Kromhout, 1989; Rimm *et al.*, 1993, 1995; Kawakami *et al.*, 1997; Manson *et al.*, 2000). The association was still observed after adjustment for multiple covariates, including body mass index and alcohol intake.

The biological plausibility of these findings is supported by the results from other investigations showing that cigarette smoking can induce insulin resistance (Facchini *et al.*, 1992; Hautanen & Adlercreutz, 1993; Zavaroni *et al.*, 1994; Eliasson *et al.*, 1997). Smokers have also been observed to have higher concentrations of glycosylated haemoglobin (HbA_1 and HbA_{1C}) than nonsmokers, indicating a tendency to higher glucose levels (Modan *et al.*, 1988; Simon *et al.*, 1989; Nilsson *et al.*, 1995; Sargeant *et al.*, 2001).

There are some hormonal mechanisms that might explain an association of smoking with an increased risk for diabetes. Smoking increases secretion of catecholamines, glucocorticoids and probably growth hormone; these are all 'counter-regulatory' hormones, i.e. they counteract the effects of insulin in glucose metabolism.

(iii) *Body weight and obesity*

Cigarette smoking distorts the normal association between leanness and health because current cigarette smokers weigh less than never-smokers and have a lower body mass index (Klesges *et al.*, 1989; Perkins, 1993; Flegal *et al.*, 1995; US Department of Health and Human Services, 2001). The relationship is 'U-shaped'; moderately heavy smokers weigh less than nonsmokers and also less than heavy smokers. The weight differences are larger for women and become more pronounced with age (Klesges *et al.*, 1989; Williamson *et al.*, 1991; Perkins, 1993; Rasky *et al.*, 1996; Molarius *et al.*, 1997; US Department of Health and Human Services, 2001). Initiation of smoking seems not to lead to weight loss — rather, continued smoking probably suppresses age-related weight gain (US Department of Health and Human Services, 2001).

It is clear that smoking cessation leads to weight gain, such that former smokers weigh more than current smokers of the same age (and smoking duration before cessation) (Williamson *et al.*, 1991; Perkins, 1993; Flegal *et al.*, 1995; US Department of Health and Human Services, 2001). The weight gain following cessation has generally been found to be greater in women than in men (Flegal *et al.*, 1995; O'Hara *et al.*, 1998; US Department of Health and Human Services, 2001).

The mechanisms underlying these effects have been studied extensively. The lower body weights of current smokers are not the result of taking more exercise or of lower caloric intake: if anything, smokers tend to consume more calories and be less active than never-smokers (Klesges *et al.*, 1989; Grunberg, 1990; US Department of Health and Human Services, 2001). After smoking cessation, there seems to be a transient increase in caloric intake, but this is not sufficient to explain the weight gain (Perkins, 1993). Metabolic studies, however, have repeatedly shown that smoking acutely increases energy expenditure, particularly in individuals who are not at rest (Perkins, 1993). Animal experiments and studies of individuals who use nicotine replacement as an aid to stop smoking suggest that nicotine is responsible for the weight differences (Grunberg, 1990). This may be due to the release of catecholamine associated with smoking (US Department of Health and Human Services, 1983).

In addition to its effects on body weight, cigarette smoking also affects the distribution of body weight. Although body weight is lower, the waist-to-hip ratio, an index of

abdominal obesity associated with an increased risk for cardiovascular disease, is higher in smokers. As for body weight, this association also appears to be stronger among women than among men (Duncan *et al.*, 1995; Croft *et al.*, 1996; Ishizaki *et al.*, 1999; US Department of Health and Human Services, 2001).

(iv) *Growth hormone, insulin-like growth factors and insulin-like growth factor-binding proteins*

Growth hormone is secreted by the pituitary gland; most of its effects are mediated through insulin-like growth factors (IGFs) that are synthesized under the influence of growth hormone in a variety of tissues. Relatively heavy exposures to tobacco smoke (e.g. smoking of two or more cigarettes in succession) acutely increase the levels of circulating growth hormone, at least in men (Cryer *et al.*, 1976; Winternitz & Quillen, 1977; Wilkins *et al.*, 1982). In women, data are limited, but are consistent with a similar effect. The increase in growth hormone concentration is similar in obese and lean female smokers (Szostak-Wegierek *et al.*, 1996).

Under the control of growth hormone, the liver synthesizes IGFs that are secreted into the circulation. High serum concentrations of IGF1 have been associated with cancers of the breast, prostate, colorectum and lung (Chan *et al.*, 1998; Ma *et al.*, 1999; Yu & Rohan, 2000; Kaaks *et al.*, 2000; Toniolo *et al.*, 2000; Giovannuci, 2001; Fürstenberger & Senn, 2002). The data regarding circulating IGF1 levels and cigarette smoking are conflicting. Although the studies on growth hormone have suggested that IGF1 levels might be increased by smoking (Eliasson *et al.*, 1993; Kaklamani *et al.*, 1999), a few studies have reported decreased IGF1 levels in smokers (Landin-Wilhelmsen *et al.*, 1994; Probst-Hensch *et al.*, 2001) and other investigations have found no association (Goodman-Gruen & Barrett-Connor, 1997; Ma *et al*., 1999; Lukanova *et al*., 2001). One study calculated free IGF1 levels and reported lower values in ever-smokers than in non-smokers, but this result is biased by the inclusion of former smokers with current smokers, and by the apparent lack of adjustment for covariates (Janssen *et al.*, 1998).

Research in this area is complicated by the presence of IGF-binding proteins, which can alter the availability and effects of the IGFs. There are few data regarding the effect of smoking on the binding proteins and some have suggested that smoking may decrease the levels of IGFBP3, the principal binding protein for IGF1 (Kaklamani *et al.*, 1999; Lukanova *et al.*, 2001), although other studies have found no association (Yu *et al.*, 1999; Probst-Hensch *et al.*, 2001).

(v) *Vitamin D*

Vitamin D is well known as a family of hormones that regulate calcium, magnesium, phosphorus and bone metabolism. Vitamin D also has important effects on cell differentiation and proliferation, and may be inversely related to the risks for cancers of the breast, prostate and colorectum (Schwartz & Hulka, 1990; Martinez & Willett, 1998; Lipkin & Newmark, 1999; Bretherton-Watt *et al.*, 2001; Polek & Weigel, 2002).

Cigarette smoking has repeatedly been associated with reductions in serum levels of 25-hydroxyvitamin D (25-OH vitamin D), the compound that best reflects vitamin D status. A number of studies have reported that smokers have lower serum concentrations of 25-OH vitamin D than nonsmokers (Mellstrom *et al.*, 1993; Brot *et al.*, 1999; Harris *et al.*, 2000; Rapuri *et al.*, 2000; Chapurlat *et al.*, 2001; Need *et al.*, 2002). Most of these investigations adjusted for several covariates such as bone mineral density, vitamin D intake and exposure to sunlight (Brot *et al.*, 1999; Harris *et al.*, 2000; Rapuri *et al.*, 2000). 1,25-Dihydroxyvitamin D (1,25-$(OH)_2$ vitamin D) levels are tightly regulated and do not reflect vitamin D status except under conditions of obvious deficiency or excess. Nevertheless, in some studies (Brot *et al.*, 1999; Need *et al.*, 2002), but not all (Rapuri *et al.*, 2000), serum concentrations of this hormone have been found to be decreased in smokers.

The data reviewed in this section can be summarized as follows:

- Cigarette smoking has widespread and serious effects on reproductive function in women. Some of these effects may have implications for cancer risks in women.
- Cigarette smoking has important hormonal and metabolic effects that may be related to cancer risk at several sites. Smokers have an increased risk for type 2 diabetes, which may, in turn, increase the risk for cancer at several sites. Smokers also have a lower average body weight than nonsmokers, and smoking cessation has been associated with weight gain. Although this weight gain is admittedly a negative outcome, the benefits of smoking cessation still far exceed it.
- The 'anti-estrogenic' effect of cigarette smoking may be relevant to the development of cancers at several anatomical sites in women, and the effects of smoking on vitamin D status may be involved in the carcinogenic effects of tobacco.
- The implications of the findings regarding the association between smoking, insulin-like growth factors and adrenal androgens are not clear.

4.3.2 *Animals*

(*a*) *Reproductive and perinatal effects*

(i) *Effects on embryonic growth and malformations*

A study was conducted to determine whether chronic treatment of gestating monkeys with nicotine alters the concentrations of known regulators of energy balance in the newborn offspring. Gestating rhesus monkeys were treated with nicotine tartrate (1.5 mg/kg bw per day) starting on day 26 of gestation and were maintained until day 160 of gestation. Exposure to nicotine had no significant effect on absolute birth weights of the monkeys, although there was a 10% reduction in birth weights in animals exposed to nicotine when normalized to maternal weight. Plasma leptin concentrations on postnatal day 1 were lower by about 50% in the nicotine-treated group than those in controls, suggesting that the infant monkeys exposed to nicotine may also have lower body-fat levels. These data suggest that exposure to nicotine during gestation may increase energy expenditure in the developing fetus through actions on hypothalamic systems, resulting in lower birth weights and body-fat levels (Grove *et al*, 2001).

Gestating C57BL or mutant 'curly tail' mice were exposed to tobacco smoke in a smoking machine for 10 min, three times a day, either on the day of conception (day 0) and days 1 and 2, on days 3, 4 and 5, or from day 0 until day 17. After the first two treatments, embryonic development was subsequently assessed on day 9. Both these periods of exposure were associated with a dose-related retardation in embryonic growth, but the retardation was more marked in embryos exposed on days 0, 1 and 2. It would seem, therefore, that even brief episodes of maternal smoking are detrimental to the very early embryo, and even if smoking is stopped, the effects persist at least for some days and there is no immediate catch-up growth. In mice exposed continuously for 17 days, the fetuses were studied on day 18: a significant reduction in fetal body weight was observed in both strains of mice. There was also a reduction in the number of skeletal ossification centres, showing that developmental delay also occurred. In C57BL mice, one rib abnormality occurred, but no major congenital malformations were seen. However, in the curly tail mutants, 60% of which normally have a curly tail or an open neural tube defect, there was a modest increase in the frequency of open spina bifida and exencephaly; a few minor rib abnormalities also occurred, and one case of cleft lip with cleft palate. These results indicate that tobacco smoke, although detrimental to the developing fetus, is not a potent teratogen in the mouse, but may have minor effects in those individuals genetically predisposed to an abnormality. These results may explain the generally inconclusive findings regarding congenital malformations in the children of women who smoked during pregnancy. In all experiments, the detrimental effects were seen with both higher-tar cigarettes (tar and nicotine yields, 12.9 and 1.19 mg/cigarette, respectively) and lower-tar cigarettes (4.8 and 0.54 mg/cigarette, respectively), indicating that tobacco modification is not beneficial to the developing fetus (Seller & Bnait, 1995).

(ii) *Effects on the fetal respiratory system*

Exposure of fetal rats to nicotine gives rise to increased mortality when animals are challenged postnatally with hypoxia. In one study, gestating rats received nicotine infusions simulating the plasma nicotine concentrations of smokers. At 1–2 days postpartum, the nicotine-treated group displayed normal heart rates, electrocardiogram waveforms and respiratory rates under normal oxygen conditions. With hypoxia (5% O_2, for 10 min), controls showed initial tachycardia and a subsequent slight decline in heart rate. Atrioventricular conduction was gradually impaired and repolarization abnormalities also appeared. The group exposed to nicotine showed no tachycardia and their heart rate declined rapidly and precipitously within a few minutes after the start of hypoxia. Changes in respiration were identical in the two groups: initial tachypnoea and subsequent decline. These results suggest that prenatal exposure to nicotine affects sinoatrial reactivity to hypoxia without impairing cardiac conduction *per se*. These mechanisms would explain the increased hypoxia-induced mortality noted in animals exposed to nicotine prenatally, and could contribute to increased morbidity, mortality and sudden infant death syndrome in humans (Slotkin *et al*., 1997).

Rats were exposed to cigarette smoke or room air from days 2–22 of gestation. Immunoblots of dorsocaudal brainstem lysates at day 2 postpartum revealed no differences in protein kinase C (PKC) (α and β) or endothelial NOS expression. However, the immunoreactivities of PKC-γ, PKC-δ and neuronal NOS were reduced in the smoke-exposed group. The results indicate that smoking during gestation is associated with selective reductions in PKC and NOS isoforms within the dorsocaudal brainstem, which could decrease respiratory drive and lead to enhanced vulnerability to hypoxia in infants of mothers who smoke. These conditions are implicated in sudden infant death syndrome (Hasan *et al*., 2001).

Gestating rats received either nicotine (6 mg/kg bw per day) or vehicle administered continuously with an osmotic minipump from day 6 of gestation to days 5 or 6 postpartum. On days 5 or 6 postpartum, pups were either exposed to a single period of hypoxia (97% N_2; 3% CO_2) and their time to last gasp was determined, or exposed repeatedly to hypoxia and their ability to autoresuscitate from primary apnoea was determined. Perinatal exposure to nicotine did not alter the time to last gasp, but it did impair the ability of pups to autoresuscitate from primary apnoea. In the control group, pups were able to autoresuscitate from 18 ± 1 (SD) periods of hypoxia, whereas, after exposure to nicotine, the treated pups were able to autoresuscitate from only 12 ± 2 periods ($p < 0.001$) of hypoxia. These data provide evidence that perinatal exposure to nicotine impairs the ability of newborn rats to autoresuscitate from primary apnoea during repeated exposure to hypoxia, such as may occur during episodes of prolonged sleep apnoea (Fewell & Smith, 1998).

(iii) *Mutagenic effects in the embryo*

Long-term chronic exposure to tobacco smoke is believed to be necessary for carcinogenesis. An investigation was conducted into the relationship between short-term exposure to smoke and the frequency of deletions in the mouse embryo. Deletions and other genome rearrangements are associated with carcinogenesis and inheritable diseases. The pink-eyed unstable (p^{un}) mutation in C57BL/6J mice is the result of internal duplication of 70 kb of DNA within the *p* gene. Spontaneous reversion events in homozygous p^{un}/p^{un} mice occur by deletion of one copy of the duplicated sequence. Reversion events occurring in the embryonic premelanocytes of the developing fetus give rise to black spots on the grey fur of the offspring after birth. The effects of exposure of pregnant p^{un} mice to cigarette smoke and cigarette-smoke condensate on the frequency of black spots occurring in the offspring were investigated. Gestating dams were exposed (whole body) to smoke generated by either filtered or unfiltered cigarettes for 4 h, or alternatively, mice were given a 15-mg/kg bw dose of cigarette-smoke condensate during day 10 of gestation. The concentrations of total particulate matter, CO, plasma nicotine and cotinine were determined to characterize the smoke exposure. There was a significant increase in the number of DNA deletions in the embryo as indicated by spotted offspring in both of the smoke-exposed groups and in the condensate-exposed group. The results suggest that

embryos are highly sensitive to the genotoxic activity of cigarette smoke following a single exposure of only 4 h (Jalili *et al*., 1998).

(iv) *Effects on the postnatal brain*

The effects of prenatal exposure to CO, a major component of cigarette smoke, on the structural and neurochemical development of the postnatal brain at 1 and 8 weeks were studied alone or in combination with postnatal hyperthermia. Gestating guinea-pigs ($n = 11$) were exposed to 200 ppm CO for 10 h per day from mid-gestation until term (68 days), whereas control dams ($n = 10$) breathed room air. On postnatal day 4, neonates from the control and CO-exposed groups were exposed to hyperthermia (35 °C) for 75 min or remained at ambient temperature (23 °C). Semiquantitative immunohistochemical techniques revealed the following neurotransmitter alterations in the medulla after 1 week: a decrease in met-enkephalin-immunoreactivity following postnatal hyperthermia and an increase in 5-hydroxytryptamine immunostaining following a combination of exposure to CO and hyperthermia. No alterations were observed in substance P- or tyrosine-hydroxylase staining in animals subjected to any of the treatments. At 8 weeks of age, the combination of prenatal exposure to CO followed by a brief hyperthermic stress postnatally resulted in lesions throughout the brain and an increase in immunoreactivity of glial fibrillary acidic protein in the medulla. Such effects on brain development could be of relevance in cardiorespiratory control in the neonate and could have implications for the etiology of sudden infant death syndrome, in which smoking and hyperthermia are major risk factors (Tolcos *et al*., 2000).

Because the identity of the teratogenic agent in cigarette smoke remains controversial, a study was conducted to investigate whether nicotine can cause neural dysmorphology and, hence, act as a nervous system teratogen in cultured rat embryos. This in-vitro study confirmed the conclusion of previous reports on in-utero exposure that nicotine leads to growth retardation and impaired development of the nervous system, particularly of the forebrain and the branchial arches. This could lead to microcephaly and cleft palate in term fetuses. Cellular disruption and necrosis occurred in the neuroepithelium and underlying mesenchyme; the effect was dose-dependent. There was severe disruption of cell and organelle membranes, and many healthy cells were found to contain engulfed, whole condensed or remnants of dead cells. The results show that nicotine acts as a nervous system teratogen leading to gross and cellular dysmorphology. This could be explained by a direct effect of this highly lipid-soluble compound on the membranes, or by an indirect effect through oxidative membrane damage (Joschko *et al*., 1991).

(*b*) *Hormonal effects*

(i) *Estrogens*

Two groups of female rats (aged 2.5–3 months and 6 months) were exposed to mainstream cigarette smoke for 2 h per day for 3 weeks or 3 months. Exposure to tobacco smoke did not induce any changes in uterine weight or estrous cycle, but led to a decrease in the estradiol (E2) concentration in uterine tissue, in particular in the 6-month-old rats

and in the young rats after 3 months of exposure. No signs of aneuploidy were found in the uterus of the smoke-exposed animals. Flow cytometry analysis showed that both the cell proliferation index and the proportion of cells in S-phase were increased by 3 weeks of exposure and both were decreased by 3 months of exposure (Berstein *et al*., 1999)

(ii) *Glucose tolerance, insulin*

Cigarette smoking is a major risk factor for coronary heart disease. The effect of nicotine on blood pressure and glucose tolerance was studied in adult male Sprague-Dawley rats randomly assigned to receive either nicotine or placebo pellets as subcutaneous implants. Body-weight gain was controlled by pair-feeding, and was not significantly different between nicotine-treated and placebo-treated animals. Blood pressure increased throughout a 3-week treatment period in nicotine-treated animals and was significantly higher ($p < 0.05$) than in placebo-treated rats; it returned to normal within 1 week following exhaustion of the pellets. Oral glucose tolerance tests conducted at 2.5 weeks after implantation showed similar glucose, insulin and free fatty acid profiles in both groups. The results show that exposure to nicotine leads to sustained but reversible hypertension in rats without deterioration of glucose tolerance or insulin action, under conditions of controlled body-weight gain. Smokeless nicotine adversely affects the coronary risk profile by increasing blood pressure (Swislocki *et al*., 1997).

(iii) *Vitamin D*

The effects of 2 months of nicotine treatment on bone formation and resorption were studied in adult female rats. In addition, the concentrations of calciotropic hormones, including parathyroid hormone, calcitonin, 25-OH vitamin D and 1,25-$(OH)_2$ vitamin D were determined. Groups of seven animals received either saline or nicotine at 3.0 or 4.5 mg/kg bw per day, delivered by subcutaneously implanted osmotic minipumps, for 2 months. Serum, right tibia, left femur and lumbar vertebrae (3–5) were collected to determine hormonal concentrations as well as histomorphometric parameters, bone-mineral density, bone-mineral content and vertebral strength. Although nicotine-treated rats had a lower level of 25-OH vitamin D (54.4 ± 3.1 ng/mL for the lower-dose group and 55.8 ± 2.8 ng/mL for the higher-dose group (mean ± SEM)) than the controls (74.8 ± 2.8 ng/mL) ($p < 0.01$), no significant difference could be detected between the levels of the remaining hormones. Similarly, no statistical differences were detected in histomorphometric parameters, bone-mineral density, bone-mineral content or vertebral strength between nicotine-treated and control rats. The results indicate that exposure to nicotine for 2 months causes a 30% reduction in serum concentration of 25-OH vitamin D, but no alteration in bone mass, strength or formation and resorption (Fung *et al*., 1998).

(iv) *Effects on the hypothalamus–hypophysis–adrenal hormones*

The possible long-term effects of postnatal exposure to cigarette smoke were studied in male Sprague-Dawley rats exposed to the smoke from two Kentucky reference IR-1 type cigarettes every morning from day 1 after birth for a period of 5, 10 or 20 days. The

rats were killed 24 h (for exposure periods of 5, 10 and 20 days), 1 week (for 20 days of exposure) or 7 months (for 20 days of exposure) after termination of the last exposure. Catecholamine levels and changes in catecholamine utilization in discrete hypothalamic regions were analysed by quantitative histofluorimetry. Serum prolactin, luteinizing hormone, thyroid-stimulating hormone and corticosterone concentrations were determined by radioimmunoassay. In the postnatal period, serum levels of luteinizing hormone were significantly increased 24 h after a 10-day or 20-day period of exposure to cigarette smoke. A highly significant increase in serum prolactin concentrations was observed in adults who had been exposed postnatally to cigarette smoke for a 20-day period, although the levels had been unaltered by this exposure when measured during the postnatal period. Twenty-four hours following a 20-day postnatal exposure, catecholamine utilization was increased in the medial palisade zone of the median eminence and was substantially reduced in the parvocellular and magnocellular parts of the paraventricular hypothalamic nucleus. Following 20 days of postnatal exposure to cigarette smoke, measurements made 1 week and 7 months later revealed no alterations in levels or utilization of catecholamine in various hypothalamic areas including the median eminence. No alteration in the development of body weight was observed with any of the above changes. The results indicate that marked but temporary increases in the secretion of luteinizing hormone occur 24 h after postnatal exposure to cigarette smoke, whereas increases in prolactin secretion develop only in adult life, when maturation of the brain and/or the anterior pituitary gland is complete. Changes in levels and utilization of catecholamine have been found in discrete hypothalamic nerve terminal networks, but do not play a major role in mediating the above changes in anterior pituitary function and are probably the result of a withdrawal phenomenon (Jansson *et al*., 1992).

Male rats were exposed to the smoke of 1–4 Kentucky reference IR-1 type cigarettes. Catecholamines in the diencephalon were measured by quantitative histofluorimetry in discrete dopamine (DA) and noradrenaline (NA) nerve terminal systems. Blood concentrations of thyroid-stimulating hormone, prolactin, luteinizing hormone, follicle-stimulating hormone, adrenocorticotropic hormone, vasopressin and corticosterone were determined by radioimmunoassays. Exposure to unfiltered, but not to glass fibre-filtered cigarette smoke resulted in dose-dependent reductions of NA levels in the various hypothalamic NA nerve terminal systems, and in dose-dependent increases of amine turnover in the various DA and NA nerve terminal systems in the hypothalamus. The decrease that was observed in secretion of thyroid-stimulating hormone, luteinizing hormone and prolactin after exposure to unfiltered smoke was probably induced by nicotine activating the lateral and medial tubero-infundibular DA neurons. Furthermore, unfiltered cigarette smoke produced a dose-related increase in corticosterone secretion (Andersson *et al*., 1985).

4.4 Genetic and related effects

This topic was reviewed previously by DeMarini (1983) and Obe (1984) and summarized in the first *IARC Monograph* on tobacco smoking (IARC, 1986). The present monograph provides only a brief overview of work prior to 1986 and, instead, summarizes work published since then.

4.4.1 *Humans*

(*a*) *Mutagenicity, sister chromatid exchange,* HPRT *mutation and other effects*

(i) *Urinary mutagenicity*

Urinary mutagenicity in smokers was detected first by Yamasaki and Ames (1977) by testing the XAD/acetone-extractable organic compounds from urine in the *Salmonella* (Ames) mutagenicity assay. Several years later, studies using essentially the same methods confirmed and clarified this original observation (Putzrath *et al.*, 1981; Kriebel *et al*., 1985). The general approach to these studies has remained similar over the years. It involves concentration of the organic compounds from the urine by means of a solid-phase resin followed by elution with an organic solvent and then testing the resulting concentrate, after its fractional analysis by HPLC, in the *Salmonella* (Ames) mutagenicity assay in the presence of rat liver S9 mix for metabolic activation.

A comparison of three types of resin (C18, XAD-2 and CN) followed by elution with acetone showed that the highest levels of urinary mutagenicity were detected using C18 resin. This study found that urinary genotoxicity was higher in smokers of black tobacco than in smokers of blond tobacco (Kuenemann-Migeot *et al.*, 1996). A study of the stability of stored urine samples showed that no significant loss of mutagenic activity occurred in urine stored frozen for as long as 175 days, although near significance was reached, as a result of decreasing mutant response as storage time increased, for two of the higher doses tested (Williams *et al.*, 1990). A *Salmonella* microsuspension assay is generally more sensitive at detecting urinary mutagens from smokers than the standard plate-incorporation assay (Kado *et al.*, 1983; Nylander & Berg, 1991). Peak mutagenic activity of the urine occurred 4–5 h after the beginning of smoking and decreased to pre-smoking levels 12 h after the cessation of smoking in occasional smokers and after 18 h in heavy smokers (Kado *et al.*, 1985). This study suggested that the mutagens are absorbed rapidly (3–5 h) and are eliminated from the body following first-order kinetics; the excretion rate constant for the occasional smoker was ~0.1 h^{-1}, and the half-life ($T_{1/2}$) was ~7 h. A study in which the SOS Chromotest was used as the indicator assay showed that urine from smokers that was mutagenic in *Salmonella typhimurium* TA98 was not mutagenic in the SOS Chromotest; this test is therefore not suitable for assaying urinary mutagens (De Méo *et al.*, 1988). Urine concentrates from subjects who both smoked tobacco and chewed areca nuts induced sister chromatid exchange and chromosomal aberrations in Chinese hamster ovary cells (Trivedi *et al.*, 1993, 1995).

The urine of smokers who smoked cigarettes that heated, but did not burn tobacco had levels of urinary mutagenicity similar to those of nonsmokers (Doolittle *et al.*, 1989; deBethizy *et al.*, 1990; Smith *et al.*, 1996). However, the urine of occupationally exposed bidi tobacco rollers was mutagenic (Bhisey & Govekar, 1991), suggesting that exposure to tobacco *per se* rather than tobacco pyrolysate products may be sufficient to produce mutagenic urine. Urinary mutagenicity generally correlated with the number, but not the tar level, of cigarettes smoked (Tuomisto *et al*., 1986; Kuenemann-Migeot *et al*., 1996). Interestingly, the urine of smokers of black tobacco was twice as mutagenic as the urine from smokers of blond tobacco, and there was a higher risk for bladder cancer in smokers of black tobacco than in smokers of blond tobacco (Vineis *et al.*, 1984; Bryant *et al.*, 1988; Malaveille *et al.*, 1989; see also Section 2.1.2.(*a*)(iii)). One study of bladder cancer patients showed that there was no association between levels of urinary mutagenicity and tumour status or recurrence of the bladder tumours (Kanaoka *et al*., 1990).

Although consumption of fried meat can also produce mutagenic urine, experiments with subjects eating controlled diets showed that the higher urinary mutagenicity in smokers compared with nonsmokers was not the result of enhanced mutagenicity caused by diet-related heterocyclic amine mutagens in their urine (Doolittle *et al.*, 1990a). Although not reviewed exhaustively here, smoking was generally a potential factor in studies investigating urinary mutagenicity of occupational exposures, such as inks and pharmaceuticals (Dolara *et al.*, 1981), tyres (Crebelli *et al.*, 1985), coke or graphite-electrodes (Ferreira *et al.*, 1994), steel and coal processing (De Méo *et al.*, 1987) and benzidine (DeMarini *et al.*, 1987).

Indirect evidence suggests that the chemicals responsible for smoking-related urinary mutagenicity are primarily aromatic amines and/or heterocyclic polyaromatic amino compounds. For example, the urine of smokers was much more mutagenic in strain YG1024 of *Salmonella*, which overproduces *O*-acetyltransferase, than in strains with less of this activity (e.g. TA98) or that overproduce nitroreductase (YG1021) (Einistö *et al.*, 1990; Camoirano *et al.*, 2001). One study in which the urine of smokers was fractionated by reversed-phase HPLC and the fractions were then evaluated for their ability to induce chromosomal aberrations in Chinese hamster ovary cells concluded that clastogenic agents were present in the urine of smokers. This clastogenic activity was reduced by the addition of catalase or superoxide dismutase, suggesting that the activity of these agents may result from the production of active oxygen species (Dunn & Curtis, 1985).

Urinary mutagenicity has been shown to correlate with the levels of a 4-ABP–DNA adduct[1] in exfoliated urothelial cells from smokers (Talaska *et al.*, 1991b). However, the levels of a 4-ABP-haemoglobin adduct[2] showed a more complex association with urinary mutagenicity (Bartsch *et al.*, 1990). Chemical analysis of urine from a smoker with exceptionally high urinary mutagenicity revealed the presence of the mutagen 2-amino-7-naphthol, which is a metabolite of the bladder carcinogen 2-aminonaphthalene (β-naphthyl-

[1] 4-ABP–DNA adduct: *N*-(deoxyguanosin-8-yl)-4-aminobiphenyl–DNA adduct

[2] 4-ABP–haemoglobin adduct: *N*-(deoxyguanosin-8-yl)-4-aminobiphenyl–haemoglobin adduct

amine), a component of cigarette smoke (Connor *et al.*, 1983). Chemical fractionation of mutagenic urine from smokers indicated that much of the mutagenic activity may be due to PAHs and/or heterocyclic amines (Mure *et al.*, 1997). Although the concentration of urinary nicotine plus its metabolites correlated with urinary mutagenicity in smokers (Rahn *et al.*, 1991; Granella *et al.*, 1996), nicotine and its metabolites were not responsible for the mutagenicity. The absence of urinary mutagens in subjects who smoke cigarettes in which tobacco is heated but not burned has been demonstrated, although large quantities of nicotine and cotinine were found in the urine of such subjects (Curvall *et al.*, 1987; Rahn *et al.*, 1991).

(ii) HPRT *mutations*

Several reviews (Cole & Skopek, 1994; Robinson *et al.*, 1994; Curry *et al.*, 1999) have noted that smoking generally increases the hypoxanthine-guanine phosphoribosyltransferase (*HPRT*) (also called *HGPRT*) mutant frequency in peripheral blood lymphocytes by ~50%. However, the increases did not reach statistical significance in some studies because of the large interindividual variability of *HPRT* mutant frequencies. Using the autoradiographic *HPRT* assay, some elevated portion of the *HPRT* mutant frequency was shown to reflect recent exposure to tobacco smoke rather than the cumulative effect of past exposure. The two categories of smoker (light and heavy) had frequencies of mutant cells significantly different from each other and both were significantly higher than those of nonsmokers and former smokers (Ammenheuser *et al.*, 1997). Most importantly, *HPRT* mutant frequencies were similar in patients with lung cancer and in controls with the same smoking status, indicating that lung cancer *per se* has little if any effect on *HPRT* mutant frequency in lymphocytes. However, when cases and controls were combined, the *HPRT* mutant frequency was significantly higher in ever-smokers than in never-smokers (Hou *et al.*, 1999). Although some analyses have found no difference in the mutation spectrum at the *HPRT* locus between smokers and nonsmokers (Curry *et al.*, 1999), an increase in transversions, in particular, GC→TA, has been frequently noted among smokers (Burkhart-Schultz *et al.*, 1996; Podlutsky *et al.,* 1999; Hackman *et al.*, 2000). This is the primary class of base substitution induced by those PAHs that form bulky DNA adducts giving rise to transversion mutations. An excess of this class of mutation in the *HPRT* mutation spectrum of smokers would be consistent with exposure to the PAHs in cigarette smoke.

(iii) *Genotoxic effects in reproductive tissues/fluids and in children of smokers*

Pregnant women who smoke not only had elevated *HPRT* mutant frequencies themselves, but analysis of cord blood indicated that their children also had elevated frequencies (Ammenheuser *et al.*, 1994, 1998). Sequencing of *HPRT* mutants in cord blood from mothers who smoke indicated that most (85.7%) of the mutations were illegitimate V(D)J recombinase activity-associated exon 2-3 deletions (Bigbee *et al.*, 1999). V(D)J recombinase is an enzyme system that mediates genomic rearrangements of germ-

line-encoded variable (V), diversity (D) and junctional (J) regions responsible for generating T-cell receptor and immunoglobulin gene diversity for antigen-specific recognition. These genomic *HPRT* deletions are an illegitimate recombination event associated with haematopoietic malignancies in early childhood (Gu *et al.*, 1992). In-utero exposure to tobacco smoke increased translocation frequencies in the newborn, and a significant association was found between the *CYP1A1 MspI* polymorphism (variant genotypes of *CYP1A1*) and frequencies of chromosomal aberration in the newborns (Pluth *et al.*, 2000). Evidence has been obtained to suggest that smoking by the mother may cause detectable DNA strand breaks and alkali-labile damage in the lymphocytes of newborns detected by single-cell gel electrophoresis; the percentage of damaged cells increased with the frequency of smoking (Sardas *et al.*, 1995).

Smoking was shown to induce aneuploidy in sperm for certain chromosomes, including 1, 13, and YY disomy (Rubes *et al.*, 1998; Härkönen *et al.*, 1999; Shi *et al.*, 2001), but not for others, such as XX, XY, 7 or 8 (Robbins *et al.*, 1997; Rubes *et al.*, 1998; Härkönen *et al.*, 1999). Smoking also appeared to induce oxidative damage to sperm DNA as indicated by higher levels of 8-OHdG in sperm DNA of smokers than in that of nonsmokers (Shen *et al.*, 1997). Consistent with this was the finding of higher levels of DNA strand breaks in the sperm from smokers than in that from nonsmokers (Potts *et al.*, 1999).

In investigations on the effects of smoking on oocytes, smokers were found to have fewer retrieved oocytes than nonsmokers, a finding consistent with the known reduction in their fertility (Zenzes *et al.*, 1995). The oocytes with diploid complements of chromosomes were more frequent in smokers than in nonsmokers. This diploidy probably resulted from the prevention of first polar body extrusion, which indicates meiotic immaturity. The proportion of diploid oocytes was strongly associated with the number of cigarettes smoked per day (Zenzes *et al.*, 1995). In addition, triploid zygotes occurred more frequently among smokers than nonsmokers, suggesting that digynic fertilization is an important mechanism leading to triploidy among smokers (Zenzes *et al.*, 1995). These results strongly indicated that cigarette smoking is hazardous to the viability and function of developing oocytes and their resulting embryos, and a recent study suggested that expression of the aromatic hydrocarbon receptor-driven *Bax* gene is required for premature ovarian failure caused by exposure of mice to PAHs. This ovarian damage caused by PAHs was prevented by aromatic hydrocarbon receptor Ah2 or *Bax* inactivation. Oocytes in human ovarian biopsies grafted into immunodeficient mice also accumulated Bax and underwent apoptosis after exposure to PAHs *in vivo* (Matikainen *et al.*, 2001). These data also suggest that the early onset of menopause in women smokers is caused, at least in part, by the pro-apoptotic action of tobacco smoke-derived PAHs in human oocytes.

The cervical mucus of smokers was more mutagenic than that of nonsmokers when tested in the *Salmonella* (Ames) mutagenicity assay (Holly *et al.*, 1986), and XAD/acetone extracts of amniotic fluid from mothers who smoke induced a higher number of sister chromatid exchanges in Chinese hamster ovary cells than did extracts from nonsmokers (Lähdetie *et al.*, 1993). This is consistent with the finding that cervical epithelial cells

from smokers had higher numbers of micronuclei than those from nonsmokers (Cerqueira *et al.*, 1998).

As noted in the reviews by Sastry (1991) and Zenzes (2000), smoking causes numerous reproductive problems, as well as effects on meiotic spindle function, DNA damage (oxidative damage as well as PAH adducts) to spermatozoa and oocytes, in addition to gametic and placental transmission of genetic damage. As discussed above, smoking is also associated with second-generation effects. Together, these data provide suggestive evidence for paternal and possible maternal gametic transmission of genetic damage as well as indirect support for the possibility that tobacco smoke may be a germ-cell mutagen.

(iv) *Cytogenetic effects*

Micronuclei

Bonassi *et al*. (2003) reviewed many studies that examined the influence of smoking on the frequency of micronuclei in peripheral lymphocytes. However, mixed results have been obtained. A pooled re-analysis of 24 databases from the Human MicroNucleus (HUMN) international collaborative project showed that smokers did not have an overall increase in the frequency of micronuclei in their lymphocytes. However, when the interaction with occupational exposure was considered, smokers of 30 cigarettes or more per day had a significantly higher frequency of micronuclei than did nonsmokers (Bonassi *et al.*, 2003). An increased frequency of micronuclei in smokers has been observed to occur preferentially in B lymphocytes and suppressor/cytotoxic T8 lymphocytes (Larramendy & Knuutila, 1991). Elevated frequencies of micronuclei have also been found in the tracheobronchial epithelium of smokers (Lippman *et al.*, 1990). Workers exposed to tobacco while making bidi cigarettes also had an elevated frequency of micronuclei in buccal epithelium (Bagwe & Bhisey, 1993).

Sister chromatid exchange

In contrast to micronuclei, the frequency of sister chromatid exchange in peripheral lymphocytes was generally higher in smokers than in nonsmokers. Numerous studies of the frequencies of sister chromatid exchange in peripheral lymphocytes in environmentally or occupationally exposed or unexposed populations have found that cigarette smoking induces sister chromatid exchange and can be a confounding factor in occupational studies (Sarto *et al.*, 1985; Stenstrand, 1985; Nagaya & Toriumi, 1985; Wulf *et al.*, 1986; Husgafvel-Pursiainen, 1987; Perera *et al.*, 1987; Bender *et al.*, 1988; Kelsey *et al.*, 1988; Reidy *et al.*, 1988; Thompson *et al.*, 1989; Nordic Study Group, 1990; Brinkworth *et al.*, 1992; Górecka & Gorski, 1993; Lazutka *et al.*, 1994; Rajah & Ahuja, 1995; Anderson *et al.*, 1997; Lemasters *et al*., 1997; Bukvic *et al.*, 1998; Cebulska-Wasilewska *et al.*, 1999; Rowland & Harding, 1999). Of all the cytogenetic end-points, sister chromatid exchange is the most sensitive to the effect of smoking. One study even demonstrated that smoking was associated with higher frequency of sister chromatid exchange in peripheral lymphocytes than in bone marrow. An explanation of this finding

may be that circulating lymphocytes, with an average lifespan of 4.4 years, may accumulate more DNA damage than bone-marrow cells because they have a shorter lifespan (Kao-Shan *et al.*, 1987). However, among healthy adults, smoking may account for only 19% of the variation in frequencies of sister chromatid exchange between individuals (Husum *et al.*, 1986). There was a decrease in sister chromatid exchange in former smokers during the first 78 days after stopping smoking; the decrease then was much slower from the 78th to the 233rd day after cessation (Sarto *et al.*, 1987). The mechanism by which smoking induced sister chromatid exchange does not appear to involve extracellularly generated free radicals (Lee *et al.*, 1989).

The smoking of various types of tobacco product, including bidis (Ghosh & Ghosh, 1987; Murthy *et al.*, 1997; Yadav & Thakur, 2000a) and hookah (Yadav & Thakur, 2000b) also induced sister chromatid exchange.

Chromosomal aberrations

Studies of large populations using classical cytogenetic banding techniques for chromosomal aberrations have given mixed results. One study found that the frequencies of chromosomal aberrations were not increased by smoking (Bender *et al.*, 1988), whereas another found that smoking caused a 10–20% increase in such aberrations (Nordic Study Group, 1990). The results of smaller studies have also been mixed although several have found significantly higher frequencies of chromosomal aberrations in lymphocytes from smokers than in those from nonsmokers (Littlefield & Joiner, 1986; Sinués *et al.*, 1990; Tawn & Whitehouse, 2001). Molecular cytogenetic techniques, such as fluorescence in-situ hybridization, have also yielded mixed results. Some studies found that smoking:

— did not increase the frequency of stable or unstable aberrations, but did increase the frequency of hyperploidy (van Diemen *et al.*, 1995);
— produced a marginal increase in translocation frequency (Pressl *et al.*, 1999); or
— caused a significant increase in stable aberrations (translocations and insertions) (Ramsey *et al.*, 1995).

Chromosomal aberration frequencies were found to be elevated among workers in a bidi tobacco plant who were exposed to tobacco particles and volatile constituents by the cutaneous and nasopharyngeal routes (Mahimkar & Bhisey, 1995).

Mechanistic considerations include the observation that smokers had lower levels of folic acid in their red cells than nonsmokers and this decrease in folic acid may play a role in the higher levels of chromosomal aberrations detected in smokers relative to those in nonsmokers, probably as a result of induction of common fragile sites (Chen *et al.*, 1989). Various studies have found that exposure of peripheral lymphocytes from smokers to various mutagens such as radiations or chemical compounds *in vitro* resulted in higher frequencies of chromosomal aberrations than such types of exposure caused in lymphocytes from nonsmokers (Au *et al.*, 1991; Ban *et al.*, 1995; Strom *et al.*, 1995; Wang, L.-E. *et al.*, 2000; Paz-y-Miño *et al.*, 2001). The levels of methylpurine–DNA glycosylase and 2,6-diamino-4-hydroxy-5N formamidopyrimidine (FaPy)–DNA glycosylase were higher in the peripheral blood leukocytes of smokers than in those of nonsmokers (Hall

et al., 1993). Collectively, these studies suggested that the cells of smokers, especially those from men, were less able to repair DNA damage and that DNA repair enzyme levels, fragile sites and telomeric associations can be affected by recent exposure.

A large international study showed that an elevated frequency of chromosomal aberrations in lymphocytes predicted the risk for cancer independently of exposure to carcinogens, including cigarette smoke (Bonassi *et al.*, 2000). However, many studies have demonstrated an association between smoking and certain genetic changes specifically predictive of various types of tumour. For example, in comparison with those of nonsmokers, the lymphocytes of smokers had higher frequencies of fragile sites and metaphases with extensive breakage, as well as elevated expression of fragile sites at cancer break-points and oncogene sites (Kao-Shan *et al.*, 1987). Analysis of normal bronchial epithelium from smokers using fluorescence in-situ hybridization found a considerable percentage of cancer-free tobacco smokers with trisomy 7 (Lechner *et al.*, 1997), and the frequence of loss of heterozygosity involving microsatellite DNA at three specific loci-chromosomes was significantly elevated at chromosomal sites containing putative tumour-suppressor genes in histologically normal bronchial epithelium from chronic smokers (Mao *et al.*, 1997). Perhaps most importantly, the fractional allelic loss or gain occurred at a much higher frequency in lung tumours from smokers (48%) than in those from nonsmokers (11%), suggesting that lung cancer in smokers resulted from genetic alterations distinct from those resulting in lung cancer in nonsmokers (Sanchez-Cespedes *et al.*, 2001).

Other genetic changes

Microsatellite instability in colon tumours (Slattery *et al.*, 2000) and chromosome 9 alterations in bladder tumours (Zhang *et al.*, 1997) have been associated with cigarette smoking. Smoking has also been associated with mutagen sensitivity of lymphocytes as a predictor of upper aerodigestive tract cancer (Spitz *et al.*, 1993). In another study, smoking was found not to be significantly associated with mutagen sensitivity of lymphocytes as an indication of predisposition to oral premalignant lesions (Wu *et al.*, 2002). Various cytogenetic changes and smoking have been associated with risk for leukaemia and other myelodysplastic syndromes (Sandler *et al.*, 1993; Davico *et al.*, 1998; Björk *et al.*, 2000, 2001; Moorman *et al.*, 2002).

DNA strand breaks and oxidative damage

A higher frequency of DNA strand breaks detected by the single-cell gel electrophoresis ‘comet’ assay has been found in lymphocytes (Einhaus *et al.*, 1994; Piperakis *et al*., 1998; Poli *et al.*, 1999), buccal cells (Rojas *et al.*, 1996) and urothelial cells (Gontijo *et al.*, 2001) of cigarette smokers than in those of nonsmokers. Smoking also increased the level of F(2)-isoprostanes (one of the lipid peroxidation biomarkers), an index of oxidant stress (Dietrich *et al.*, 2002).

The role of smoking-induced oxidative DNA damage is discussed elsewhere in this monograph (see Section 4.1.1(*c*)).

(v) *Chemoprevention of the formation of smoking-associated biomarkers of genotoxicity*

In humans, the administration of *N*-acetylcysteine to smokers significantly reduced the level of urinary mutagenicity (De Flora *et al.*, 1996) as well as the frequency of micronuclei in the mouth floor and in the soft palate cells (Van Schooten *et al.*, 2002). Administration of vitamins C and E as antioxidants to smokers also reduced the frequency of micronuclei in blood lymphocytes (Schneider *et al.*, 2001). Higher intakes of vitamin A and selenium were associated with a reduced frequency of sister chromatid exchange in smokers (Cheng *et al.*, 1995). However, administration to smokers of the anti-carcinogenic dithiolethione, oltipraz, had no influence on the levels of urinary mutagenicity (Camoirano *et al.*, 2001). Similarly, supplementary niacin (nicotinic acid precursor of NAD^+, a substrate for the DNA repair-related enzyme poly(ADP-ribose)polymerase (PARP)) did not decrease the frequencies of *HPRT* variants or micronuclei in peripheral blood lymphocytes in smokers. However, sister chromatid exchange was increased in these cells after the same supplementation (Hageman *et al.*, 1998). Thus, the levels of smoking-associated urinary mutagenicity and micronuclei can be reduced by appropriate chemoprevention.

(*b*) *Mutations in* TP53*,* K-RAS *and related genes*

Smoking is associated with cancer of various organs, and mutations in these smoking-associated tumours have been identified in both oncogenes and tumour-suppressor genes. The gene most frequently found to be mutated in smoking-associated lung tumours is *TP53*, and the studies of this observation have been extensively reviewed (Hernandez-Boussard & Hainaut, 1998; Hainaut & Pfeifer, 2001; Hussain *et al.*, 2001). Briefly, *TP53* mutations are more common in smokers than in nonsmokers, and the frequency of *TP53* mutations shows a direct correlation with the number of cigarettes smoked. *TP53* mutations are found in preneoplastic lesions of the lung, indicating that they are early events that are linked temporally to DNA damage caused by smoking.

The *TP53* mutation spectrum in lung tumours of smokers contains 30% GC→TA transversions, whereas only 10% of the *TP53* mutations in nonsmokers or other tumours are of this type. This percentage in lung exceeds 75% only after exposure resulting from the use of a PAH-rich smoky coal in poorly ventilated homes (DeMarini *et al.*, 2001). The elevated frequency of GC→TA transversion in smokers reflects the type of DNA damage and resulting mutations produced by PAHs, which are important carcinogenic components of cigarette smoke. There is a precise correspondence between the mutational hot spots and the sites of DNA adducts remaining after cells exposed to BPDE and other diol epoxides have undergone a period of DNA repair (Denissenko *et al.*, 1996; Smith *et al.*, 2000). These mutations are targeted at methylated CpG sites. There is a bias for most of the mutated guanines of the GC→TA mutations to be in the nontranscribed DNA strand in lung tumours from smokers. This bias results from the preferential binding and slow repair of BPDE adducts formed on the nontranscribed strand at mutational hot spot sites

in the *TP53* gene and therefore the preferential repair of DNA adducts on the transcribed strand (Denissenko *et al.*, 1998). Taken together, these and other data indicate strongly that the *TP53* mutations in lung tumours of smokers are a result of direct DNA damage caused by the carcinogens in cigarette smoke. Although one report argued that *TP53* mutations in smoking-associated lung cancer were not induced by mutagens in cigarette smoke, but were pre-existing mutations selected by physiological, non-genotoxic stress (Rodin & Rodin, 2000), subsequent analysis has refuted this proposal (Hainaut & Pfeifer, 2001).

Mutations at the *K-RAS* or (*KRAS* 2) gene (codons 12, 13 or 61) occur in ~30% of the lung adenocarcinomas of smokers and are primarily GC→TA transversions as seen in *TP53* (Slebos *et al.*, 1991; Husgafvel-Pursiainen *et al.*, 1993; Westra *et al.*, 1993; Gealy *et al.,* 1999; Ahrendt *et al.*, 2001). These mutations are associated with smoking and occur less frequently in nonsmokers (Marchetti *et al.*, 1998; Gealy *et al.*, 1999).

Mutations in *TP53* and other genes, such as *FHIT*[1], *BCL-2* and *BAX*, loss of heterozygosity at specific chromosomal locations and gene overexpression (*TP53*, MDM_2) have also been characterized in smoking-associated tumours, including those of the bladder, oral cavity and breast (Spruck *et al.*, 1993; Schreiber *et al.*, 1997; Sozzi *et al.*, 1997; Baral *et al.*, 1998; Kaur *et al.*, 1998; Dosaka-Akita *et al.*, 1999; Gealy *et al.*, 1999; Tseng *et al.*, 1999; LaRue *et al.*, 2000; Hirao *et al.*, 2001; Conway *et al.*, 2002). Collectively, these observations are consistent with the mutagenic effects of cigarette smoke condensate and tobacco smoke as demonstrated in experimental systems.

(*c*) *Influence of polymorphisms in carcinogen-metabolizing genes on smoking-associated biomarkers*

Numerous polymorphisms have been studied for their modulating effect on smoking-associated biomarkers, such as urinary mutagenicity or *HPRT* mutant frequency. However, much of this literature reports studies using small populations, and many studies have either not been repeated, or conflicting results have been obtained in repeated studies (Vineis *et al.*, 1999). Where effects were observed, they were frequently quite modest. Because of the incomplete and/or conflicting nature of this literature, firm conclusions cannot be drawn regarding the modulating effects of polymorphisms on smoking-associated biomarkers.

4.4.2 *Experimental systems*

(*a*) *Genotoxic effects, mutagenicity of cigarette-smoke condensate, urinary mutagenicity and mutation spectra*

As reviewed previously (IARC, 1986), cigarette-smoke condensate (CSC) is mutagenic in a variety of systems. Most studies have used condensate generated from various reference cigarettes, such as K1R4F, which was developed jointly by the US National Cancer Institute, the US Department of Agriculture and the University of Kentucky Tobacco and Health Research Institute (Steele *et al.*, 1995). The average mutagenicity of cigarette-smoke condensates of mainstream smoke from US commercial brands and K1R4F reference cigarettes in the *Salmonella* mutagenicity assay (on a revertants/mg condensate or revertants/cigarette basis) was not significantly different between cigarettes representing > 70% of the US cigarette market (Steele *et al.*, 1995). Similar results were recently obtained in the studies of the K1R5F cigarette (Chepiga *et al.*, 2000), indicating that these reference cigarettes are acceptable standards with which to compare mutagenicity of cigarettes typically purchased in the USA.

More recent studies have confirmed and extended the initial observations showing that cigarette-smoke condensate is mutagenic in *Salmonella* and SOS assays (Morin *et al.*, 1987; Ong *et al.*, 1987; Chen & Lee, 1996), induces micronuclei in *Vicia faba* root tips (Ji & Chen, 1996), deletions at the $Tk^{+/-}$ locus in mouse lymphoma cells (Cobb *et al.*, 1989), *Hprt* mutants in Chinese hamster ovary cells (Jongen *et al*., 1985), and can transform human endocervical cells in culture to a malignant line with up-regulated levels of *B-Myb*, *p53* and WAF_1 genes (Yang *et al.*, 1997). Comparisons with wood-smoke condensate or liquid smoke food flavourings have shown that some flavourings are more cytotoxic than cigarette-smoke condensate. Nevertheless none of the liquid smoke food flavourings or wood-smoke condensates was mutagenic in an assay using *S. typhimurium* TA98 and only some of the liquid smoke food flavourings tested were positive with strain TA100, while cigarette-smoke condensate was mutagenic in both strains (Putnam *et al.*, 1999). However, the levels of exposure must be considered in evaluating the risk posed by such substances (Fitzgerald, 2001; Smith *et al.*, 2001). The relative mutagenic potencies of organic extracts of cigarette-smoke condensate and other combustion emissions rank similarly in *Salmonella*, mouse lymphoma $Tk^{+/-}$ and mouse skin tumour-initiation assays, suggesting that the results obtained using these different systems are reasonably comparable (Williams & Lewtas, 1985).

Most of the sister chromatid exchange-inducing ability of cigarette-smoke condensate appears to reside in its neutral and highly polar, acidic/neutral fractions (Curvall *et al.*, 1985; Salomaa *et al.*, 1988); the sister chromatid exchange response of the acidic/neutral fraction was observed only after metabolic activation, suggesting that the PAHs and acidic compounds in cigarette-smoke condensate are responsible for this activity. Also, the acidic fraction was the most potent direct-acting fraction that induced mutations involving deletions and/or chromosomal loss by non-disjunction in mammalian A_L hybrid cells of CHO-K1, a Chinese hamster ovary cell containing one human chromosome 11 (Matsukura *et al.*,

1991). The acid fraction included phenolic compounds such as catechol and hydroquinone (Jansson *et al.*, 1986) that may generate free radicals (quinone and oxygen radicals) that could have produced the clastogenic effects observed. Reconstruction of a mixture containing the primary PAHs in cigarette-smoke condensate failed to reproduce the mutagenic activity of the condensate, suggesting that PAHs were not the primary cause of the activity (Asita *et al.*, 1991).

Nicotine and its metabolites were not mutagenic in *Salmonella*, did not induce sister chromatid exchange in Chinese hamster ovary cells in a study by Doolittle *et al.* (1995) and nicotine did not produce mutagenic urine in rats (Doolittle *et al.,* 1991). However, nicotine was reported to induce sister chromatid exchange in Chinese hamster ovary cells (Trivedi *et al.*, 1990). Although cigarette-smoke condensate contains a wide variety of agents of varying toxicity (Smith & Hansch, 2000), varying the amounts of 333 ingredients (e.g. casing materials, volatile top flavourings and menthol) added to typical commercially blended test cigarettes did not add significantly to the overall mutagenicity, cytotoxicity or inhalation toxicity of the resulting cigarettes (Carmines, 2002; Roemer *et al.*, 2002).

Several lines of evidence indicate that the primary source of mutagenic activity of cigarette-smoke condensate in the *Salmonella* mutagenicity assay is the aromatic amine and heterocyclic amine protein pyrolysate products. As reviewed previously (DeMarini, 1983; Obe, 1984; IARC, 1986), most of the mutagenic activity of this condensate resides in the basic or base/neutral fraction (Austin *et al.*, 1985; Salomaa *et al.*, 1988), which contains the aromatic amines and heterocyclic amines. The removal of protein and peptides from flue-cured or burley tobacco using water extraction followed by protease digestion reduced the mutagenicity of the resultant condensate by ~80% in *S. typhimurium* TA98 and ~50% in *S. typhimurium* TA100 (Clapp *et al.*, 1999). Condensates produced from tobacco smoke aerosols generated at temperatures below 400 °C or 475 °C were not mutagenic in TA98 or TA100, respectively, but those produced above those temperatures were (White *et al.*, 2001). Heterocyclic amine pyrolysate products from proteins are formed only at high temperatures, and the fact that mutagenic activity is found only in cigarette-smoke condensate produced at high temperatures indicates that such compounds are important contributors to this mutagenic effect. Exposure of hamsters to cigarette smoke enhanced the ability of their livers to convert heterocyclic amines to mutagens, suggesting that cigarette smoke, like heterocyclic amines themselves, induces cytochrome P4501A2. Therefore, this induced isoform metabolizes heterocyclic amines (Mori *et al.*, 1995).

Heterocyclic amines are much more mutagenic in *S. typhimurium* TA98 than in TA100. This probably explains the greatly reduced mutagenic activity of cigarette-smoke condensate in TA98 relative to TA100 when protein was removed from the tobacco prior to combustion (Clapp *et al.*, 1999). In addition, some of the activity detected in TA100 may be due to PAHs, which are more mutagenic in TA100 than in TA98. At the molecular level, the mutation spectrum of cigarette-smoke condensate in TA98 was identical to that of the heterocyclic amine Glu-P-1 (2-amino-6-methyldipyrido[1,2-a:3′,2′-*d*]imidazole),

suggesting that this class of compound was primarily responsible for the frameshift mutagenic activity of the condensate detected in TA98 (DeMarini *et al.*, 1995). In contrast, most of the mutations (78%) induced by CSC in TA100 were GC→TA transversions; this most closely resembled the mutation spectrum of a model PAH, benzo[*a*]pyrene (DeMarini *et al.*, 1995). GC→TA transversions are not only the primary class of base-substitution induced by cigarette-smoke condensate in TA100, but are also a primary class of base-substitution found in lung tumours of cigarette smokers (see Section 4.4.1(*b*)).

(*b*) *Cytogenetic effects of cigarette smoke and its condensate* in vitro

Data reviewed previously (IARC, 1986) and confirmed by Rutten and Wilmer (1986) have shown that cigarette smoke and its condensate induced sister chromatid exchange in mammalian cells in culture. Tobacco particulate matter has also been shown to induce structural and numerical chromosomal aberrations (Lafi & Parry, 1988) and micronuclei (Jones *et al.*, 1991) in cultured mammalian cells. Based on the lack of association between micronuclei induction and DNA adducts, Jones *et al.* (1991) suggested that the micronuclei were not induced by aromatic compounds but, perhaps, by a direct-acting agent that may induce small alkylations or damage caused by radicals in DNA. Jansson *et al*. (1986, 1988) and Curvall *et al.* (1985) showed that the neutral fractions and weakly acidic, semi-volatile components of cigarette-smoke condensate were the most potent inducers of sister chromatid exchange in cultured human lymphocytes. They identified a number of potential candidate compounds, most of which were alkylphenols and benzaldehydes (benzenes having vicinal oxygenation or a conjugated double bond), that may be responsible for this activity. Whole smoke also induced micronuclei in Chinese hamster V79 cells without a metabolic activation system (S9) (Massey *et al.*, 1998). In another study based on immunocytochemical antikinetochore staining, which allowed differentiation between the clastogenic and aneugenic action of cigarette smoke, V79 cells exposed to cigarette smoke appeared to be kinetochore-positive, suggesting that the micronuclei formed were due to aneuploidy rather than clastogenicity (Veltel & Hoheneder, 1996).

(*c*) *Cytogenetic effects of cigarette smoke* in vivo

As noted in the earlier review (IARC, 1986), exposure of rodents to cigarette smoke has generally produced sister chromatid exchange in the bone marrow. However, studies on the induction of chromosomal aberrations in pulmonary alveolar macrophages by exposure of rodents to cigarette smoke have produced some negative results (Lee, C.K. *et al.*, 1992, 1993) and one positive result (Rithidech *et al.*, 1989). Exposure of rodents to cigarette smoke has consistently produced micronuclei in polychromatic erythrocytes of the bone marrow (Balansky *et al.*, 1987; Mohtashamipur *et al*., 1987; Balansky *et al.*, 1988; Mohtashamipur *et al*., 1988; Stoichev *et al.*, 1993; Nersessian & Arutyunyan, 1994; Balansky *et al.*, 1999), in normochromatic erythrocytes in peripheral blood (Balansky *et al*., 1988, 1999) and in pulmonary alveolar macrophages (Balansky *et al.*, 1999).

(*d*) *DNA strand breaks*

Several studies have demonstrated that both cigarette smoke and its condensate can induce DNA strand breaks either in rodents, mammalian cells in culture or in DNA *in vitro* (Nakayama *et al.*, 1985; Willey *et al*., 1987; Fielding *et al.*, 1989; Leanderson & Tagesson, 1990; Bermudez *et al.*, 1994; Leanderson & Tagesson, 1994; Spencer *et al.*, 1995; Seree *et al.*, 1996; Yoshie & Ohshima, 1997; Liu *et al.*, 1999; Yang, Q. *et al.*, 1999). Cigarette smoke also induced nuclear accumulation of TP53 protein in mouse cells in culture, providing an indirect indication of DNA damage (Hess & Brandner, 1996). Collectively, these studies are consistent with the demonstrated clastogenicity of cigarette smoke and its condensate in experimental systems and humans. Several of these studies have indicated that reactive oxygen or nitrogen species formed in cigarette smoke and its condensate are the primary cause of the strand breaks.

(*e*) *Studies on cigarettes that primarily heat but not burn tobacco, and modified cigarettes*

Although cigarettes that primarily heat rather than burn tobacco (Borgerding *et al.*, 1998) are not generally available commercially, studies generally found that their smoke condensate was not mutagenic in *Salmonella* and did not induce sister chromatid exchange, chromosomal aberrations or *Hprt* mutations in Chinese hamster ovary cells or unscheduled DNA synthesis in rat cells (Doolittle *et al.*, 1989; deBethizy *et al.*, 1990; Doolittle *et al.*, 1990b; Bombick, B.R. *et al.*, 1997). Whole smoke from such cigarettes was also either non-mutagenic or only slightly mutagenic in *Salmonella* and a weak inducer of sister chromatid exchange in Chinese hamster ovary cells, and it was negative in rat bone marrow for chromosomal aberrations, micronuclei and sister chromatid exchange. The relative cytotoxic and genotoxic potential observed in Chinese hamster ovary cells exposed to the whole smoke from these cigarettes is likely to reside in the vapour phase (Lee *et al.*, 1990a,b; Bombick *et al.*, 1998). Humans who smoked these cigarettes produced urine that was ~70% less mutagenic than the urine of smokers of standard cigarettes (Doolittle *et al.*, 1990b; Smith *et al.*, 1996; Bowman *et al.*, 2002).

In 1990, ~20% of the ~5200 deaths from fires in the USA occurred in those started by cigarettes (Brunnemann *et al.*, 1994). The smoke condensate from an experimental cigarette that has low-ignition propensity, and is therefore less likely than regular cigarettes to ignite surrounding material, was as mutagenic as that of reference cigarettes (Brunnemann *et al.*, 1994). An experimental carbon filter that reduces the amounts of certain vapour-phase components of tobacco smoke relative to charcoal filters currently used in commercial cigarettes produced whole smoke that was less mutagenic in *Salmonella* and induced less sister chromatid exchange in Chinese hamster ovary cells than smoke from cigarettes with the usual type of charcoal filter; however, the genotoxicity of the resulting smoke condensate was not significantly different from that of the condensate from standard cigarettes (Bombick, D.W. *et al.*, 1997).

Masheri, a pyrolysed tobacco product mainly used in India to clean the teeth, induced chromosomal aberrations, sister chromatid exchange and micronuclei in bone-marrow cells of mice and *Hprt* mutations in Chinese hamster lung fibroblast V79 cells as well as mutations in *Salmonella* (Kulkarni *et al.*, 1987).

(*f*) *Transplacental effects*

Exposure of gestating mice to cigarette smoke showed that fetal liver, and peripheral blood and liver of newborn mice had elevated levels of micronuclei (Balansky & Blagoeva, 1989), and such exposure also induced sister chromatid exchange in mouse fetal liver (Karube *et al.*, 1989). Therefore, tobacco smoke contains clastogens that cross the mouse placental barrier and cause chromosomal damage in erythroblasts in fetal liver. Both tobacco smoke and its condensate have been shown to induce DNA deletions (reversion of the pink-eye unstable mutation) in the embryo of exposed mice (Jalili *et al.*, 1998).

(*g*) *Modulation of genotoxicity of tobacco smoke and cigarette-smoke condensate*

Many studies have examined the ability of various agents to modulate the genotoxicity of tobacco smoke or its condensate *in vitro* or in experimental animals. Studies in rodents exposed to tobacco smoke (De Flora *et al.*, 2003) or those in *Salmonella* exposed to cigarette-smoke condensate (Camoirano *et al.*, 1994; Romert *et al.*, 1994) have identified a variety of agents that either inhibit or modulate the genotoxicity of tobacco smoke and/or its condensate. Such agents include *N*-acetylcysteine, chlorophyllin, phenolic compounds, isothiocyanates, dithiocarbamates, indoles, tetrapyroles and flavonoids. As noted in Section 4.4.1(*a*)(v), some of these agents have been shown to modulate the formation of smoking-associated biomarkers in humans.

4.5 Mechanistic considerations

Classically, tobacco smoke has been described as acting both as a tumour initiator and a tumour promoter (IARC, 1986). In the light of recent developments in the understanding of the molecular effects of tobacco smoke, this knowledge can be extended to describe how genetic and epigenetic changes cooperate in tobacco-induced carcinogenesis.

The modern synthesis of molecular biology and cancer biology identifies at least six major pathways that must be disrupted for a normal cell to become a tumour cell. These include self-sufficiency in growth signals, insensitivity to anti-growth signals, evasion of apoptosis, tissue invasion and metastasis, sustained angiogenesis and limitless replicative potential. Disruption of these major pathways can occur through genetic or genomic alterations in well-defined genes or through a number of epigenetic processes, including methylation of DNA, post-translational modifications of proteins and modification of gene expression patterns (Hanahan & Weinberg, 2000). There is evidence that smoking is

associated with some of the genetic and epigenetic changes affecting these major pathways (Heusch & Maneckjee, 1998; Aoshiba *et al.*, 2001; Brandau & Bohle, 2001; Chang *et al.*, 2001; Forgacs *et al.*, 2001; Hittelman, 2001; Jull *et al.*, 2001; Kang & Park, 2001; Kim, D.H. *et al.*, 2001; Wistuba *et al.*, 2001). Some of these genetic and epigenetic changes have also been observed in smoking-associated diseases other than cancer, such as atherosclerosis and rheumatoid arthritis, indicating that these diseases share common pathways with cancer, and that these pathways are disrupted by tobacco smoke (Chen & Loo, 1995; Albano *et al.*, 2001; Wang, H. *et al.*, 2001).

Conceptually, the effects of tobacco smoke as a carcinogen can be viewed as the result of both genetic and epigenetic changes. Although epigenetic changes can trigger a complex, suppressive cellular stress response, genetic changes may endow some cells with a capacity to escape normal immunosuppression. Thus, the changes in the cellular environment inflicted by tobacco smoke may produce a selection procedure that favours the emergence of cells that have acquired the capacity to undergo clonal expansion. This phenomenon can occur simultaneously at several sites within an exposed tissue field, resulting in multifocal lesions, some of which can progress to cancer (field carcinogenesis).

Moreover, there is a remarkable convergence between the molecular changes induced by tobacco smoke summarized here, such as DNA damage and mutation, and recent experimental evidence for mechanisms of carcinogenesis. Collectively, these data support a multistep model of carcinogenesis in which the components of tobacco smoke are the direct cause of the cellular changes that accumulate to drive the carcinogenenic process.

The previous *IARC Monographs* on tobacco smoking (IARC, 1986) provided convincing evidence of the carcinogenicity of tobacco smoke. The present volume extends this evidence and provides compelling molecular data that explain some of the mechanisms by which tobacco smoke is carcinogenic. Most importantly, these data have largely been obtained from studies in humans, rather than in experimental animals. Thus, their relevance cannot be denied, and their explanatory powers cannot be easily dismissed.

5. Summary of Data Reported and Evaluation

5.1 Exposure data

Smoking of tobacco is practised worldwide by over one thousand million people. However, while smoking prevalence has declined in many developed countries, it remains high in others and is increasing among women and in developing countries. Between one-fifth and two-thirds of men in most populations smoke. Women's smoking rates vary more widely but rarely equal male rates.

Tobacco is most commonly smoked as cigarettes, both manufactured — which are a highly sophisticated nicotine-delivery system — and hand-rolled. Pipes, cigars, bidis and other products are used to a lesser extent or predominantly in particular regions. Cigarettes are made from fine-cut tobaccos which are wrapped in paper or a maize leaf. Cigars consist of cut tobacco filler formed in a binder leaf and with a wrapper leaf rolled spirally around the bunch. Bidis contain shredded tobacco wrapped in non-tobacco leaves, usually dried *temburni* leaves.

The chemical composition of tobacco smoke, although influenced by the specific manner in which individuals smoke, is primarily determined by the type of tobacco. It is also influenced by the design of the smoking device or product and, for cigarettes, by the presence or absence of filters, and by other factors including ventilation, paper porosity and types of additives. As a result, concentrations of individual chemicals in smoke vary. Analysis of the ways in which people smoke modern cigarettes shows that actual doses of nicotine, carcinogens and toxins depend on the intensity and method of smoking and have little relation to stated tar yields. The total volume of smoke drawn from cigarettes as a result of specific smoking patterns is the principal determinant of dose to the smoker. All presently available tobacco products that are smoked deliver substantial amounts of established carcinogens to their users.

The yields of tar, nicotine and carbon monoxide from cigarettes, as measured by standard machine-smoking tests, have fallen over recent decades in cigarettes sold in most parts of the world, but have remained higher in some countries. The tar and nicotine yields as currently measured are misleading and have only little value in the assessment of human exposure to carcinogens.

The regulation of smoking and smoke yields varies widely around the world in scope and degree of enforcement. Certain regulatory actions, such as taxes and workplace smoking bans, are effective in reducing smoking rates and protecting nonsmokers.

5.2 Human carcinogenicity data

In the previous 1986 *IARC Monograph* on tobacco smoking, cancers of the lung, oral cavity, pharynx, larynx, oesophagus (squamous-cell carcinoma), pancreas, urinary bladder and renal pelvis were identified as caused by cigarette smoking. Many more studies published since this earlier monograph support these causal links. In addition, there is now sufficient evidence for a causal association between cigarette smoking and cancers of the nasal cavities and nasal sinuses, oesophagus (adenocarcinoma), stomach, liver, kidney (renal-cell carcinoma), uterine cervix and myeloid leukaemia.

In cancer sites that were causally linked to cigarette smoking in the previous *IARC Monograph* on tobacco smoking, the observed relative risks ranged generally from approximately 3 for pancreatic cancer to more than 20 for lung cancer. For those cancer sites that were now also linked to cigarette smoking in this monograph, generally two- to threefold increased risks were observed.

Cigarettes

Lung

Lung cancer is the most common cause of death from cancer in the world. The total number of cases is now estimated to be 1.2 million annually and is still increasing. The major cause of lung cancer is tobacco smoking, primarily of cigarettes. In populations with prolonged cigarette use, the proportion of lung cancer cases attributable to cigarette smoking has reached 90%.

The duration of smoking is the strongest determinant of lung cancer in smokers. Hence, the earlier the age of starting and the longer the continuation of smoking in adulthood, the greater the risk. Risk of lung cancer also increases in proportion to the numbers of cigarettes smoked.

Tobacco smoking increases the risk of all histological types of lung cancer including squamous-cell carcinoma, small-cell carcinoma, adenocarcinoma (including bronchiolar/-alveolar carcinoma) and large-cell carcinoma. The association between adenocarcinoma of the lung and smoking has become stronger over time. The carcinogenic effects of cigarette smoking appear similar in both women and men.

Stopping smoking at any age avoids the further increase in risk of lung cancer incurred by continued smoking. The younger the age at cessation, the greater the benefit.

Urinary tract

Tobacco smoking is a major cause of transitional-cell carcinomas of the bladder, ureter and renal pelvis. Risk increases with the duration of smoking and number of cigarettes smoked. As for lung cancer, stopping smoking at any age avoids the further increase in risk incurred by continued smoking.

Evidence from several cohort and case–control studies published since the previous *IARC Monograph* on tobacco smoking has indicated that renal-cell carcinoma is associated with tobacco smoking in both men and women. The association is not explained by

confounding. A dose–response relationship with the number of cigarettes smoked has been noted in most studies, and a few also noted a reduction in risk after cessation.

Oral cavity

Tobacco smoking, including cigarette smoking, is causally associated with cancer of the oral cavity (including lip and tongue) in both men and women. Since the previous *IARC Monograph* on tobacco smoking, evidence from many more studies has accumulated that further confirms this association. Use of smokeless tobacco and/or alcohol in combination with tobacco smoking greatly increases the risk of oral cancer. Risk increases substantially with duration of smoking and number of cigarettes smoked. Risk among former smokers is consistently lower than among current smokers and there is a trend of decreasing risk with increasing number of years since quitting.

Nasal cavity and paranasal sinuses

An increased risk of sinonasal cancer among cigarette smokers has been reported in all nine case–control studies for which results are available. Of seven studies that have analysed dose–response relationships, a positive trend was found in five and was suggested in the other two. In all the five studies that have analysed squamous-cell carcinoma and adenocarcinoma separately, the relative risk was clearly increased for squamous-cell carcinoma.

Nasopharynx

An increased risk for nasopharyngeal cancer among cigarette smokers was reported in one cohort study and nine case–control studies. Increased relative risks were reported in both high- and low-risk geographical regions for nasopharyngeal cancer. A dose–response relationship was detected with either duration or amount of smoking. A reduction in risk after quitting was also detected. The potential confounding effect of infection with Epstein–Barr virus was not controlled for in these studies; however, such an effect was not considered to be plausible. No important role was shown for other potential confounders.

Oropharynx and hypopharynx

Oropharyngeal and hypopharyngeal cancer are causally associated with cigarette smoking. The risk increased with increased duration of smoking and daily cigarette consumption and decreased with increasing time since quitting.

Oesophagus

Tobacco smoking is causally associated with cancer of the oesophagus, particularly squamous-cell carcinoma. Tobacco smoking is also causally associated with adenocarcinoma of the oesophagus. In most of the epidemiological studies, the risk for all types of oesophageal cancer increased with numbers of cigarettes smoked daily and duration of smoking. However, risk for oesophageal cancer remains elevated many years after cessation of smoking.

Tobacco and alcohol in combination with tobacco smoking greatly increase the risk for squamous-cell carcinoma of the oesophagus. In India, use of smokeless tobacco in combination with smoking also greatly increases the risk.

Larynx

Laryngeal cancer is causally associated with cigarette smoking. The risk increases substantially with duration and number of cigarettes smoked. Use of alcohol in combination with tobacco smoking greatly increases the risk for laryngeal cancer. A few studies also reported that relative risks for cancer of the larynx increased with decreasing age at start of smoking. The relative risk decreased with increasing time since quitting smoking.

Pancreas

Cancer of the pancreas is causally associated with cigarette smoking. The risk increases with duration of smoking and number of cigarettes smoked daily. The risk remains elevated after allowing for potential confounding factors such as alcohol consumption. The relative risk decreased with increasing time since quitting smoking.

Stomach

The data available in 1986 did not permit the earlier IARC Working Group to conclude that the association between tobacco smoking and stomach cancer was causal. Since that time, further studies have shown a consistent association of cancer of the stomach with cigarette smoking in both men and women in many cohort and case–control studies conducted in various parts of the world. Confounding by other factors (e.g. alcohol consumption, *Helicobacter pylori* infection and dietary factors) can be reasonably ruled out. Risk increases with duration of smoking and number of cigarettes smoked, and decreases with increasing duration of successful quitting. In studies that had adequate numbers, the relative risks for men and women were similar.

Liver

In the previous *IARC Monograph* on tobacco smoking, a causal relationship between liver cancer and smoking could not be established, chiefly due to possible confounding from alcohol intake and hepatitis B and hepatitis C virus infections. Many cohort studies and case–control studies have provided additional information on smoking and liver cancer since then. Most of the cohort studies and the largest case–control studies (most notably those that included community controls) showed a moderate association between tobacco smoking and risk of liver cancer. In many studies, the risk for liver cancer increased with the duration of smoking or the number of cigarettes smoked daily. Former smokers who had stopped smoking for more than 10 years showed a decline in liver cancer risk. Confounding from alcohol can be ruled out, at least in the best case–control studies, by means of careful adjustment for drinking habits. An association with smoking has also been demonstrated among non-drinkers. Many studies, most notably from Asia, have shown no attenuation of the association between smoking and liver cancer after adjustment/strati-

fication for markers of hepatitis B/hepatitis C virus infection. There is now sufficient evidence to judge the association between tobacco smoking and liver cancer as causal.

Cervix

An association of invasive cervical squamous-cell carcinoma with smoking has been observed in the large number of studies reviewed. The most recent studies have controlled for infection with human papillomavirus, a known cause of cervical cancer. The effect of smoking was not diminished by the adjustment for human papillomavirus infection, or analysis restricted to cases and controls both positive for human papillomavirus (as ascertained by human papillomavirus DNA or human papillomavirus serological methods). There is now sufficient evidence to establish a causal association of squamous-cell cervical carcinoma with smoking. In the small number of studies available for adeno- and adenosquamous-cell carcinoma, no consistent association was observed.

Leukaemia

Myeloid leukaemia in adults was observed to be causally related to smoking. Risk increased with amount of tobacco smoked in a substantial number of adequate studies. No clear evidence of any risk was seen for lymphoid leukaemia/lymphoma.

Support for a causal relationship of smoking with myeloid leukaemia is provided by the finding of known leukaemogens in tobacco smoke, one of which (benzene) is present in sufficient amounts to account for up to half of the estimated excess of acute myeloid leukaemia.

Colorectal cancer

There is some evidence from prospective cohort studies and case–control studies that the risk of colorectal cancer is increased among tobacco smokers. However, it is not possible to conclude that the association between tobacco smoking and colorectal cancer is causal. Inadequate adjustment for various potential confounders could account for some of the small increase in risk that appears to be associated with smoking.

Female breast

Most epidemiological studies have found no association with active smoking, after controlling for established risk factors (e.g. age at time of first birth, parity, family history of breast cancer and alcohol). The large multicentre pooled analysis of the association of smoking with breast cancer in non-drinkers confirms the lack of an increased risk of breast cancer associated with smoking.

Endometrium

Cigarette smoking is not associated with an increased risk for endometrial cancer.

An inverse relationship of cigarette smoking with endometrial cancer is observed consistently in most case–control and cohort studies, after adjustment for major confounders. This pattern is stronger in post-menopausal women.

Prostate

No clear evidence of any risk for prostate cancer is seen in case–control studies or in studies of incident cases in cohort studies. The small excess observed in some analytical mortality studies can reasonably be explained by bias in the attribution of the underlying cause of death.

Other

There is inconsistent and/or sparse evidence for association between cigarette smoking and other cancer sites that were considered by the Working Group.

Cigars and pipes

Cigar and/or pipe smoking is strongly related to cancers of the oral cavity, oropharynx, hypopharynx, larynx and oesophagus, the magnitude of risk being similar to that from cigarette smoking. These risks increase with the amount of cigar and/or pipe smoking and with the combination of alcohol and tobacco consumption. Cigar and/or pipe smoking is causally associated with cancer of the lung and there is evidence that cigar and/or pipe smoking are also causally associated with cancers of the pancreas, stomach and urinary bladder.

Bidi

Bidi smoking is the most common form of tobacco smoking in India and is also prevalent in other south-Asian countries and an emerging problem in the USA. Bidi smoke was considered as carcinogenic in the earlier *IARC Monograph* on tobacco smoking, and later studies have provided further evidence of causality. Case–control studies demonstrated a strong association at various sites: oral cavity (including subsites), pharynx, larynx, oesophagus, lung and stomach. Almost all studies show significant trends with duration of bidi smoking and number of bidis smoked.

Synergy

For public health purposes, synergy should be characterized as a positive departure from additivity. The epidemiological literature often inadequately describes combined effects of smoking with co-exposures to other carcinogenic agents and in many studies power is limited for characterizing combined effects. The issue of synergistic effects can be appropriately addressed by epidemiological studies that show stratified analysis and have sufficient power. The studies reviewed found evidence of synergy between smoking and several occupational causes of lung cancer (arsenic, asbestos and radon), and between smoking and alcohol consumption for cancers of the oral cavity, pharynx, larynx and oesophagus and between smoking and human papillomavirus infection for cancer of the cervix. Data were inadequate to evaluate the evidence for synergy between smoking and other known causes of cancer (e.g. hepatitis B and alcohol for liver cancer).

5.3 Animal carcinogenicity data

Cigarette smoke has been tested for carcinogenicity by inhalation studies in rodents, rabbits and dogs. The model systems for animal exposure to tobacco smoke do not fully simulate human exposure to tobacco smoke, and the tumours that develop in animals are not completely representative of human cancer. Nevertheless, the animal data provide valuable insights regarding the carcinogenic potential of tobacco smoke.

The most compelling evidence for a positive carcinogenic effect of tobacco smoke in animals is the reproducible increase observed in several studies in the occurrence of laryngeal carcinomas in hamsters exposed to whole tobacco smoke or to its particulate phase. In four of five studies in rats, exposure to whole smoke led to modest increases in the occurrence of malignant and/or benign lung tumours. Similarly, in four of eight studies in mice of varying susceptibility to lung tumour development, exposure to whole smoke led to a modest increase in the frequency of lung adenomas. An increased incidence of lung 'tumours' has also been reported in dogs exposed to tobacco smoke, but it is uncertain whether the histopathological features of the lesions are consistent with malignancy. In hamsters exposed to both cigarette smoke and chemical carcinogens (*N*-nitrosodiethylamine and 7,12-dimethylbenz[*a*]anthracene), the tumour response in the respiratory tract was higher than in hamsters exposed to either agent alone. The same is true in rats exposed simultaneously to cigarette smoke and radionuclides (radon progeny and plutonium oxide).

Cigarette smoke condensate both initiates and promotes tumour development in animals. It reproducibly induces both benign and malignant skin tumours in mice following topical application. Similarly, it produces skin tumours in rabbits following topical application. Topical application to the oral mucosa also produced an increased incidence of lung tumours and lymphomas in mice. In rats, cigarette smoke condensate produced lung tumours after intrapulmonary injection. In initiation/promotion assays in mouse skin, a single topical application of cigarette smoke condensate followed by application of croton oil was sufficient to initiate both benign and malignant skin tumours. Smoke condensates of Indian bidi administered to mice by gavage were found to induce tumours in a number of organs. Collectively, these data provide evidence of the carcinogenic effect of mainstream tobacco smoke in experimental animals.

5.4 Other relevant data

Causal associations have been clearly established between active smoking and adverse reproductive outcomes and numerous non-neoplastic diseases, including chronic obstructive pulmonary disease and cardiovascular diseases.

Tobacco smoking is addictive, and nicotine has been established as the major addictive constituent of tobacco products. Measurement of the nicotine metabolite, cotinine, in human blood, urine or saliva provides a specific and sensitive test for exposure to tobacco smoke and can be used to distinguish active and passive smokers from nonsmokers.

Active smoking raises the concentrations of carbon monoxide, benzene and volatile organic compounds in exhaled air. The concentrations of urinary metabolites of some important tobacco smoke carcinogens and related compounds are consistently higher in smokers than in nonsmokers. These include metabolites of benzene, a known carcinogen in humans, as well as metabolites of several carcinogens that cause lung tumours in rodents. Covalent binding to blood proteins by carcinogens present in tobacco smoke has been demonstrated to occur at significantly higher levels in smokers than in nonsmokers. The adducts are derived from various compounds including aromatic amines (e.g. 4-aminobiphenyl), polycyclic aromatic hydrocarbons (e.g. benzo[*a*]pyrene), tobacco-specific nitrosamines (e.g. 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone), benzene, acrylamide and acrylonitrile.

Smoking-related DNA adducts have been detected by a variety of analytical methods in the respiratory tract, urinary bladder, cervix and other tissues. In many studies the levels of carcinogen–DNA adducts have been shown to be higher in tissues of smokers than in tissues of nonsmokers. Some but not all studies have demonstrated elevated levels of these adducts in the peripheral blood and in full-term placenta. Smoking-related adducts have also been detected in cardiovascular tissues. Collectively, the available biomarker data provide convincing evidence that carcinogen uptake, activation and binding to cellular macromolecules, including DNA, are higher in smokers than in nonsmokers.

The exposure of experimental animals, primarily rodents, to mainstream tobacco smoke results in a number of biological effects that include (i) increases or decreases in the activities of phase I and phase II enzymes involved in carcinogen metabolism, (ii) increases in the activation of antioxidant enzymes, (iii) increased expression of nitric oxide synthase and of various protein kinases and collagenase, (iv) the formation of tobacco smoke-related DNA adducts in several tissues and (v) reduced clearance of particulate material from the lung.

Smoking is known to have inhibitory or inducing effects on the activities of many enzymes in human tissues. These include xenobiotic metabolizing enzymes, which affect drug and carcinogen metabolism. Numerous studies have reported effects on enzymes in cells treated in culture with tobacco smoke or tobacco smoke condensates.

In humans, smoking produces gene mutations and chromosomal abnormalities. Urine from smokers is mutagenic. Relative to nonsmokers, lung tumours of smokers contain higher frequencies of *TP53* and *KRAS* mutations, and the spectrum of mutations has unique features. Most of the genetic effects seen in smokers are also observed in cultured cells or in experimental animals exposed to tobacco smoke or smoke condensate. Tobacco smoke is genotoxic in humans and in experimental animals.

5.5 Evaluation

There is *sufficient evidence* in humans that tobacco smoking causes cancer of the lung, oral cavity, naso-, oro- and hypopharynx, nasal cavity and paranasal sinuses, larynx, oesophagus, stomach, pancreas, liver, kidney (body and pelvis), ureter, urinary bladder, uterine cervix and bone marrow (myeloid leukaemia).

There is *evidence suggesting lack of carcinogenicity* of tobacco smoking in humans for cancers of the female breast and endometrium.

There is *sufficient evidence* in experimental animals for the carcinogenicity of tobacco smoke and tobacco smoke condensates.

Overall evaluation

Tobacco smoking and tobacco smoke *are carcinogenic to humans (Group 1)*.

INVOLUNTARY SMOKING

1. Composition, Exposure and Regulations

1.1 Composition

1.1.1 *Secondhand smoke*

During smoking of cigarettes, cigars, pipes and other tobacco products, in addition to the mainstream smoke drawn and inhaled by smokers, a stream of smoke is released between puffs into the air from the burning cone. Once released, this stream (also known as the sidestream smoke) is mixed with exhaled mainstream smoke as well as the air in an indoor environment to form the secondhand smoke to which both smokers and nonsmokers are exposed. A small additional contribution to the smoke issues from the tip of the cigarette and through the cigarette paper during puffing and through the paper and from the mouth end of the cigarette between puffs (IARC, 1986; NRC, 1986; US EPA, 1992). Thus, secondhand tobacco smoke is composed of aged exhaled mainstream smoke and diluted sidestream smoke.

Secondhand tobacco smoke contains a variable proportion of exhaled mainstream smoke ranging from 1 to 43% (Baker & Proctor, 1990). Because of its rapid dilution and dispersion into the indoor environment, secondhand tobacco smoke acquires different physicochemical properties to those of mainstream smoke and sidestream smoke and the concentrations of the individual constituents are decreased. The principal physical change is a decrease in the proportion of smoke constituents found in the particulate phase as opposed to the vapour phase of the smoke. The median particle size of secondhand tobacco smoke is subsequently smaller than that of the particles of mainstream smoke. The principal chemical change is in the composition (i.e. in the relative quantities of the individual constituents present); this is caused by differences in the ways in which individual constituents respond to ventilation and to contact with indoor surfaces. There is some indication that chemical transformation of reactive species also occurs.

The effects of exposure to secondhand tobacco smoke, or involuntary (passive) smoking, cannot be estimated from any individual constituents. Secondhand tobacco smoke is actually a complex mixture, containing many compounds for which concentrations can vary with time and environmental conditions. Cigarette smoking is the main source for involuntary exposure because it is by far the most prevalent form of tobacco smoking although specific patterns may differ between countries. Emissions of sidestream smoke in indoor environments with low ventilation rates can result in concentrations of

toxic and carcinogenic agents above those generally encountered in ambient air in urban areas (IARC, 1986; Jenkins *et al.*, 2000).

Studies on the complex composition of secondhand tobacco smoke in 'real world' conditions have been limited partly because of the presence of additional sources of secondhand smoke constituents. Therefore compositional and physical studies of secondhand tobacco smoke have often been performed in environmental chambers (also known as a 'controlled experimental atmosphere'). The disadvantage of the controlled experimental atmosphere is that it does not reflect real life situations. The studies of the chemical composition of secondhand tobacco smoke, either in a controlled experimental atmosphere or in the field, have been limited. This is mainly because there are still no standardized criteria for the development of experimental atmospheres that represent secondhand tobacco smoke (Jenkins *et al.*, 2000).

Respirable suspended particles (only those particles that are small enough to reach the lower airways of the human lung) can exist in many forms in indoor air: those resulting from secondhand tobacco smoke are present in the form of liquid or waxy droplets. They are smaller than the particles in mainstream smoke. The mass median diameter of mainstream smoke particles averages 0.35–0.40 μm. Gravimetric determination indicates that the respirable suspended particles of secondhand tobacco smoke in typically encountered environments may comprise one-third of the respirable suspended particles in indoor air. However, in some environments, this fraction may be as much as two-thirds (Jenkins *et al*., 2000).

Respirable suspended particle concentrations of 4091 $\mu g/m^3$ were measured in an experimental room in which 120 cigarettes were smoked during 9 hours in 1 day for the evaluation of exposure to benzene and other toxic compounds (Adlkofer *et al*., 1990).

Worldwide in indoor environments where people smoke, the mean levels of respirable suspended particles ranged from 24 to 1947 $\mu g/m^3$. Background levels of respirable suspended particles depend on many factors including local vehicular traffic patterns, quality of ventilation systems and the presence of other sources (e.g. cooking and wood-burning stoves). Comparisons between smoking and nonsmoking locations revealed up to threefold higher concentrations of respirable suspended particles in smoking areas. The US EPA-proposed maximal level for fine particles in outdoor ambient air (65 $\mu g/m^3$ particulate matter, that is 2.5 μm or smaller in size, for 24 h) is frequently exceeded in indoor situations where people are smoking (Jenkins *et al*., 2000).

Besides respirable suspended particles and nicotine (see Section 1.2), carbon monoxide (CO) has been the most extensively studied constituent of secondhand tobacco smoke. The contemporary commercial cigarettes in the USA deliver approximately 15 mg CO in mainstream smoke and an additional 50 mg in sidestream smoke (Jenkins *et al*., 2000). In an indoor environment, CO concentrations are rapidly diluted. The measured mean concentrations reported for CO in offices, other workplaces, functions and public gatherings, transportation, restaurants and cafeterias, bars and taverns where people smoke ranged from 0.2 to 33 ppm. The American Society of Heating, Refrigerating and

Air-Conditioning Engineers (ASHRAE) standard for CO concentration in indoor air is 9 ppm (Jenkins *et al*., 2000).

The mean levels of nitric oxide (NO) in indoor areas were reported from not detected to 500 ppb and those of nitrogen dioxide (NO_2) from not detected to 76 ppb (Jenkins *et al*., 2000).

There are a number of studies that have addressed the composition of secondhand tobacco smoke beyond the 'common' constituents such as nicotine, CO and respirable suspended particles. A few of these are shown in Table 1.1 (Eatough *et al*., 1989; Löfroth *et al*. 1989; Higgins *et al.*, 1990; Löfroth, 1993; Martin *et al*., 1997). The focus of these studies was primarily on vapour-phase constituents. Vapour phase represents the bulk of the mass of secondhand tobacco smoke whereas the respirable suspended particle-related constituents are present at very low concentrations that are very difficult to quantify. For example, if the levels of respirable suspended particles are in the range of 20 to 1000 $\mu g/m^3$, constituents of the particulate phase present at concentrations of 1–100 ppm in the particles themselves will be present at airborne concentrations from 20 pg/m^3 to 100 ng/m^3. These are very low concentrations for detection by any sampling and analysis method (Jenkins *et al*., 2000).

As can be seen from the data in Table 1.1, the field studies show considerable variation in the measured levels of constituents of secondhand tobacco smoke. Similar concentrations of benzene and isoprene to those shown in Table 1.1 were reported in a smoke-filled bar (from 26 to 36 $\mu g/m^3$ and 80–106 $\mu g/m^3$, respectively), although the nicotine levels were much lower (22 $\mu g/m^3$). The concentration of 1,3-butadiene measured in the smoke-filled bar was from 2.7 to 4.5 $\mu g/m^3$ (Brunnemann *et al*., 1990). In a field study of 25 homes of smokers, Heavner *et al*. (1995) estimated that the median fraction of benzene contributed by secondhand tobacco smoke was 13% (ranging from 0 to 63%).

In a study of six homes of smokers, secondhand tobacco smoke was found to make a substantial contribution to the concentrations of 1,3-butadiene (Kim *et al*., 2001).

The levels of carbonyl compounds measured in an experimental room under extremely high concentrations of secondhand tobacco smoke (Adlkofer *et al*., 1990) were: formaldehyde, 49 $\mu g/m^3$; acetaldehyde, 1390 $\mu g/m^3$ and propionaldehyde, 120 $\mu g/m^3$. The concentrations of other constituents of secondhand tobacco smoke were: nicotine, 71 $\mu g/m^3$; benzene, 206 $\mu g/m^3$; benzo[*a*]pyrene, 26.7 ng/m^3; pyrene, 25 ng/m^3 and chrysene, 70.5 ng/m^3.

Benzo[*a*]pyrene was also detected in natural environments containing secondhand tobacco smoke, with concentrations ranging from not detected to 3.6 ng/m^3 (or up to 3.35 ng/m^3 when the background concentration was subtracted) (Jenkins *et al*., 2000). Trace levels of some other polycyclic aromatic hydrocarbons (PAHs; such as naphthalene, chrysene, anthracene, phenanthrene and benzofluoranthenes) were also reported. The vapour-phase 2- to 3-ring PAHs predominate quantitatively over the higher-ring system PAHs.

Table 1.1. Concentrations (in μg/m^3) of selected constituents of secondhand tobacco smoke in some experimental and real-life situations[a]

Constituent	18-m^3 chamber: mean for 50 best-selling US cigarettes (Martin *et al.*, 1997)	Living quarters (Löfroth, 1993)	Tavern (Löfroth *et al.*, 1989)	Discothèque (Eatough *et al.*, 1989)	Home (Higgins *et al.*, 1990)

Modified from Jenkins *et al*. (2000)

–, not reported

[a] These are not typical average concentrations, but represent the higher end of the exposure scale.

[b] Fine particles (< 2 μm size)

The levels of *N*-nitrosodimethylamine (NDMA) measured in the field (e.g. in workrooms, conference rooms, restaurants and bars where people smoked) ranged from less than 10 ng/m^3 to 240 ng/m^3 (Jenkins *et al*., 2000). In unventilated offices in which 11–18 cigarettes were smoked during a 2-h period, up to 8.6 ng/m^3 *N*-nitrosodiethylamine (NDEA) and up to 13 ng/m^3 *N*-nitrosopyrrolidine (NPYR) were measured.

The *N*′-nitrosonornicotine (NNN) concentrations measured in a poorly ventilated office where heavy smoking of cigarettes, cigars and pipes took place ranged from not detected to 6 ng/m^3 and those of 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) from not detected to 13.5 ng/m^3 (Klus *et al*., 1992). The upper levels reported by Klus *et al*. (1992) and by Adlkofer *et al*. (1990) for the 'heavily smoked rooms' (11 cigarettes smoked in 2 h in a 84 m^2 office) were somewhat lower than those measured by Brunnemann *et al.* (1992): NNN concentrations ranged from not detected to 22.8 ng/m^3 and NNK concentrations between 1.4 and 29.3 ng/m^3, measured inside bars, restaurants, trains, and a car, an office and a smoker's home (Brunnemann *et al*., 1992).

The effects of cigar smoking on indoor levels of CO, respirable suspended particles and particle-bound PAH particles were investigated in an office where several brands of cigar were machine smoked, in a residence where two cigars were smoked by a person and at cigar social events where up to 18 cigars were smoked at a time. The average concentrations of CO at cigar social events were comparable with, or larger than, those measured on a main road during rush-hour traffic. A mass balance model developed for predicting secondhand tobacco smoke was used in this study to obtain CO, respirable suspended particle and PAH emission. These factors show that cigars can be a stronger source of CO than cigarettes. In contrast, cigars may have lower emissions of respirable suspended particles and PAHs per gram of tobacco consumed than cigarettes, but the greater size and longer smoking time of a single cigar results in greater total respirable suspended particle and PAH emission than from a single cigarette (Klepeis *et al.*, 1999). Nelson *et al*. (1997) tested six brands of cigar and the yields of respirable suspended particles averaged 52 mg/cigar. Yields of CO, nitric oxide (NO) and nitrogen dioxide (NO_2) averaged 32, 10.5 and 2.1 mg/cigar, respectively, and that of volatile organic compounds (VOC) (analysed with gas chromatograph-flame ionization detection (FID)) was estimated to be 340 mg/cigar (propane equivalent). Ratios of secondhand tobacco smoke respirable suspended particles to the surrogate standards for the particulate markers ultraviolet particulate matter (UVPM) and fluorescent particulate matter (FPM) were 6.5 and 27.8, respectively. Another particulate marker, solanesol, made up 2.1% of the particles from cigars. For the two gas-phase markers, the ratio of 3-ethenyl pyridine to other gas-phase species was more consistent than ratios involving nicotine.

The comparative analysis of the composition of secondhand tobacco smoke from Eclipse (a cigarette that primarily heats tobacco rather than burning it) and from four commercial cigarettes with a wide range of Federal Trade Commission (FTC) yields is shown in Table 1.2 (Bombick *et al*., 1998). Eclipse contributed similar amounts of CO to secondhand tobacco smoke to those contributed by burning-tobacco cigarettes but contributed 86–90% less respirable suspended particles. Commercial cigarettes, however,

Table 1.2. Mean concentrations (in μg/m^3) of selected components of secondhand smoke of four commercial cigarette brands and Eclipse[a] measured in a chamber with a controlled experimental atmosphere

Constituent	Full-flavour brand	Full-flavour light	100-mm brand	Ultra-light	Eclipse
Respirable suspended particles	1458	1345	1706	1184	181
Nicotine	54	63	58	51	4.3
CO (ppm)	6.5	6.2	7.9	6.6	5.2
3-Ethenylpyridine	25	28	28	34	0.56
Acetaldehyde	313	301	384	312	46

Total hydrocarbons[b]	2.6	2.6	3.0	2.8	0.47

From Bombick *et al*. (1998)

[a] A cigarette that primarily heats (rather than burns) tobacco

[b] Analysed with gas chromatograph–flame ionizing detector (ppm)

contributed a similar amount of constituents to secondhand tobacco smoke, regardless of their ranking on the FTC scale.

1.1.2 *Exhaled mainstream smoke*

Baker and Proctor (1990) estimated that exhaled mainstream smoke contributes 3–11% of CO, 15–43% of particles and 1–9% of nicotine to secondhand tobacco smoke. Non-inhaling smokers can contribute larger amounts. There is little information on how much exhaled mainstream smoke contributes to the overall composition of secondhand tobacco smoke except that the contribution to the particulate phase is more significant than that to the vapour phase (see monograph on tobacco smoke/Section 4 — breath compounds).

1.1.3 *Sidestream smoke*

The composition of cigarette sidestream smoke is similar to that of mainstream smoke. However, the relative quantities of many of the individual constituents of sidestream smoke are different from those found in mainstream smoke. Also, the absolute quantities of most of the constituents released in sidestream smoke differ from those delivered in mainstream smoke (Jenkins *et al.*, 2000).

Like mainstream cigarette smoke, sidestream smoke contains many compounds that are emitted as gases and particles. The distinction between particle and vapour-phase constituents is appropriate for those constituents that are non-volatile (e.g. high-mole-

cular-weight organic compounds and most metals) and those that are clearly gases (e.g. CO). Constituents with appreciable vapour pressure (i.e. most of the constituents of tobacco smoke) can be found in both the particulate phase and the vapour phase of cigarette smoke. The term 'semivolatiles' has been used to describe such constituents. The degree to which these compounds are distributed between the particle and vapour phases is determined by their volatility (and stability) and the characteristics of their environment. These constituents are distributed preferentially in the particulate phase in highly concentrated smokes, such as those inhaled by smokers, and preferentially in the particle and vapour phases in highly diluted smokes, such as those encountered by involuntary smokers. The phase distribution and the ultimate fate of any given constituent released into the ambient environment is likely to differ depending upon ambient conditions and upon the chemical or physical properties of that constituent.

The manner in which cigarettes are smoked greatly influences their mainstream delivery and sidestream emissions. For the different machine-smoking protocols referred to in this monograph, see Table 1.9 in the monograph on tobacco smoke. Particulate matter that is released in mainstream smoke during active smoking enters the respiratory tract largely intact, whereas the particulate matter in sidestream smoke is available for inhalation only after dilution in ambient air and after the physical and chemical changes that occurred during that dilution. However, conventional analysis of sidestream smoke provides only information on the quantities of individual smoke constituents released into the air. Moreover, the methods for analysis of sidestream smoke are not as well defined as those for mainstream smoke (Jenkins *et al.*, 2000).

As they leave the cigarette, sidestream smoke particles are initially slightly smaller than mainstream smoke particles (geometric mean diameter, 0.1 μm versus 0.18 μm; Guerin *et al*., 1987). The natural dissipation rates of sidestream smoke particles dispersed in an experimental chamber were studied from the standpoint of a static atmosphere and were expressed as half-lives of residence in the air. The half-lives for particles with diameters less than 0.3 μm, 0.3–0.5 μm and 0.5–1 μm were found to be 25.5, 12.8 and 4.9 h, respectively. Total particulate matter decreased by half over 6.2 h (Vu Duc & Huynh, 1987). However in real-life situations the ageing of sidestream smoke over several minutes may lead to an increase in particle size of secondhand tobacco smoke due to the coagulation of particles and the removal of smaller particles that attach to surfaces in the environment. Sidestream smoke is produced at generally lower temperatures and with a very different oxygen flux to that of mainstream smoke.

The ratio of sidestream smoke to mainstream smoke is customarily used to express the distribution of individual constituents between the two smoke matrices. The distribution of specific components is dependent on their mechanism of formation. Higher ratios of sidestream smoke to mainstream smoke between cigarettes or smoking conditions generally reflect a lower mainstream smoke delivery with no significant change in sidestream smoke delivery. Under similar smoking conditions, filter-tipped cigarettes will have lower mainstream smoke yields than their untipped analogues. Sidestream smoke yields will not vary greatly, because they reflect the weight of tobacco burned during

smouldering. In general, more tobacco is burned during smouldering than during puffing (Guerin *et al.*, 1987).

Adams *et al.* (1987) reported that sidestream smoke contains more alkaline and neutral compounds than mainstream smoke (the pH of the sidestream smoke of cigarettes with a wide range of FTC yields averaged 7.5 [7.2–7.7], whereas the pH of mainstream smoke averaged 6.1 [6.0–6.3]). The differences are due to temperature during burning and mechanisms of chemical transfer (release) from unburned tobacco.

Many constituents of sidestream smoke belong to chemical classes known to be genotoxic and carcinogenic. These include the IARC group 1 carcinogens benzene, cadmium, 2-aminonaphthalene, nickel, chromium, arsenic and 4-aminobiphenyl; the IARC group 2A carcinogens formaldehyde, 1,3-butadiene and benzo[*a*]pyrene; and the IARC group 2B carcinogens acetaldehyde, isoprene, catechol, acrylonitrile, styrene, NNK, NNN and lead among others.

Adams *et al*. (1987) determined the levels of selected toxic and carcinogenic agents in the mainstream and sidestream smoke of four different types of US commercial cigarette brands — untipped and filter-tipped — with a wide range of FTC yields. In this study, smoke was generated by a machine using the standard FTC method. The concentrations of all agents except NNN were higher in the sidestream than in the mainstream smoke of both untipped and filter-tipped brands. The tar yields in sidestream smoke ranged from 14 to 24 mg per cigarette (similar to the range reported by Ramsey *et al*., 1990) and were, on average, 5.3 times higher than those in mainstream smoke. The highest sidestream smoke/mainstream smoke ratio for tar was calculated for ultra low-yield cigarettes (ratio, 15.7) and the lowest for untipped cigarettes (ratio, 1.12). The mainstream smoke yields are strongly affected by variables that only slightly affect sidestream smoke yields (Guerin *et al*., 1987). The ratios of sidestream smoke to mainstream smoke for nicotine, CO and NNK for the ultra low-yield brand were 21.1, 14.9 and 22.3, respectively. The highest emissions of nicotine, NNK and NNN were measured in the sidestream smoke of untipped cigarettes (4.62 mg, 1444 ng and 857 ng, respectively). In mainstream smoke, these values were 2.04 mg, 425 ng and 1007 ng, respectively. The levels of volatile *N*-nitrosamines in sidestream smoke greatly exceeded those measured in mainstream smoke (e.g. 735 ng versus 31.1 ng NDMA per untipped cigarette and 685 ng versus 4.1 ng NDMA for ventilated filter-tipped cigarettes; average ratio, 95). The average ratio of sidestream smoke to mainstream smoke for the carcinogen NPYR was 10. The authors concluded that the availability of cigarettes with greatly reduced amounts of carcinogens in mainstream smoke had little bearing on the emissions of carcinogens in sidestream smoke.

Chortyk and Schlotzhauer (1989) compared the emissions of various smoke components for 19 low-yield brands of filter-tipped cigarettes with those measured for a reference high-yield untipped brand. It was found that low-yield cigarettes produced large quantities of tar in sidestream smoke, about equal to that of the high-yield cigarette. On an equal weight basis, the low-tar cigarettes emitted more of these hazardous compounds into sidestream and secondhand smoke than did the high-tar cigarette.

The yields of various constituents of sidestream smoke of 15 Canadian cigarette brands measured using the FTC machine-smoking protocol with the exception that cigarettes were smoked to a butt length of 30 mm, ranged as follows: tar, from 15.8 to 29.3 mg per cigarette in non-ventilated brands and from 24.2 mg to 36.0 mg in ventilated brands; nicotine, from 2.7 mg to 4.6 mg in non-ventilated brands and 3.0 mg to 6.1 mg in ventilated brands, and CO, from 40.5 mg to 67.3 mg in non-ventilated brands and 46.5 mg to 63.1 mg in ventilated brands. Yields in sidestream smoke were much higher than those in mainstream smoke for all brands tested. The average ratios for sidestream smoke to mainstream smoke were 3.5, 6.6 and 6.8 for tar, nicotine and CO, respectively. The highest yields from sidestream smoke were obtained from the brands with the lowest mainstream smoke yields (Rickert *et al*., 1984). The concentrations of carbon monoxide in the sidestream smoke in the Canadian cigarettes were higher than those reported for four different types of American blend cigarettes smoked according to the FTC protocol (Adams *et al*., 1987). Differences in the tobacco blend may be one explanation for this discrepancy and Canadian cigarettes are made predominantly from flue-cured tobacco.

The average yields of total particulate matter and nicotine in sidestream smoke generated by the machine-smoking of two cigarette brands that are popular among smokers in India (one filter-tipped and one untipped) were 16.51 and 0.9 mg per cigarette, respectively (Pakhale & Maru, 1998). In the sidestream smoke from bidis, these concentrations were 5.5 mg total particulate matter and 0.25 mg nicotine. The sidestream smoke released from chuttas contained 19.8 mg total particulate matter and 2.07 mg nicotine per unit. In all Indian products, the emissions of total particulate matter were much higher in mainstream smoke than in sidestream smoke, which is demonstrated clearly by the ratio of sidestream smoke to mainstream smoke which ranged from 0.13 to 0.49 (see also the monograph on tobacco smoke, Section 1.2.7). This is a modified, more intensive smoking standard (two puffs per minute instead of one) used because of the poor burning properties of the tobacco in Indian products.

In the 1999 Massachusetts Benchmark Study (Borgerding *et al.*, 2000), a subset of 12 brands was analysed for the chemical composition of the sidestream smoke that was generated by machine-smoking using the 'more intense' Massachusetts method. The data obtained are summarized in Table 1.3. The concentrations of the constituents of the sidestream smoke determined in this study differed significantly from those obtained using the standard FTC method that had been reported by Adams *et al*. (1987): the yields of CO, ammonia and benzo[*a*]pyrene were higher, those of tar and catechol were of the same order of magnitude and those of NNN and NNK were significantly lower. NNN and NNK levels were even lower than those measured in the mainstream smoke generated by the same intense machine-smoking method. The values obtained by the Massachusetts Study for some gaseous compounds such as 1,3-butadiene, acrolein, isoprene, benzene and toluene were also far below those obtained by machine-smoking using the FTC method (Brunnemann *et al*., 1990; Table 1.4). For the 12 commercial cigarette brands tested by the Massachusetts puffing parameters, the highest median sidestream smoke/mainstream smoke ratios in the Massachusetts study were obtained for ammonia (ratio, 147),

Table 1.3. Average values of 44 smoke constituents in the sidestream smoke of 12 commercial cigarette brands assayed in the 1999 Massachusetts Benchmark Study using Massachusetts smoking parameters

Constituent	Unit	Range	SS/MS ratio[a]
Ammonia	mg/cig.	4.0–6.6	147

3-aminobiphenyl (ratio, 10.8), formaldehyde (ratio, 14.8), pyridine (ratio, 16.1) and quinoline (ratio, 12.1).

Often, conflicting results concerning the phase distribution of individual constituents and poor agreement between laboratories for quantitation of sidestream emissions are attributed to different methods used for smoke generation and collection.

Table 1.5 shows the yields of IARC carcinogens in sidestream smoke generated under standard International Organization for Standardization (ISO) and the more intense Health Canada methods, of four popular regular-size Canadian cigarette brands.

On the basis of their mainstream smoke tar yields as measured by the ISO/FTC machine-smoking method, the four cigarette brands may be classified as ‘full flavour’, ‘light’, ‘extra light’ and ‘ultra light’. British Columbia has established the Tobacco Testing and Disclosure Regulation and became the first jurisdiction in the world to require Canadian tobacco manufacturers to disclose on a brand-by-brand basis the contents of cigarettes and tobacco and the levels of potentially toxic chemicals in tobacco smoke.

Among the 44 smoke components reported by the manufacturers on a yearly basis, there are seven IARC group 1 carcinogens (benzene, cadmium, 2-aminonaphthalene, nickel, chromium, arsenic and 4-aminobiphenyl), three IARC group 2A carcinogens (formaldehyde, 1,3-butadiene and benzo[*a*]pyrene) and eight IARC group 2B carcinogens (acetaldehyde, isoprene, catechol, acrylonitrile, styrene, NNK, NNN and lead).

Of the seven IARC group 1 carcinogens, arsenic yields in sidestream smoke were below the detection limits of both the ISO and Health Canada smoking methods. In general, yields of the six other IARC group 1 carcinogens in sidestream smoke were higher when measured by the ISO than by the Health Canada smoking method. The ISO and Health Canada methods gave similar yields for nickel and chromium in the 'light' cigarette and for chromium in the 'ultra light' cigarette.

For most IARC group 2A and 2B carcinogens, the yields in sidestream smoke measured by the Health Canada method were 40–80% of corresponding yields measured by the ISO method. Exceptionally, for NNK and lead the yields measured by the Health Canada method were higher than the yields measured by the ISO method, but only for the 'extra light' and 'ultra light' brands. The yields of NNK measured by the Health Canada method were up to 2.6-fold higher than the yields measured by the ISO method (Government of British Columbia, 2003).

Table 1.5 also allows comparisons of sidestream smoke yields between the brands. There is no significant difference between the total sidestream smoke yields of IARC group 1 carcinogens of 'full flavour' and 'light', extra light and ultra light cigarettes when measured by either the ISO or Health Canada methods.

The data in Tables 1.3 and 1.5 suggest that during more intense smoking (as employed by the Massachusetts and Health Canada methods: i.e. larger puffs, shorter interval between puffs and partial or complete blockage of ventilation holes), smaller quantities of tobacco are burned during the smouldering of the cigarette, thus affecting the emissions of toxins in sidestream smoke. Therefore, the real-life contribution of sidestream smoke to the overall concentrations of selected components of secondhand tobacco smoke may have been overestimated in the past because most smokers draw smoke from their cigarettes with an intensity more similar to that of the Massachusetts or Health Canada methods than the FTC machine-smoking method (Djordjevic *et al*., 2000). This concept needs to be investigated more thoroughly, especially in view of the finding that an increase in puff volume from 17.5 mL to 50 mL and in filter ventilation from 0 to 83% failed to reduce the levels of tar, CO and nicotine in the sidestream smoke, whereas the yields in mainstream smoke and subsequently the ratios of sidestream smoke to mainstream smoke changed significantly (Guerin *et al*., 1987).

In addition to the constituents listed in Table 1.3, some further constituents have been quantified in sidestream smoke since the publication of the 1986 *IARC Monograph*. These are NDMA (up to 735 ng per cigarette), *N*-nitrosopiperidine (NPIP, 19.8 ng) and NPYR (up to 234 ng) (Adams *et al*., 1987); and volatile hydrocarbons, e.g. ethene up to 1200 μg, propene up to 1300 μg, butenes up to 900 μg and pentenes up to 2100 μg. The sidestream smoke emissions of various unsaturated gaseous hydrocarbons were 3–30 times those reported for the mainstream smoke emissions. These compounds constitute a potential health risk as they are metabolized *in vivo* to reactive genotoxic epoxides (Löfroth *et al*., 1987; Löfroth, 1989). High-molecular-weight *n*-alkanes (C_{27} [66–86.5 μg per cigarette], C_{29} [28–39 μg per cigarette] C_{31} [148–197 μg per cigarette], C_{33} [43.5–62 μg per cigarette]) were also quantified in the sidestream smoke of commercial cigarettes (Ramsey *et al.*, 1990).

The co-mutagenic beta-carbolines, norharman and harman, were quantified in the sidestream smoke condensates of some Japanese cigarette brands. The concentrations per cigarette were 4.1–9.0 μg for norharman and 2.1–3.0 μg for harman (Totsuka *et al.*, 1999).

1.2 Exposure

Exposure to secondhand smoke can take place in any of the environments where people spend time. A useful conceptual framework for considering exposure to secondhand smoke is offered by the microenvironmental model that describes personal exposure to secondhand smoke as the weighted sum of the concentrations of secondhand smoke in the microenvironments where time is spent and the weights supplied by the time spent in each (Jaakkola & Jaakkola, 1997). A microenvironment is a space, e.g. a room in a

dwelling or an office area, with a relatively uniform concentration of secondhand smoke during the time that is spent in that particular microenvironment. For research purposes and for considering health risks, personal exposure is the most relevant measure for evaluating and projecting risk (Samet & Yang, 2001).

Within the framework of the microenvironmental model, there are several useful indicators of exposure to secondhand smoke, ranging from surrogate indicators to direct measurements of exposure and of biomarkers that reflect dose (Table 1.6). One useful surrogate, and the only indicator available for many countries, is the prevalence rate of smoking among men and women. It provides at least a measure of likelihood of exposure. For the countries of Asia, for example, where smoking rates among men are very high and those among women are low, the prevalence data for men imply that most women are exposed to tobacco smoke at home (Samet & Yang, 2001).

The components of secondhand smoke include a number of irritating and odiferous gaseous components, such as aldehydes. Nonsmokers typically identify the odour of secondhand smoke as annoying, and the odour detection thresholds determined for secondhand smoke is at concentrations that are three or more orders of magnitude lower

Table 1.6. Indicators of exposure to secondhand tobacco smoke

Measure	Indicator
Surrogate measures	Prevalence of smoking in men and women
Indirect measures	Report of secondhand tobacco smoke exposure in the home and in the workplace
	Smoking in the household Number of smokers Smoking by parent(s) Number of cigarettes smoked
	Smoking in the workplace Presence of secondhand tobacco smoke Number of smokers
Direct measures	Concentration of secondhand tobacco smoke components Nicotine Respirable particles Other markers
	Biomarker concentrations Cotinine Carboxyhaemoglobin

From Samet & Yang (2001)

than the secondhand smoke concentrations measured in field settings and correspond to a fresh air dilution volume > 19 000 m^3 per cigarette (Junker *et al.*, 2001).

The indirect measures listed in Table 1.6 are generally obtained by questionnaires. These measures include self-reported exposure and descriptions of the source of secondhand smoke (e.g. smoking), in relevant microenvironments, most often the home and workplace. Self-reported exposure to secondhand smoke is a useful indicator of being exposed, although questionnaire-based reports of intensity of exposure are of uncertain validity. Questionnaires have been used to ascertain the prevalence of passive smoking; some of these have included questions directly related to the WHO definition of passive smoking: i.e. exposure for at least 15 minutes per day on more than 1 day per week (Samet & Yang, 2001).

Questionnaires have been used widely for research purposes to characterize smoking (the source of secondhand smoke) in the home and work environments. A simple mass-balance model gives the concentration of secondhand smoke as reflecting the rate of its generation, i.e., the number of smokers and of cigarettes smoked, the volume of the space into which the smoke is released, and the rate of smoke removal by either air exchange or air cleaning (Ott, 1999). Information on smoking can be collected readily by adults within the household (the source term), although reports of numbers of cigarettes smoked in the home are probably less valid than exposure predicted using the mass balance model. For workplace environments, smoking can be reported by co-workers, although the complexity of some workplace environments may preclude the determination of the numbers of smokers in the work area or the numbers of cigarettes smoked. The other determinants of secondhand smoke concentration, namely, room volume and air exchange are not readily determined by questionnaire and are assessed only for specific research purposes (Samet & Yang, 2001).

The direct measures of exposure to secondhand smoke include measurement of the concentrations of components of secondhand smoke in the air and of the levels of secondhand smoke biomarker in biological specimens. Using the microenvironmental model, researchers can estimate exposure to secondhand smoke by measuring the concentration of secondhand smoke in the home, workplace, or other environments and then combining the data on concentrations with information on the time spent in the microenvironments where exposure took place. For example, to estimate exposure to secondhand smoke in the home, the concentration of a marker in the air, e.g. nicotine, would be measured and the time spent in the home would be assessed, possibly using a time–activity diary in which information on all locations where time is spent is collected (Samet & Yang, 2001).

Because cigarette smoke is a complex mixture, exposure assessment depends on the choice of a suitable marker compound that is found in both mainstream smoke and secondhand tobacco smoke. No compound has a consistent ratio with all other components. Therefore, the choice of marker can affect the estimate of exposure.

The selection of a particular secondhand smoke component for monitoring is largely based on technological feasibility. Air can be sampled either actively, using a pump that passes air through a filter or a sorbent, or passively, using a badge that operates on the

principle of diffusion. A number of secondhand smoke components have been proposed as potential indicators; these include small particles in the respirable size range and the gases, nicotine, which is present in the vapour phase in secondhand smoke, and carbon monoxide. Other proposed indicators include more specific measures of particles and other gaseous components (Guerin et al., 1992; Jenkins & Counts, 1999). The most widely studied components have been respirable particles, which are sampled actively with a pump and filter, and nicotine, which can be collected using either active or passive sampling methods. The respirable particles in indoor air have sources other than active smoking and are nonspecific indicators of secondhand smoke; nicotine in air, by contrast, is highly specific because smoking is its only source (Jenkins *et al.*, 2000). Nicotine concentration can be measured readily using a passive filter badge, which is sufficiently small to be worn by a child or an adult or to be placed in a room (Hammond, 1999).

Biomarkers of exposure are compounds that can be measured in biological materials such as blood, urine or saliva. Cotinine, a metabolite of nicotine, is a highly specific indicator of exposure to secondhand smoke in nonsmokers (Benowitz, 1999). Some foods contain small amounts of nicotine, but for most persons cotinine level offers a highly specific and sensitive indicator of exposure to secondhand smoke (Benowitz, 1999). In nonsmokers, the half-life of cotinine is about 20 h; it therefore provides a measure of exposure to secondhand smoke over several days. It is an integrative measure that reflects exposure to secondhand smoke in all environments where time has been spent. Cotinine can be readily measured in blood, urine and even saliva with either radioimmunoassay or chromatography. New methods for analysis extend the sensitivity to extremely low levels (Benowitz, 1996; Benowitz, 1999). Alternatives to nicotine as a tobacco-specific marker substance are few. One such compound is 3-ethenylpyridine (also called 3-vinyl pyridine); it is a pyrolisis product of nicotine degradation during smoking present almost exclusively in the vapour phase of tobacco smoke. It has been employed to a small extent for measuring the concentrations of secondhand tobacco smoke in air (Heavner *et al.*, 1995; Hodgson *et al.*, 1996; Scherer *et al.*, 2000; Vainiotalo *et al.*, 2001), and a correlation between nicotine and 3-ethenylpyridine has been reported in some studies (Jenkins *et al.*, 1996; Moschandreas & Vuilleumier, 1999; Hyvärinen *et al.*, 2000). 3-Ethenylpyridine, solanesol and ultraviolet-absorbing particulate matter as markers of secondhand smoke have been suggested as being potentially better correlated with other constituents of secondhand smoke than nicotine and respirable particles (Hodgson *et al.*, 1996; Jenkins *et al.*, 1996). There are however many fewer data available on measurements using other tobacco-specific marker compounds than those based on air nicotine.

1.2.1 *Measurements of nicotine and particulate matter in indoor air*

The report of the US Environmental Protection Agency (US EPA, 1992) summarizes over 25 separate studies that reported concentrations of nicotine in air measured in more than 100 different indoor microenvironments. Hammond (1999) also reported an extensive survey of the concentrations of nicotine in air. Based on the large numbers of

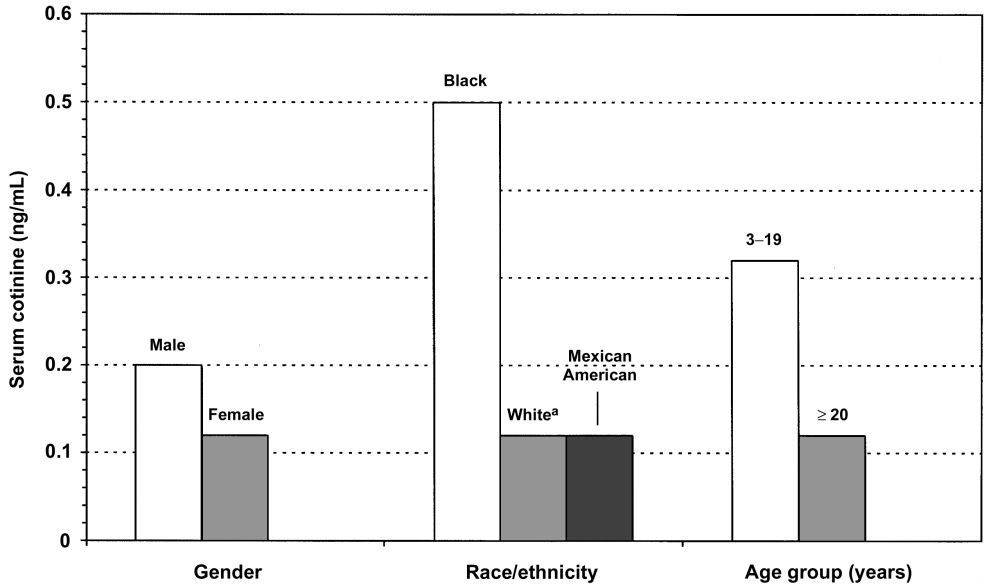
measurements made in various indoor environments in the USA between 1957 and 1991, the average concentrations of nicotine in air showed about 100-fold variation, i.e. from 0.3–30 μg/m^3 (US EPA, 1992). The average concentrations in homes with one or more smokers typically ranged from 2 to 10 μg/m^3, with the highest averages being up to 14 μg/m^3. Data from the mid 1970s until 1991 indicate that the nicotine concentrations in offices were similar to those measured in homes, with a large overlap in the range of air concentrations for the two types of environment. The maximum levels of nicotine, however, were considerably higher in offices than in domestic environments (US EPA, 1992; California EPA, 1997). In studies using controlled and field conditions, the concentrations of nicotine in air were found to increase as a function of the number of smokers present and the number of cigarettes consumed (US EPA, 1992).

Jenkins *et al*. (1996) studied exposure to secondhand tobacco smoke in 16 cities in the USA by sampling personal breathing zone air from about 100 nonsmokers in each city. The demographics of the study subjects were comparable with the population of the USA in general, although more women than men participated in the study. The mean 24-h time-weighted average concentration of nicotine was 3.27 μg/m^3 for those exposed to secondhand tobacco smoke both at work and away from work, 1.41 μg/m^3 for those only exposed away from work and 0.69 μg/m^3 for those who were exposed only at work. The mean 24-h time-weighted average concentration of nicotine in air measured by personal monitoring, for those who were not exposed to secondhand tobacco smoke was 0.05 μg/m^3 (Jenkins *et al*., 1996).

Personal exposure to particulate matter associated with secondhand tobacco smoke was determined using the set of specific markers such as respirable suspended particles, fluorescent particulate matter and solanesol-particulate matter. The ranges of mean concentrations of these particles for workers exposed to secondhand smoke in 11 countries were: respirable suspended particles, from 24 to 112 μg/m^3; fluorescent particulate matter, from 5.7 to 57 μg/m^3; and solanesol-particulate matter, from 3.6 to 64 μg/m^3 (Jenkins *et al.*, 2000). By measuring the levels of solanesol-particulate matter and nicotine, the exposure to secondhand tobacco smoke of office workers living and working with smokers was determined to be higher in winter than in summer (median 24-h time-weighted average concentrations, 25 μg versus 2.4 μg solanesol-particulate matter and 1.3 μg versus 0.26 μg nicotine, respectively) (Phillips & Bentley, 2001).

1.2.2 *Population-based measurements of exposure*

Most population-based estimates of exposure to secondhand tobacco smoke have been obtained from self-reports. When measuring exposure to secondhand smoke in indoor areas, nicotine or respirable suspended particles can be measured in air sampled using personal monitors. In a few studies, biomarkers such as cotinine have been measured in physiological fluids.



(*a*) *Adults*

Some studies suggest that exposure to secondhand tobacco smoke is related to occupation and socioeconomic status, and that higher exposure is more common among adults employed in blue-collar jobs, service occupations and poorly paid jobs and among the less well educated (Gerlach *et al*., 1997; Curtin *et al*., 1998; Whitlock *et al*., 1998). Exposure to secondhand tobacco smoke may also be higher among racial and ethnic minority groups in areas of the USA, although it is unclear if this is due to different socioeconomic status (Gerlach *et al.*, 1997).

Relatively few data are available on the prevalence of nonsmokers' exposure to secondhand tobacco smoke on a population basis, using biomarkers. Survey data from a study in the USA in 1988–91 showed that 37% of adult non-tobacco users lived in a home with at least one smoker or reported exposure to secondhand tobacco smoke at work, whereas serum cotinine levels indicated more widespread exposure to nicotine. Of all the non-tobacco users surveyed including children, 88% had detectable serum cotinine levels, indicating widespread exposure to secondhand tobacco smoke in residents of the USA (Pirkle *et al.*, 1996). Data were recently published on the serum cotinine levels measured in 2263 nonsmokers in 12 locations across the USA (Figure 1.1) (CDC, 2001). As reported previously (Pirkle *et al.*, 1996), exposure to secondhand tobacco smoke tended to be higher among men than among women. Among racial/ethnic groups, blacks had the highest cotinine levels. People younger than 20 years of age had higher cotinine levels than those aged 20 years and older.

Table 1.7 summarizes the data obtained from a number of recent population-based studies that used questionnaires to characterize exposure. Some of these studies were national in scope, e.g. the national samples in Australia, China and the USA, whereas others were from single states or specific localities. Several of the studies incorporated cotinine as a biomarker. Unfortunately, few data are available from developing countries (Samet & Yang, 2001). In a case–control study of lung cancer and exposure to secondhand smoke in 12 centres from seven European countries, 1542 control subjects up to 74 years of age were interviewed between 1988 and 1994 about their exposure to secondhand smoke. Exposure of adults to secondhand smoke from a spouse who smoked was reported by 45% of the subjects (including 2% who were exposed to smoke from cigars or pipes only); an additional 8% were not exposed to spousal smoke, but reported exposure to secondhand smoke produced by cohabitants other than spouses. Exposure to secondhand smoke in the workplace was reported by 71% of men and 46% of women. Combined exposure to secondhand smoke both from the spouse and at the workplace was reported by 78%. Exposure to secondhand smoke in vehicles was reported by 20% and exposure in public indoor settings such as restaurants was reported by 29% (Boffetta *et al.*, 1998). Recent data from Finland illustrate trends in self-reported exposure to secondhand tobacco smoke at work and at home over a 15-year period. In 1985, 25% of employed nonsmoking men and 15% of employed nonsmoking women were exposed to

Figure 1.1. 75th percentile of serum cotinine concentrations for the US nonsmoking population aged 3 years and older, National Health and Nutrition Examination Survey, 1999

From CDC (2001)
[a] Includes other racial/ethnic groups

secondhand tobacco smoke at work. In contrast, the figures for exposure to secondhand smoke in 2000 were 8% of men and 4% of women (Jousilahti & Helakorpi, 2002).

In a 1993 review of existing studies, Siegel (1993) noted wide variation in the concentrations of secondhand tobacco smoke by location when measured by weighted mean levels of nicotine in the ambient air of offices (4.1 μg/m^3), restaurants (6.5 μg/m^3), bars (19.7 μg/m^3) and dwellings with at least one smoker (4.3 μg/m^3).

The recently published study in the USA of the median serum cotinine concentration measured in nonsmokers aged 3 years and older found a 75% decrease over the period 1991–99 (CDC, 2001), suggesting positive effects of policies for cleaner indoor air.

(*b*) *Children*

Because the home is a predominant location for smoking, children are exposed to tobacco smoke as they go about their daily lives, i.e. while eating, playing and even sleeping. The exposure at home may be added to exposure at school and in vehicles. Consequently, in many countries, children cannot avoid inhaling tobacco smoke (Samet & Yang, 2001).

Table 1.7. Prevalence of exposure to secondhand tobacco smoke — population-based studies

Reference	Study design and population	Results
Europe		
Somerville *et al.* (1988)	Cross-sectional study; 4337 children aged 5–11 years in England and 766 in Scotland, from the 1982 National Health Interview Survey on Child Health in the United Kingdom	Prevalence = 42% in England and 60% in Scotland
Dijkstra *et al.* (1990)	Cohort study; nonsmoking children aged 6–12 years over a 2-year period, in the Netherlands	Prevalence = 66%
Jaakkola *et al.* (1994)	Population-based cross-sectional study; random sample of 1003 children aged 1–6 years in Espoo, Finland	25.2% reported exposure to secondhand tobacco smoke at home; 74.8% of children did not, assessed by parent-completed questionnaire.
Brenner *et al.* (1997)	Cross-sectional study; survey of 974 predominantly blue-collar employees of a south German metal company	> 60% of nonsmoking blue collar workers reported being exposed to secondhand smoke at work; 52% of nonsmoking white collar workers exposed if smoking allowed in immediate work area, and 18% if smoking not allowed
Boffetta *et al.* (1998)	Case–control study of lung cancer and exposure to secondhand tobacco smoke in 12 centres from seven European countries, 1542 control subjects up to 74 years of age were interviewed between 1988 and 1994 about exposure to secondhand tobacco smoke	Prevalence during childhood was 66%. Prevalence in adulthood (spousal smoke) was 45% (including 2% with exposure to cigar or pipe smoke only). In addition, 8% who were not exposed to spousal smoke were exposed to secondhand tobacco smoke produced by cohabitants other than spouse. Prevalence in the workplace was 71% among men and 46% among women. Combined prevalence from the spouse and at the workplace was 78%. Prevalence of exposure to secondhand tobacco smoke in vehicles was 20% and in public indoor settings such as restaurants, it was 29%.

Table 1.7 (contd)

Reference	Study design and population	Results
Lund *et al.* (1998)	Children born in 1992; descriptive study of exposure to secondhand tobacco smoke at home in 3547 households in Denmark, Finland, Iceland, Norway and Sweden in 1995–96	Prevalence of weekly exposure was 47% in Denmark, 7% in Finland, 46% in Iceland, 32% in Norway and 15% in Sweden.
Jousilahti & Helakorpi (2002)	A cohort of 58 721 men and women aged 15 to 64 years was followed-up by annual questionnaires on exposure to secondhand smoke at work and at home between 1985 and 2000 in Finland.	In the middle of the 1980s, about a quarter of employed nonsmoking men and 15% of nonsmoking women were exposed for at least 1 hour daily to environmental tobacco smoke at work. In 2000, the proportions were 7.9% and 4.4%, respectively. Exposure to environmental tobacco smoke at home also decreased slightly. In 2000, 14.3% of the nonsmoking men and 13% of the nonsmoking women aged 15 to 64 years were exposed to secondhand smoke either at work or at home.
America		
Coultas *et al.* (1987)	Cross-sectional study; 2029 Hispanic children and adults in New Mexico (1360 nonsmokers and ex-smokers also had salivary cotinine measured)	Prevalence = 39% ≥ 18 years; 48%, 13–17 years; 45%, 6–12 years, and 54% < 5 years. Mean salivary cotinine concentrations = 0 to 6 ng/mL; 35% of members of nonsmoking households had detectable levels of cotinine.
Greenberg *et al.* (1989)	Questionnaire-based cross-sectional study; mothers of 433 infants from a representative population of healthy neonates from 1986–87 in North Carolina	55% lived in a household with at least one smoker; 42% of infants had been exposed during the week preceding data collection; cotinine was detected in 60% of urine samples (median = 121 ng/mg creatinine).
Chilmonczyk *et al.* (1990)	Cross-sectional study; 518 infants aged 6–8 weeks receiving well-child care in the offices of private physicians in greater Portland, Maine	91% of infants living in households where only the mother smoked (43 households) had urinary cotinine levels ≥ 10 µg/L; 8% of infants living in households where no smoking was reported (305 households) had urinary cotinine levels ≥ 10 µg/L.

Table 1.7 (contd)

Reference	Study design and population	Results
Overpeck & Moss (1991)	Cross-sectional study; sample of 5356 children ≤ 5 years of age from the National Health Interview Survey in 1988	Approximately 50% of all US children ≤ 5 years of age exposed to prenatal maternal smoking and/or secondhand smoke from household members after birth; 28% were exposed both prenatally and postnatally, 21% only after birth and 1.2% only prenatally.
Borland *et al.* (1992)	Cross-sectional study; sample of 7301 nonsmokers from the larger study of Burns & Pierce (1992)	31.3% of nonsmoking workers reported exposure at work ≥ 1 time in the preceding 2 weeks; 35.8% males vs 22.9% females; 41.9% < 25 years vs 26.4% for older workers; 43.1% with < 12 years of education vs 18.6% with ≥ 16 years of college education
Burns & Pierce (1992)	Cross-sectional study; head of household in 32 135 homes in California, contacted by stratified random-digit dialling from June 1990 to July 1991	32.2% of children aged 5–11 years and 36.5% of adolescents aged 12–17 years were exposed at home.
Jenkins *et al.* (1992)	Cross-sectional study; telephone interviews with 1579 English-speaking adults and 183 adolescents (12–17 years of age) from October 1987 to September 1988 in California	46% of nonsmokers were exposed during the day: 43% of adult nonsmokers and 64% of adolescent nonsmokers. Exposure most frequently occurred at home, in restaurants or in cars. The average duration of exposure was longest in workplaces.
Jenkins *et al.* (1992); Lum (1994)	Cross-sectional study; same population as described above and additional 1200 children aged ≤ 11 years (< 8 years old with a parent or guardian) from April 1989 to February 1990 in California	Prevalence of exposure among smokers and nonsmokers = 61% for adults and 70% for adolescents during the day; 35% to 45% of children, infants, and preschoolers were reported to be exposed to secondhand smoke; average duration = 3.5 h.
Pierce *et al.* (1994)	Cross-sectional study; using the California Adult Tobacco Surveys in 1990, 1992 and 1993 with 8224 to 30 716 adults 18 years and older and 1789 to 5531 teenagers 12–17 years of age interviewed	15.1% smoked prior to pregnancy and of these, 37.5% quit after the pregnancy (between 1988 and 1992, 9.4% of women smoked during pregnancy).

Table 1.7 (contd)

Reference	Study design and population	Results
Pletsch (1994)	Cross-sectional study; 4256 Hispanic women aged 12–49 years who participated in the Hispanic Health and Nutrition Examination Survey (HHANES) from 1982 to 1984	Age-specific household exposure for nonsmokers was 31%–62% for Mexican-Americans, 22%–59% for Puerto Ricans and 40%–53% for Cuban-Americans; 59% of Puerto Rican and 62% of Cuban-American adolescents had high levels of exposure.
Thompson *et al.* (1995)	Cross-sectional study; 20 801 US employees from 114 work sites	52.4% of respondents reported being exposed to secondhand tobacco smoke at work
Kurtz *et al.* (1996)	Questionnaire-based cross-sectional survey; sample of 675 African-American students enrolled in grades 5–12 in an urban public school district in Detroit, Michigan	Smoking rates were higher among students with parents who smoked; 48% reported paternal smoking; 46% reported maternal smoking.
Mannino *et al.* (1996)	17 448 children aged 1–10 years from 1991 US National Health Interview Survey	41% of children with lower socioeconomic status experienced daily exposure at home; 21% of children with higher socioeconomic status experienced daily exposure at home.
Pirkle *et al.* (1996)	Cross-sectional study; 9744 adults aged 17 years or older from the NHANES III Study, 1988–91	Prevalence for males was 43.5% and for females, 32.9%; 87.9% had detectable serum cotinine levels.
Stamatakis *et al.* (2002)	Cross-sectional study of ethnically diverse non-smoking women, aged 40 years and older, across the United States (n = 2326)	Exposure to secondhand tobacco smoke at home was associated with being American Indian/Alaska Native (aOR, 1.5; 95% CI, 1.0–2.6). Compared with college graduates, exposure to secondhand tobacco smoke at work was higher among women with some high school education (aOR, 2.8; 95% CI, 1.5–5.3) and high school graduates (aOR, 3.1; 95% CI, 1.9–5.1) and substantially higher for women who worked where smoking was allowed in some (aOR, 15.1; 95% CI, 10.2–22.4) or all (aOR, 44.8; 95% CI, 19.6–102.4) work areas.

Table 1.7 (contd)

Asia		
Lam *et al.* (1998)	Questionnaire-based cross-sectional study; sample of 6304 students aged 12–15 years, from 172 classes of 61 schools in Hong Kong	53.1% were living in a household with at least one smoker; 35.2% had only one smoker; 9.5% had two and 2.5% had three or more smokers in the household; 38% of fathers and 3.5% of mothers smoked.
Yang *et al.* (1999)	Cross-sectional study; 120 298 records (63 793 males and 56 020 females) of persons aged 15–69 years from the 1996 National Prevalence Survey of Smoking in China	Of the nonsmoking respondents, 53.5% reported passive exposure to smoke. Over 60% of female nonsmokers between ages 25 and 50 years were passively exposed to tobacco smoke; 71% of participants reported exposure to smoke at home, 32% in public places and 25% in their workplace.
Africa		
Steyn *et al.* (1997)	Questionnaire-based cross-sectional study; 394 pregnant women attending antenatal services in Johannesburg, Cape Town, Port Elizabeth and Durban in urban South Africa, 1992	Most women who smoked stopped or reduced tobacco use during their pregnancy; 70% lived with at least one smoker in the house.
Australia and New Zealand		
Sherrill *et al.* (1992)	Cohort study; 634 children aged 9–15 years; New Zealand	Overall prevalence = 40%
Lister & Jorm (1998)	Cross-sectional study; data from the Australian Bureau of Statistics 1989–90 National Health Survey of parents and their children (n = 4281) aged 0–4 years; Australia	45% of children lived in households with ≥ 1 current smoker; 29% had a mother who smoked.

Modified from Samet & Yang (2001)
aOR, adjusted odds ratio for sociodemographic characteristics (race, age, education, location and having children in the home), health risk behaviours, and the type of smoking policy in the workplace

Data on the exposure of children to secondhand tobacco smoke are limited. In perhaps the most comprehensive cross-sectional study to date, researchers examined exposure to secondhand tobacco smoke in 17 448 children aged 1–10 years in the USA. Exposure varied considerably according to socioeconomic status: 41% of children of lower socioeconomic status experienced daily exposure to secondhand tobacco smoke in their home, whereas only 21% of children of higher socioeconomic status were exposed daily. Exposure to secondhand tobacco smoke did not vary by race, family size, gender or season (Mannino *et al*., 1996). In a multicentre study conducted in 1988–94 in seven European countries, exposure to secondhand smoke in childhood was reported by 66% of respondents (Boffetta *et al*., 1998). Parent-reported exposure to secondhand tobacco smoke among children varied widely across the countries of Denmark, Finland, Iceland, Norway and Sweden (Lund *et al*., 1998). For example, Finnish parents were more likely than all other Nordic parents to protect their children from secondhand tobacco smoke. Exposure was highest in Denmark and Iceland, where children were exposed in almost half of all households and in nine of ten households with daily smokers. The lack of common metrics for measuring exposure to secondhand tobacco smoke in children is a significant challenge when comparing data between countries.

1.3 Regulations

1.3.1 *Policy options*

There are a range of options available for the regulation of secondhand tobacco smoke. Of these options, the least effective is designating smoking areas that have no separate ventilation. This option provides only minimal protection to nonsmokers; studies have shown that substantial exposure to secondhand tobacco smoke occurs in workplaces where there are smoking areas without separate ventilation (Repace, 1994). A more effective option is the use of separately ventilated smoking lounges; this protects non-smokers but is costly and may elevate lung cancer risk in smokers (Siegel *et al*., 1995). Separately ventilated smoking lounges also endanger workers (e.g. waiting staff) who must enter these areas as part of their job. Finally, the most effective alternative is a totally smoke-free workplace (Brownson *et al*., 2002).

1.3.2 *Prevalence of regulations*

In 1985, only about 38% of workers in the USA were employed by firms that had policies restricting smoking (Farrelly *et al*., 1999). Since that time, smoking restrictions have become increasingly common. According to the 1999 National Worksite Health Promotion Survey, 79% of workplaces with 50 or more employees had formal smoking policies that prohibited smoking or allowed it only in separately ventilated areas (US Department of Health and Human Services, 2000). Data showed that, from 1995–96, 64% of indoor workers in the USA were covered by a total ban on smoking in the workplace.

The proportion of workers in the USA who work in a smoke-free workplace varies considerably by state — from 84% in Maryland and Utah to 40% in Nevada (Burns *et al*., 2000). There are few systematic data available on the enforcement of existing policies to restrict smoking in the workplace, although existing studies suggest that compliance is likely to be high (Stillman *et al*., 1990; Wakefield *et al.*, 1996). National data from the USA also suggest that despite some protective laws, workers in blue-collar and service occupations remain much more likely to be exposed to secondhand tobacco smoke in the workplace than other categories of workers (Gerlach *et al*., 1997). In the USA, hospitals are the only sector that has voluntarily implemented a nationwide smoking ban. This ban was announced in November 1991 and full implementation was required by December 31, 1993. Two years after implementation, the policy was found to have been successful with 96% of hospitals complying with the smoking ban standard (Longo *et al.*, 1995; Brownson *et al.*, 2002).

A recent overview of the legislation restricting smoking at work in different countries has been provided by the American Cancer Society (Corrao *et al*., 2000) (Table 1.8). Despite using a wide range of already published sources together with Internet searches, no information could be found for many countries. Thus, absence of an entry in this Table does not imply certainty that no legislation exists in a particular country. Conversely, the existence of a law banning or restricting smoking implies nothing about its enforcement. In general, it appears that voluntary restrictions under control of the employer are more common in developing countries than in developed countries (Brownson *et al.*, 2002). A country that relies on voluntary action to ban or restrict smoking may have quite high rates of worker protection. For example, although Australia banned smoking in all federal government workplaces in 1988, it has been left to individual employers to determine their own policies. Yet, in 1999, 71% of indoor workers in the state of Victoria reported a total ban on smoking at their workplace, 21% reported some restrictions on smoking and 8% reported unrestricted smoking (Letcher & Borland, 2000). As in other countries, employees in small Australian workplaces are less likely to report protection, as are workers in particular types of employment (Wakefield *et al.*, 1996; McMaugh & Rissell, 2000). In a survey of indoor workers, 38% of those employed in a restaurant or hotel, 15% of warehouse/store workers and 17% of those working in a workshop or factory reported unrestricted smoking where they worked, compared with only 3% of workers in open-plan offices (Letcher & Borland, 2000). In the United Kingdom, workplace restrictions are also voluntary. In 1997, 40% of the workforce was estimated to be working in a totally smoke-free environment (Freeth, 1998). A survey of 1500 workplaces in Scotland found that 79% of them had designated nonsmoking areas, but only 22% had banned smoking completely (ASH, 2001). Despite the limitations of the data presented in Table 1.9, it is apparent that most countries have some laws that restrict smoking. However, it is very likely that there is considerable need for improvement in protection of workers from secondhand tobacco smoke in almost all countries (Brownson *et al.*, 2002).

A few researchers have begun to examine the prevalence of smoking restrictions in the home because such restrictions are likely to have beneficial effects on the health of

Brownson *et al.* (2002); adapted from Corrao *et al*. (2000); number of additional countries for which no information is available: Africa = 38; Americas = 15; Eastern Mediterranean = 13; Europe = 15; South-East Asia = 5; Western Pacific = 11.

[a] B, smoking is prohibited in workplaces according to national legislation and/or regulations; facilities with a designated smoking area are included in this category if nonsmoking areas must always remain uncontaminated by smoke; R, smoking is restricted, but not prohibited, in workplaces according to national legislation and/or regulations; V, employers voluntarily prohibit or restrict smoking in areas under their management; X, different state and county laws apply.

Table 1.9. Summary of selected studies on the effects of workplace smoking bans and restrictions on exposure to secondhand tobacco smoke

Reference/location	Industry/setting	Sample size	Outcome(s) studied/size of effect[a]
Millar (1988)/ Ontario, Canada	Department of Health and Welfare	4200 (12 locations)	Change in mean respirable suspended particulates = –6 μg/m^3 to –22 μg/m^3 (depending on the storey of the building)
Becker *et al.* (1989)/ Maryland, USA	Children's hospital	951 (9 locations)	Change in average nicotine vapour concentrations = –12.53 μg/m^3 to + 0.08 μg/m^3 (depending on the location)
Biener *et al*. (1989)/ Rhode Island, USA	Hospital	535	Percentage of workers 'bothered' by secondhand smoke in various workplace locations: offices = –20%; lounges = –20%
Gottlieb *et al*. (1990)/Texas, USA	Government agency	1158	Percentage of workers 'never bothered' by secondhand smoke = + 38.8%
Mullooly *et al*. (1990)/Oregon, USA	Health maintenance organization	13 736 1985: pre-ban 764 post-ban 1027 1986: pre-ban 1352 post-ban 1219	Presence of smoke in workplace = –21% (1985 sites); –35% (1986 sites)
Stillman *et al*. (1990)/Maryland, USA	Medical centre	8742 (7 locations)	Change in average 7-day nicotine vapour concentrations = –7.71 μg/m^3 to –0.72 μg/m^3 (depending on the location)
Borland *et al*. (1992)/ California, USA	Indoor workers in California	7301	Percentage of employees exposed to secondhand smoke at work = –42.1% between no policy and smoke-free policy
Broder *et al*. (1993)/ Toronto, Canada	Public sector workplaces	179 (3 buildings; 8–12 samples per floor)	Change in the mean measurements (for several secondhand smoke components) Volatile organic compounds = –0.7 mg/m^3
Patten *et al*. (1995)/California, USA	Statewide workers	8580 (at baseline survey)	Percentage of employees exposed to secondhand smoke at work = –56.3% difference between work area ban and no ban

Table 1.9 (contd)

Reference/location	Industry/setting	Sample size	Outcome(s) studied/size of effect[a]
Etter *et al*. (1999)/ Geneva, Switzerland	University	2908	Exposure to secondhand smoke (score 0–100; 'not at all' (0) to 'very much' (100)) = –4% (follow-up compared to baseline)

Brownson *et al.* (2002); modified from Hopkins *et al.* (2001)
[a] Values noted are absolute differences from baseline.

children. In 1997, a population-based, cross-sectional telephone survey was conducted using random-digit-dialling asking 6199 adult Oregonians to provide baseline data on tobacco use in Oregon. Seventy per cent of the households were composed of nonsmokers only, and 85% of those had a full ban on smoking inside the home. Of the households containing one or more smokers, 38% had a full household ban on smoking. Fifty per cent of households with at least a smoker and a child present did not have a full ban on indoor smoking (Pizacani *et al.*, 2003). Face-to-face interviews were conducted with 380 rural, low-income Native American and white parents of children aged 1–6 years in Oklahoma. The prevalence of complete smoking bans was 49% in Native American homes and 43% in white homes. Bans on smoking in cars were less common, with 35% of Native American and 40% of white caregivers reporting complete bans (Kegler & Malcoe, 2002). In Victoria, Australia, the percentage of respondents who reported discouraging visitors from smoking in the home rose from 27% in 1989 to 53% in 1997 (Borland *et al*., 1999), and not smoking in the presence of children rose from 14% in 1989 to 33% in 1996. Similarly, attitudes toward smoking in the home have changed in Ontario, Canada. The percentage of respondents favouring not smoking in homes where there were children increased from 51% in 1992 to 70% in 1996 (Ashley *et al*., 1998).

Only minimal regulation applies to constituents of cigarettes and tobacco smoke. This covers only the content of tar, nicotine and carbon monoxide (cf. Section 1.4(*e*) of the monograph on tobacco smoke).

1.3.3 *Effectiveness of regulations*

Evaluations of the effects and effectiveness of workplace smoking policies have used a wide variety of study designs and measurements of exposure to secondhand tobacco smoke and tobacco use behaviours. Most of the published studies are simple assessments conducted before and after adoption of a workplace policy, although more recent (and more complex) investigations have employed cross-sectional surveys of workers in work-places operating different policies. Few studies have evaluated or controlled for potential bias and confounding of the observed differences or changes in exposure to secondhand smoke or in tobacco use behaviours (Brownson *et al.*, 2002).

The effectiveness of workplace smoking policies has been measured by differences or changes in perceived air quality in the workplace following a ban or restriction, and by differences or changes in active measurements of nicotine vapour concentrations, metabolites, or levels of particles. Overall, workplace smoking policies have been highly effective in reducing the exposure of nonsmokers to secondhand tobacco smoke. The 'best evidence subset' comprised ten studies, including cross-sectional surveys, before-and-after comparisons, different settings or locations (offices, public sector workplaces, medical centres, workplaces community-wide) and different outcome measurements (Table 1.9) (Briss *et al*., 2000; Hopkins *et al*., 2001). In nine of ten studies, workplace smoking policies had a significant impact on exposure to secondhand tobacco smoke. In assessments conducted between 4 and 18 months after implementation of the policy, the median relative percentage difference in self-reported exposure to secondhand tobacco smoke was –60%, range +4% to –97%. Workplaces with smoking bans tended to show greater reduction in exposure to secondhand tobacco smoke than did workplaces with smoking restrictions (Hopkins *et al*., 2001; Brownson *et al*., 2002).

Hammond (1999) summarized the existing literature on average indoor nicotine concentrations when various workplace smoking policies were enacted. In workplaces with policies that had banned smoking, nicotine concentrations were generally decreased to less than 1 $\mu g/m^3$. The mean concentrations of nicotine in workplaces that allowed smoking ranged from 2 to 6 $\mu g/m^3$ in offices, 3 to 8 $\mu g/m^3$ in restaurants and from 1 to 6 $\mu g/m^3$ in the workplaces of blue-collar workers. By comparison, studies of nicotine concentrations that included at least 10 homes of smokers and that were sampled for 14 h to 1 week found average nicotine concentrations of between 1 and 6 $\mu g/m^3$.

2. Studies of Cancer in Humans

2.1 Lung cancer

The section summarizes the results of the relevant cohort studies and case–control studies of the association between lung cancer and exposure to secondhand smoke. They are ordered by source of exposure, i.e. secondhand smoke from partners at home, at the workplace, during childhood and from other sources. For each type of study, the results are presented first without differentiation according to the levels of exposure and then the exposure–response relationship is described.

The most commonly used measure of exposure to secondhand smoke has been from the spouse. This is because it is well defined and has been validated using cotinine studies of never-smokers who do or do not live with smokers. Spousal exposure is also a marker of exposure to tobacco smoke in general because people who live with smokers tend to mix with smokers outside the home. Other measures of exposure, at the workplace or during childhood, are not so well validated. It is more difficult to quantify exposure at the workplace than spousal exposure; the extent of exposure may vary considerably between different working environments (exposure from the spouse is clearly defined and fairly consistent); people are more likely to change jobs than to remarry or divorce and, in studies based on people who have died from lung cancer, it may be more difficult for the next of kin or other respondent to know whether or not the subject had been exposed to secondhand smoke at work. Exposure during childhood has not been validated and, in studies of exposure to secondhand smoke, the relative risk for lung cancer associated with exposure during childhood should be stratified according to spousal exposure. Few studies have done this, and, even when they have, the number of lung cancer cases has been too small to enable robust conclusions to be drawn.

2.1.1 *Cohort studies*

There have been eight cohort studies of nonsmokers who were followed for several years to determine the risk for lung cancer (these are described in Table 2.1). Six of these studies (Garfinkel, 1981; Hirayama, 1984; Butler, 1988; Cardenas *et al.*, 1997; Jee *et al*., 1999; Nishino *et al*., 2001) reported the risk of lung cancer associated with exposure to secondhand smoke from the spouse. All six studies found that the risk for nonsmoking women with partners who smoked was higher than that for those whose partner did not

Table 2.1. Cohort studies of secondhand smoke and lung cancer

Reference (country, years of study)	Cohort sample	Cohort eligibility; follow-up	Source of exposure	Incidence/death; covariates adjusted for; comments
Garfinkel (1981) (USA, 1960–72)	176 739 married nonsmoking women	ACS Study: friends, neighbours and relatives of American Cancer Society volunteers; deaths reported by volunteers; death certificates obtained from state health departments; 93% follow-up Veterans Study: questionnaire mailed to veterans holding a US Government life insurance; 85% response; death certificates supplied to the Veterans' Administration or through field work at health departments	Active smoking by current spouse	Deaths 1) Crude death rates; 2) analysis with women matched by age, race, highest educational status of husband or wife, residence and occupational exposure of husband
Hirayama (1984) (Japan, 1965–81)	91 540 married nonsmoking women	95% of the census population in the study area in 29 health centre districts; follow-up consisted of special annual census and special death registry system.	Active smoking by current spouse	Deaths SMRs
Butler (1988) (USA, 1974–82)	Spouse pairs: 9378 subjects; AHSMOG cohort: 6467 subjects (66% overlap)	Non-Hispanic white Adventists; spouse pairs with a non-smoking wife; AHSMOG cohort enrolled for air pollution study; deaths ascertained by linkage to California death certificate file, national death index and notification of death by church clerks; cases ascertained with hospital history forms and review of hospital and tumour registry records; 99% histologically confirmed	Spouse pair cohort: active smoking by current spouse; AHSMOG cohort: exposure at work	Cases/deaths Adjusted for age
DeWaard *et al.* (1995) (the Netherlands, 1977–91)	23 cases and 191 controls	Nested case–control study among women enrolled in breast cancer screening projects (DOM project, enrolment 1975–77, aged 50–64 years and Lutine Study, enrolment 1982–83, aged 40–49 years)	Exposure assessed by measurement of urinary cotinine levels in declared nonsmokers	Cases/deaths Cotinine excretion adjusted for creatinine resulted in higher odds ratios.

Table 2.1 (contd)

Reference (country, years of study)	Cohort sample	Cohort eligibility; follow-up	Source of exposure	Incidence/death; covariates adjusted for; comments
Cardenas *et al.* (1997) (USA, 1982–89)	288 776 (96 542 men, 192 234 women) nonsmoking subjects	Friends, neighbours and relatives of American Cancer Society volunteers in all 50 States; aged > 30 years; death monitored by volunteers and through national death index; cause of death classified according to ICD-9.	Active smoking by current spouse; self-reported exposure at home, at work or in other areas	Deaths Adjusted for age, race, education, blue-collar employment, asbestos exposure, consumption of vegetables, citrus fruits and fat, history of chronic lung disease
Jee *et al.* (1999) (Republic of Korea, 1992–97)	157 436 married nonsmoking women	Both spouses had to have completed the Korean Medical Insurance Corporation medical examination; aged > 40 years; cases ascertained from diagnosis on discharge summary	Active smoking by current husband	Cases Univariate analysis; multivariate analysis adjusted for age of husband and wife, socioeconomic status, residence, husband's vegetable consumption and occupation
Speizer *et al.* (1999) (USA, 1976–92)	121 700 women, US registered nurses in 1976; unknown subcohort of nonsmokers	Female nurses aged 30–55 years, Nurses' Health Study; deaths ascertained by family members, postal service or through national death index; cases confirmed by pathology reports	Information on exposure to second-hand smoke during childhood and adulthood ascertained in 1982	Cases Adjusted for age
Nishino *et al.* (2001) (Japan, 1984–92)	31 345 (13 992 men, 17 353 women) non-smokers	Residents of six primary school sectors in a city and the whole area of two towns in north-eastern Honshu, aged > 40 years; cases ascertained by linkage to the prefectural cancer registry; cancer sites coded according to ICD-9	Any smoker in the household	Cases 1) Crude relative risk; 2) stratification by smoking status of husband and other household members; 3) multivariate relative risk adjusted for age, study area, alcohol intake, green and yellow vegetable intake, fruit intake, meat intake and past history of lung disease

SMR, standardized mortality ratio

smoke (see Table 2.2). In both cohort studies that reported on the effect in nonsmoking men whose wives smoked, the relative risk was increased (Hirayama 1984; Cardenas *et al.*, 1997). The two other cohort studies, which were based on general exposure to secondhand smoke (deWaard *et al*., 1995; Speizer *et al*., 1999), obtained similar results.

Table 2.2. Epidemiological studies[a] of the risk for lung cancer in lifelong non-smokers whose spouses smoked relative to the risk in those whose spouses did not smoke[b]

CI, confidence interval

[a] Only the most recent publication is used for studies that have been updated from previously published reports. Also, studies based on subjects who are included in a larger series are not listed here.

[b] In addition, there are four studies that gave results for men and women combined: Hole *et al*. (1989) (7 cases), relative risk, 2.1 (95% CI, 0.5–12.8); Janerich *et al*. (1990) (188 cases), relative risk, 0.9 (95% CI, 0.6–1.6) for analysis based on subjects interviewed directly and 0.4 (0.2–1.0) for analysis based on interviews with surrogate respondents; Schwartz *et al*. (1996) (257 cases), relative risk, 1.1 (95% CI, 0.8–1.6); Boffetta *et al*. (1999a) (69 cases), relative risk 1.22 (95% CI, 0.7–2.1).

[c] Adjusted for at least age (other factors included dietary habits, education and social class)

Table 2.2 (contd)

[d] Not reported or estimatable from the reported results
[e] Results for adenocarcinoma only
[f] The original report presented 90% confidence intervals that were converted to 95% confidence intervals for this table.
[g] The raw data came from the US Environmental Protection Agency (1992).
[h] Results reported in the US Environmental Protection Agency report (1992), which also noted that the results reported in this article (odds ratio, 2.3) were erroneous
[i] One of the 202 controls was a smoker, but this would have a negligible effect on the result, so this study was included.
[j] Results from analysis excluding cases and controls already included in the study by Boffetta *et al*. (1998) [personal communication M. Kreuzer]
[k] Crude results are for comparisons between women married to smokers and those married to non-smokers. The adjusted result was obtained by pooling the odds ratio corresponding to women married to smokers who smoked in their presence with the odds ratio corresponding to women married to smokers who did not smoke in their presence.
[l] Authors reported a 90% confidence interval that was adjusted to a 95% confidence interval for this table. It should also be noted that this result was for a comparison of women whose husbands smoked 1–19 cigarettes/day with women whose husbands were nonsmokers, and did not include the highest exposure group (≥ 20 cigarettes/day).
[m] Fisher's exact 95% confidence intervals were estimated.

Exposure–response relationships

The analysis of exposure–response relationships provides critical evidence for or against a causal relationship between exposure to secondhand smoke and the development of lung cancer.

In the study by Garfinkel (1981), the relative risk did not increase with increasing exposure levels.

In the study by Hirayama (1984), the relative risks for women were 1.4, 1.4, 1.6 and 1.9 when their husbands were ex-smokers, and when they smoked 1–14, 15–19 or ≥ 20 cigarettes/day, respectively (p value for trend test, 0.002). Similarly the relative risk for nonsmoking men increased with exposure level: it was 2.1 when the wives smoked 1–19 cigarettes/day and 2.3 when they smoked ≥ 20 cigarettes/day (p value for trend test, 0.02).

The study by Cardenas *et al.* (1997) also found a significant exposure–response relationship. When the husbands smoked 1–19, 20–39 and ≥ 40 cigarettes/day, the relative risks for women exposed to secondhand smoke were 1.1, 1.2 and 1.9 respectively (p value for trend test, 0.03). There was no evidence of an association between risk and the length of time the couples had been married. A similar analysis for nonsmoking men exposed to secondhand smoke would not be robust because the number of cases was too small. The particular strengths of this study were the near complete data on cause of death (97%), direct questioning of both partners about their smoking habits, and the taking into account of numerous potential confounders such as previous lung disease, occupational exposure to asbestos, dietary habits and education.

Taken together, the three large cohort studies demonstrate an increased incidence of deaths from lung cancer associated with exposure to secondhand smoke from the spouse. The increase in deaths from lung cancer in the study by Hirayama (1984) is significant, and this study and that by Cardenas *et al.* (1997) also reported a significant exposure–response relationship.

2.1.2 *Case–control studies*

Many case–control studies have been undertaken in several countries (mostly China and the USA) (described in Table 2.3). In these studies lung cancer cases were ascertained and matched with controls (usually for age and other factors). The controls were selected from either the general population or the hospital in which the patients with lung cancer were diagnosed. Details of the smoking habits of the partners of both cases and controls were obtained either by interview or questionnaire. In some instances the next of kin provided the relevant information. These studies were based on various measures of exposure to secondhand smoke, including exposure from the partner, at the workplace, during childhood or exposure from other sources. The following section describes only large, relevant studies in which all cases and controls were interviewed in person and no information from the next of kin was used to reconstruct exposure.

(*a*) *Description of studies*

The study of Lam *et al.* (1987) included 199 cases and 335 controls from Hong Kong, Special Administrative Region of China. The study is characterized by good data on exposure (from various sources) to secondhand smoke, valid classification of the smoking habits of the husband and a consideration of potential confounders (including education, place of birth, duration of residence and marital status).

The study from China by Gao *et al*. (1987) included 246 cases and 375 controls. The cases were identified using a system built upon the Shanghai Cancer Registry. The analyses were controlled for age and education.

The study of Wu-Williams *et al.* (1990), also from China, included 417 cases and 602 controls. A limitation of this study is that it was not able to control for important indoor sources of exposure to potential lung carcinogens such as those produced during burning of coal and frying in oil.

The study of Brownson *et al.* (1992) in the USA included 431 cases and 1166 controls. It is characterized by good documentation of data on exposure in the home and the workplace, and took into account potential confounders (age, sex and socioeconomic status).

In the study of Fontham *et al*. (1994) in the USA, 651 cases and 1253 controls were interviewed. Possible misclassification of smokers and potential confounding by age, occupational exposure to known carcinogens, eating habits, familial history of lung cancer and education were taken into account. The smoking status was verified by means of cotinine determination to minimize the misclassification of smokers as nonsmokers.

Table 2.3. Main study design characteristics of case–control studies on exposure to secondhand smoke and lung cancer

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Chan & Fung (1982) (Hong Kong, SAR, 1976–77)	Women: 84 cases, 139 controls	Histologically confirmed cases of bronchial cancer were identified in five hospitals in Hong Kong. Controls were identified from patients in the orthopaedic ward at the same hospitals and were selected from the 'same general age group' as the cases.	None	Patients were interviewed using a questionnaire that included a question on exposure to passive smoke at home.
Correa *et al*. (1983) (USA, not reported)	Men: 8 cases, 178 controls Women: 22 cases, 133 controls	Cases of primary lung cancer identified from admission and pathology records at 29 hospitals. Patients with bronchioalveolar cancer were excluded. Controls were randomly selected from patients attending the same hospital and matched for race, sex and age. Patients with smoking-related diseases were excluded from the controls.	None	Study subjects were interviewed with a questionnaire including questions on history of exposure from smoking spouses and parental smoking.
Trichopoulos *et al*. (1983) (Greece, 1978–82)	Men and women: 77 cases, 225 controls	Cases of lung cancer other than adenocarcinoma of the terminal bronchi were identified from three hospitals in Athens. Controls were drawn from an orthopaedic hospital in the same area as the cases. The cases and controls had 'similar demographic and socioeconomic profiles'.	None	Physicians interviewed subjects concerning smoking habits of their spouses.
Buffler *et al*. (1984) (USA, 1976–80)	Men: 11 cases, 90 controls Women: 41 cases, 196 controls	Patients aged 30–79 years with histologically confirmed lung cancer were identified from hospital and state records in six counties in Texas. Population-based and deceased controls were selected from state and federal records that were matched to cases on age, race, sex, region of residence and vital status.	Age, race, sex, region of residence and vital status	Questionnaires were administered to study subjects or next of kin, which included questions on household members who smoked regularly.
Kabat & Wynder (1984) (USA, 1971–80)	Men: 25 cases, 25 controls Women: 53 cases, 53 controls	Cases of primary cancer of the lung were selected from hospitals. One control was matched to each case on age, sex, race, hospital and date of interview. Controls were selected from other hospitalized patients who had diseases that were not tobacco related.	None	Study subjects were interviewed in hospital using a standardized questionnaire that included questions on spousal and workplace exposure.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Lam (1985) (Hong Kong, SAR, 1981–84)	Women: 60 cases, 144 controls	Cases of primary lung cancer were identified from a hospital in Hong Kong. Controls were selected from patients in the orthopaedic wards of the same hospital and were reported to be comparable in age and social class to the cases. Sufficient numbers of cases were available to permit a meaningful analysis only for adenocarcinoma.	Although age and social class appear to have been matched for, they were not controlled for in the analysis.	Exposure assessment used interviews of study subjects or next of kin, which included questions on exposure to secondhand smoke from parents, spouse or other family members.
Garfinkel *et al*. (1985) (USA, 1971–81)	Women: 134 cases, 402 controls	Cases and controls were identified from three hospitals in New Jersey and one in Ohio. Controls were colon and rectum cancers matched to the cases on age and hospital. Both cases and controls were histologically confirmed.	Age and hospital in all analyses. Logistic regression also controlled for socioeconomic status and year of diagnosis	Study subjects or next of kin were interviewed using a questionnaire designed to elicit information on exposure to secondhand smoke from the spouse or other household member(s).
Wu *et al*. (1985) (USA, 1981–82)	Women: 29 patients with adenocarcinomas and 62 controls; 2 with squamous-cell carcinomas and 30 controls[a]	Cases diagnosed by microscopy were identified from a population-based tumour registry in Los Angeles County. Cases were white residents, under 76 years of age who had no prior history of cancer (except melanoma). Neighbourhood controls met the same criteria and were matched to cases on date of birth.	Age. Active smoking was included in analyses that were not restricted to nonsmokers.	A structured telephone questionnaire was used to elicit information on exposure to secondhand smoke from spouse or other household members, and during childhood from household members.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Akiba *et al*. (1986) (Japan, 1971–80)	Women: 94 cases, 270 controls Men: 19 cases, 241 controls	Cases and controls were identified from a cohort of atomic bomb survivors in Hiroshima and Nagasaki. Cases were identified from tumour, mortality and other medical registries. Controls were matched to cases by birth, sex, city of residence, vital status and whether they participated in an annual medical programme. For deceased cases, the corresponding controls were required to have died from a disease other than cancer or chronic respiratory diseases, and were matched to cases on year of death.	Age, sex, city, and year of death	Subjects or next of kin were interviewed using a structured questionnaire to elicit information on exposure to secondhand smoke from a spouse or parent.
Lee *et al*. (1986) (United Kingdom, 1979–82)	Women: 32 cases, 66 controls Men: 15 cases, 30 controls	Cases and controls were nonsmokers identified from several hospitals in England. Controls were patients who did not have lung cancer, chronic bronchitis, ischaemic heart disease or stroke. Two controls for each case were selected and matched on sex, age, marital status, and as far as possible, hospital.	Age, sex, hospital and marital status	The patients and their spouses were interviewed to obtain a history of spousal smoking.
Schwartz (1996) (USA, 1984–87)	Men and women: 401 cases, 398 controls	Cases between the ages of 40 and 84 years were identified in Detroit from an Occupational Cancer Incidence Surveillance Study (OCISS) in conjunction with the Metropolitan Detroit Cancer Surveillance System. Population-based controls were randomly selected from the controls who took part in the OCISS study. Controls were frequency-matched to cases on age, sex, race and county of residence.	Age, sex and race	Telephone interviews were conducted with cases (17%) or controls (78%) or their proxies. The questionnaire included information on exposure to secondhand smoke at work or at home.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Brownson *et al*. (1987) (USA, 1979–82)	Women: 19 cases, 47 controls Men: 4 cases, 19 controls	Cases of adenocarcinoma and controls were identified from the Colorado Central Cancer Registry. All cases were confirmed by microscopy. Controls were patients with colon and bone marrow cancer and were group-matched to cases on age and sex. Cases and controls were required to have resided for a minimum of 6 months in the Denver metropolitan area prior to diagnosis.	Age, sex and socioeconomic status	Cases and controls or next of kin were interviewed and information collected on the smoking status of the spouse and the number of hours per day exposed to secondhand smoke.
Gao *et al*. (1987) (China, 1984–86)	Women: 246 cases, 375 controls	Cases of lung cancer were identified among female residents of Shanghai aged 35–69 from a system built upon the Shanghai Cancer Registry. Female controls were randomly selected from the Shanghai area and approximately frequency-matched on age.	Age and education	Cases and controls were interviewed to obtain information on exposure in childhood and adulthood.
Geng *et al*. (1988) (China, not stated)	Women: 54 cases, 93 controls	Cases were identified among females who had lived for more than 10 years in Tianjin, China. Controls were matched to the cases on sex, race, age and marital status. The precise source of the cases or controls is not stated.	None[b]	The methods used to collect information on exposure to secondhand smoke are not described.
Humble *et al*. (1987) (USA, 1980–82)	Men: 8 cases, 130 controls Women: 20 cases, 162 controls	Cases were identified from the New Mexican Tumor Registry. An initial series was selected between 1980 and 1982 that included all individuals less than 50 years of age, Hispanics aged over 50 years, and a random sample of male (40%) and female (50%) non-Hispanics over 50 years.	Ethnicity and age	Interviews of study subjects (48% cases) or their next of kin (52% cases) were conducted to collect information on spousal smoking habits.
Koo *et al*. (1987) (Hong Kong, SAR, 1981–83)	Women: 86 cases, 136 controls	Cases were identified as part of a larger study on female lung cancer in Hong Kong from the wards and outpatient departments of eight hospitals. An equal number of 'healthy' controls were selected and matched to cases on age, district and socioeconomic status (housing type).	Age, district and housing type, formal schooling and number of live births	Cases and controls were interviewed to elicit information on exposure to secondhand smoke from spouses and other relatives at home.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Lam *et al*. (1987) (Hong Kong SAR, 1983–86)	Women: 199 cases, 35 controls	Pathologically confirmed cases of lung cancer were identified from eight hospitals. Controls were matched to the cases on age and drawn from the same neighbourhood as the corresponding case.	None	Study subjects were interviewed using a questionnaire that included questions concerning the husband's smoking habits.
Pershagen *et al*. (1987) (Sweden, 1963–80)	Women: 70 cases[c]	Cases and controls were selected from two cohort studies in Sweden. The first was a sample of men and women aged 15–65 years in the 1960 National Census who were mailed a questionnaire on smoking habits in 1963. The second was from a study of Swedish twins born between 1886 and 1925. Lung cancer cases were identified until 1980 by links with the Swedish Cancer Registry and the National Register on Causes of Death. Two control series were selected at random from the cohort. One was based on matching controls to cases based on year of birth, and the other on vital status at the end of follow-up as well as year of birth.	Age and vital status	A questionnaire was mailed in 1984 to each study subject, or if they were dead, to their next of kin (excluding the husband). The questionnaire included questions on exposure to secondhand smoke from husbands and parents.
Inoue & Hirayama (1988) (Japan, 1972–83)	Women: 22 cases[d], 62 controls	Cases and controls are from Kamakure and Miura, Japan. The methods used to identify the cases and controls were not clearly stated. Controls were individuals with cerebrovascular disease who were matched to the cases on age, year of death and district.	Age, year of death and district	Interviews were conducted using 'standard questionnaires'.
Shimizu *et al*. (1988) (Japan, 1982–85)	Women: 90 cases, 163 controls	Cases of primary lung cancer were identified from 4 hospitals in Nagoya, Japan. Controls were patients from adjacent wards with diseases other than lung cancer who were matched to the cases on age and date of admission.	Age, hospital and date of admission	Participants answered a questionnaire on the first or second day of admission that included questions on exposure to secondhand smoke from the spouse and other family members, and at the workplace.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Choi *et al.* (1989) (Republic of Korea, 1985–88)	Women: 75 cases, 144 controls	375 patients with lung cancer admitted to Korean Cancer Centre Hospital with histopathologically confirmed diagnosis. Two controls were selected per case matched by age (± 5 years), gender, admission date and area (urban/rural); patients with smoking-related diseases were excluded.	Unmatched analysis of subgroup of non-smoking study subjects	A questionnaire was administered face-to-face including questions on smoking.
Janerich *et al*. (1990) (USA, 1982–85)	Men and women: 191 cases, 191 controls	Cases were identified from 125 diagnostic or treatment facilities covering 23 counties in New York State, and from the New York State cancer registry. Cases were between 20 and 80 years of age, and had to have been resident of one of the 23 counties. Controls were identified from records of the New York Department of Motor Vehicles, and matched to the cases on age, county of residence and smoking history (i.e. nonsmokers).	Age and county of residence	Face-to-face interviews were conducted with cases or controls or their next of kin. When a next-of-kin interview was required, the next of kin of the matching controls were also interviewed. The questionnaire included questions on exposure to smoke from the spouse, at the workplace and during childhood.
Kalandidi *et al*. (1990) (Greece, 1987–89)	Women: 90 cases, 120 controls	Cases with a 'definite' diagnosis of lung cancer were identified from 7 hospitals in the greater Athens area. Controls were women hospitalized in the orthopaedic department of the same or a nearby hospital, and were randomly selected from those who entered within a week of a corresponding case. Controls had to be 35 years or older.	Age, years of schooling, interviewer and total energy consumption	A questionnaire was administered face-to-face to the cases and controls that included questions on exposure to secondhand smoke from the spouse, other household members and at the workplace.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Sobue (1990) (Japan, 1986–88)	Women: 144 cases, 731 controls	Cases of lung cancer and controls aged 40–79 years were identified from eight hospitals in Osaka, Japan. Controls were individuals with diseases other than lung cancer.	Age and education	A self-administered questionnaire was given to cases and controls at the time of admission which included questions on exposure to secondhand smoke.
Wu-Williams *et al*. (1990) (China, 1985–87)	Women: 417 cases, 602 controls	Patients under the age of 70 years with primary lung cancers were identified in the cancer registries of Shenyang and Harbin, China and of major hospitals serving these areas. Controls were randomly selected from the populations of Shenyang and Harbin, and were frequency-matched to the cases by age.	Age, education and centre	Cases and controls were interviewed using a questionnaire that included questions concerning exposure to secondhand smoke from the spouse and other co-habitants, and at the workplace.
Liu *et al*. (1991) (China, 1985–86)	Men and women: 4 cases, 19 controls	Cases of lung cancer were identified from hospitals and clinics in Xuanwei. Controls were matched to the cases on age, sex and village of residence.	Age, sex, village of residence and cooking history	Cases and controls were personally interviewed using a questionnaire that included a question on exposure to second-hand smoke at home (primarily from the spouse)
Brownson *et al*. (1992) (USA, 1986–91)	Women: 431 cases, 1166 controls	Cases of primary lung cancer among white females were identified from the Missouri cancer registry; 76% of the cases were histologically verified. Controls were selected for women under 65 years from the state driver's license files, and for women 65 years or over from the Health Care Finance Administration's roster of Medicare recipients. Controls were frequency-matched to cases on age.	Age, previous lung disease and dietary β-carotene and fat	Telephone interviews were conducted that included questions concerning exposure to secondhand smoke during childhood and adulthood.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Stockwell *et al*. (1992) (USA, 1987–91)	Women: 210 cases, 301 controls	Cases of histologically confirmed primary lung cancer were identified from hospital tumour registries, and a state-wide cancer registry in 28 counties in central Florida. Population-based controls were selected using random digit dialling.	Age, race and education	Interviews of patients or next of kin were conducted in person, by telephone or occasionally by post. The questionnaire included questions on exposure to secondhand smoke at home, at work or in social settings.
Du *et al*. (1993) (China, 1985–86)	**1985 analysis** Men and women: 120 cases, 120 controls with non-respiratory disease, 120 controls with non-respiratory cancer **1986 analysis** Women: 75 cases, 128 non-cancer patients as controls plus 126 controls with tumours other than of the lung	Cases in this study were apparently identified from deaths reported to the local police stations in Guanghzo. Two separate analyses are presented (1) for nonsmokers in 1985 and (2) for female nonsmokers in 1986. Two control groups were selected for each analysis, but it is not clear how these controls were selected. The control groups for the first analysis consisted of (1) non-respiratory system diseases and (2) non-respiratory cancers. The control groups for the second analysis consisted of (1) non-tumour disease and (2) tumours other than of the lung. In the first analysis, controls were matched to cases on sex and age, and were matched on residence in both analyses.	First analysis sex, age and residence Second analysis did not adjust for covariates.	A questionnaire was used by trained personnel to obtain information from family members; it included questions on spousal smoking habits.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Liu *et al*. (1993) (China, 1983–84)	Women: 38 cases, 69 controls	Cases of primary lung cancer were identified from eight major hospitals covering most of Guangzhou. Controls were selected from inpatients at six of these hospitals and patients with chronic obstructive lung diseases, pulmonary tuberculosis, cancers and coronary heart disease were excluded. Controls were matched to cases on age, sex, residential district and date of diagnosis or admission to hospital.	Age, sex, residential area, calendar time, education and occupation	Interviews were carried out in the homes of the subjects using a questionnaire that included questions on spousal smoking habits.
Fontham *et al*. (1994) (USA, 1986–90)	Women: 651 cases, 1253 controls	Cases of primary lung cancer confirmed by microscopy were identified between 1986 and 1988 among residents of Atlanta, and Houston; and between 1989 and 1990 among residents of New Orleans, Los Angeles and San Francisco. Population-based controls were chosen using random digit dialling and random sampling from the Health Care Financing Administration's files. Controls were frequency-matched to cases on race, study centre and age. Cases and controls were required to be between 20 and 79 years of age, to speak English, Spanish or Chinese, and to have no prior history of cancer.	Age, race, study centre, education, family history of cancer, occupational and dietary factors	In-person interviews were conducted with cases and controls or with next of kin. The questionnaire included questions on exposure to secondhand smoke during adulthood (from spouse and at work), and during childhood (from parents or other household members). Urine cotinine measurements were made and used to eliminate individuals who may have been smokers.
Kabat *et al*. (1995) (USA, 1983–90)	Women: 69 cases, 187 controls Men: 100 cases, 117 controls	Histologically confirmed cases were identified in hospitals in New York City, Chicago, Detroit and Philadelphia. Controls were patients admitted to the same hospitals with diseases thought to be unrelated to tobacco smoke. Cases were matched to controls on age, sex, race, hospital and date of interview.	Age, sex, race, education and type of hospital (cancer centre versus other)	In-person interviews were conducted that included questions on exposure to secondhand smoke in childhood and adulthood (at home and in the workplace)

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
de Waard *et al*. (1995) (the Netherlands, 1989, 1991, 1992)	Women: 23 cases, 305 controls	Cases and controls were identified from two cohorts of women screened for breast cancer in Utrecht. The first cohort included women aged 50–64 years who were screened in 1975 and 1977, and re-examined 1 year later. The second cohort included women aged 40–49 years who were screened between 1982 and 1983. Lung cancer cases were identified from mortality and cancer incidence registries. Cancer cases and controls were identified for the first cohort in 1989, 1991 and 1992, whereas cases and controls for the second cohort were identified only in 1992. Four controls were selected for each case identified in 1989 and 1991, and two controls per case in 1992 from the cohort files. Controls were matched to cases on 'about the same age and day of urine collection' for the 1989 cases, and it is unclear whether this matching criterion was also applied to cases and controls from the other years.	Possibly age and calendar time, but it is not clear if these were matched for in all cases or adjusted for in the analyses.	Urinary cotinine concentrations measured in samples collected during the screenings. Non-smokers were defined as subjects with creatinine adjusted cotinine levels of < 9.2 ng/mg creatinine
Sun *et al*. (1996) (China, not reported)	Women: 230 cases, 230 controls	This was a population based case–control study in Harbin. Only an abstract was available, and the source of the cases and controls was not described in it.	Age and education	In-person interviews of cases and controls included questions on exposure to secondhand smoke during childhood, adolescence and adulthood.
Wang *et al*. (1996) (China, 1992–94)	Women: 135 cases, 135 controls	Cases of primary lung cancer who were between 35 and 69 years of age were identified in 18 hospitals in Shenyang. Controls were randomly selected from the urban population in Shenyang, and matched to cases on age.	Cases and controls were matched for age, but it is unclear whether an unmatched analysis was performed.	Cases and controls were interviewed face-to-face using a questionnaire that included questions on exposure to secondhand smoke in childhood and adulthood.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Boffetta *et al*. (1998) (Europe, 1988–94)	Men: 141 cases, 531 controls Women: 508 cases, 1011 controls	Cases and controls were ≤ 74 years of age and had smoked < 400 cigarettes in their lifetimes. Cases were identified from 12 centres in seven European countries and 96.5% were confirmed by microscopy. Controls were hospital-based in some centres and community-based in others. Hospital-based controls were chosen to exclude those with other diseases related to smoking. Community-based controls were drawn from population registries. Controls were matched to cases on age and sex using individual matching in some centres and frequency matching in others. Questionnaire response rates ranged from 53 to > 95% except for 3 centres who had response rates < 50% among controls.	Sex, age and centre	Questionnaire on exposure to secondhand smoke from spouse, during childhood, in the workplace and from other sources was developed based on a previous study of urine cotinine levels and exposure to secondhand smoke including smoke from cigarillos, cigars and pipes as well as cigarettes.
Jöckel *et al*. (1998b) (Germany, 1988–93)	Men and women: 71 cases, 236 controls	Cases and controls were also a part of the study by Boffetta *et al.* (1998). Nonsmokers were identified from a larger case–control study from Bremen, Frankfurt and the surrounding areas. Controls were population based and matched to the cases on sex, age and region.	Sex, age, region, exposure to asbestos, social class, and intake of vegetables and fruits	Compatible with questionnaire used in study by Boffetta 1998. Individuals who had never smoked regularly for more than 6 months were classified as 'never-smokers', and were combined with workers exposed to low levels of secondhand smoke (< 75th percentile) to form the referent group.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Shen *et al*. (1998) (China, 1993)	Women: 70 cases, 70 controls	Cases of primary lung cancer (adenocarcinoma) living ≥ 20 years in Nanjing; healthy controls came from the same neighbourhood, 1:1 matched by sex and age (± 5 years); response rate was 100%.	Chronic lung disease, cooking conditions, family history of lung cancer	Standardized questionnaire administered by trained staff covered exposure to secondhand smoke for the 20 years preceding diagnosis: no. of cigarettes smoked/day, no. of years of exposure to secondhand smoke.
Zaridze *et al*. (1998) (Russia, not reported)	Women: 189 cases, 358 controls	Histologically confirmed cases of primary lung cancer were identified in two cancer treatment hospitals in Moscow. Controls were female oncology patients from the same hospitals who did not have lung or upper respiratory cancers. Cases and controls were required to be nonsmokers who lived in Moscow.	Age and education	In-person interviews were conducted within 2–3 days of hospital admission; they included questions on exposure to secondhand smoke in adulthood and childhood.
Boffetta *et al*. (1999a) (Europe, 1988–94)	Women: 208 cases, 361 controls	Same as Boffetta *et al*. (1998) except that results are stratified by type of exposure to secondhand smoke (cigarettes or cigars, cigarillos and pipes)	Age and centre	Same as Boffetta *et al*. (1998)
Boffetta *et al*. (1999b) (Europe, 1994–96)	Men: 4 cases, 41 controls Women: 66 cases, 137 controls	Histologically confirmed lung adenocarcinomas were identified from 9 centres in 7 countries from a larger study designed to assess the role of biomarkers of susceptibility in lung cancer among nonsmokers. Controls were selected from nonsmokers in the source populations or in hospital patients. Controls were frequency-matched to cases on age and gender.	Age, gender, and centre. Some models also included urban residence, education and occupational exposure.	Exposure to secondhand smoke was assessed using the same questionnaire as in Boffetta *et al*. (1998).

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Rapiti *et al*. (1999) (India, 1991–92)	Men: 17 cases, 56 controls Women: 41 cases, 67 controls	Histologically or cytologically confirmed cases of primary lung cancer were identified in a hospital in Chandigarh, Northern India. Two controls were selected for each case. One control was a patient at the same hospital who was not hospitalized for more than a month and did not have a disease related to active or passive smoking, alcohol or diet. The other control was a visitor of the patient. No matching of cases and controls was performed.	Sex, age, religion and residence	Interviews of subjects were conducted that included questions on exposure to secondhand smoke from the spouse, at the workplace and during childhood.
Zhong *et al*. (1999) (China, 1992–94)	Women: 504 cases, 601 controls	Cases of primary lung cancer aged 35–69 years were identified from the Shanghai cancer registry. Controls were randomly selected from a Shanghai residential registry and frequency-matched to the age distribution of female lung cancer patients in Shanghai in 1987–89.	Age, income, vitamin C intake, kitchen smokiness, family history of lung cancer, and potentially high risk occupations, and respondent status	Personal interviews with study subjects or their next of kin (2.3% for controls, and 20.2% for cases). The interview included questions on exposure to secondhand smoke from the spouse, at the workplace and during childhood.
Brennan *et al*. (2000) (Europe, 1994–96)	Subset of cases and controls from centres included in Boffetta *et al*. (1998) for whom dietary information was available	Same as Boffetta *et al*. (1998), but analyses were restricted to centres that had information on subjects' consumption of fruit, lettuce, tomato, carrot, cheese, carotenoids, β-carotene or retinol. Analyses were stratified by high and low consumption of these dietary variables, and high and low exposure to secondhand smoke.	Age, gender and centre	Same as Boffetta *et al*. (1998). High exposure to secondhand smoke was defined as being in the upper quartile from combined spousal and workplace exposures.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Kreuzer *et al*. (2000) (Germany, 1990–96)	Men and women: 292 cases, 1338 controls	An extension of the German part of the European multicentre study (Boffetta *et al*., 1998). The cases and controls were a subset of nonsmokers from a larger study of radon exposure in Germany. Cases were identified from 15 hospitals in the study area and were restricted to those who were < 75 years of age; resident in the study area; had lived for > 25 years in Germany; interviewed within 3 months of diagnosis, and not too ill. Controls satisfying the first three criteria listed above were identified from mandatory registries or by modified random digit dialling and were frequency-matched to the cases on sex, age and region. The response rate in the cases was 76%, but that of the controls was only 41%.	Age, region, gender; some models included occupational exposure, exposure to radon, diet, family history of cancer, previous non-malignant respiratory disease and social class.	Same as Boffetta *et al*. (1998)
Lee *et al*. (2000) (China (Province of Taiwan), 1992–98)	Women: 268 cases, 445 controls	Histologically verified cases were identified from Kaohsiung Medical University Hospital in Taiwan. Controls were patients with conditions unrelated to tobacco smoking who were selected within 3 weeks of the case admission from the same hospital, and matched on age.	Age, date of hospital admission, residential area, education, occupation, tuber-culosis, cooking fuels and presence of a fume extractor	Interviews were conducted using a structured questionnaire designed to elicit information on exposure to secondhand smoke.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Wang *et al*. (2000) (China, 1994–98)	Men: 33 cases, 1214 controls Women: 200 cases, 407 controls	Cases of lung cancer who were aged 30–75 years and residents of Pingliang or Qingyang prefectures were identified from hospitals and clinics in these and neighbouring regions. Controls were randomly selected from 1990 census lists for the 2 prefectures and frequency matched to cases on age, sex and prefecture.	Age, sex and prefecture	In person interviews were conducted with cases and controls or with their next of kin when necessary. The questionnaire included questions on exposure to secondhand smoke during adulthood, childhood and in the workplace.
Johnson *et al*. (2001) (Canada, 1994–97)	Women: 71 cases, 761 controls	Cases of histologically confirmed primary lung cancer were identified from a national cancer surveillance system that covers 8 of Canada's 10 provinces. In five provinces controls were identified from health insurance plans, in one from property assessment databases, and in two using random digit dialling. Controls were frequency-matched to the expected distribution of cancer cases by age and province.	Age, province, education and fruit and vegetable consumption	Mailed questionnaires were completed by cases and controls except in one province where next of kin completed them. The questionnaires included questions on exposure to secondhand smoke at work, at home and during childhood.
Kreuzer *et al*. (2001) (Germany, 1990–96)	Men: 58 cases, 803 controls	Same as Kreuzer *et al*. (2000) except that analyses were restricted to men.	Same as Kreuzer *et al*. (2000)	Same as Boffetta *et al*. (1998). Results only presented for low and high exposure to secondhand smoke where high was defined as having greater than the 75th percentile of cumulative duration of exposure weighted by a subjective index of intensity.

Table 2.3 (contd)

Reference (country, years of study)	No. of non-smoking cases and controls	Eligibility criteria and comments	Covariates adjusted for	Source of exposure data
Kreuzer *et al*. (2002) (Germany, 1990–96)	Women: 234 cases, 535 controls	Same as Kreuzer *et al*. (2000) except that analyses were restricted to women	Same as Kreuzer *et al*. (2000)	Same as Boffetta *et al*. (1998). Results only presented for high and medium exposure to secondhand smoke versus low or non-exposed. High was defined as having greater than the 90th percentile of cumulative duration of exposure, and low was defined as having less than the 75th percentile.

[a] This study presented results separately for patients with adenocarcinoma and for patients with squamous-cell carcinoma. However, the numbers for the squamous-cell carcinomas were too few to present meaningful results for secondhand smoke in nonsmokers.
[b] Although this study did match cases to controls on several potential confounders, an unmatched analysis was published.
[c] The study had a total of 184 controls in each of the control groups. However, it is unclear how many controls were used in the analysis of exposure to secondhand smoke because several cases (and presumably their matched controls) were dropped from these analyses.
[d] Information on spousal smoking habits was available for only some of the cases and controls. The actual number of cases and controls included in the analysis was not reported, but was smaller than the given numbers.

The study from China by Sun *et al*. (1996) included 230 cases and 230 controls. The study controlled for age and education, but not for burning of coal and frying in oil.

The study of Lee *et al*. (2000) from China (Province of Taiwan) included 268 cases and 445 controls and was an extension of the study of Ko *et al*. (1997). Detailed information on exposure to secondhand smoke was collected, and nonsmoking status was verified by household members. Potential confounding by age, education, occupation, cooking fuels and other factors was allowed for.

The participants in a European multicentre study included 650 cases and 1542 controls from 12 centres in seven countries. Potential confounders such as occupational exposure, socioeconomic status and intake of fruits and vegetables were taken into account. The main publication was by Boffetta *et al.* (1998), but additional analyses were made of effects of secondhand smoke from cigars, cigarillos and pipes (Boffetta *et al*., 1999b) and of exposure to secondhand smoke and diet (Brennan *et al.*, 2000). In addition, the data from some centres on specific aspects have been published separately and in some cases with additional data (Germany: Jöckel *et al.*, 1998a,b; Kreuzer *et al.*, 2000, 2001, 2002; Sweden: Nyberg *et al.*, 1998).

The study of Zaridze *et al*. (1998) from Russia included 189 cases and 358 controls. Information on exposure to secondhand smoke in the family and from colleagues at work was obtained, and potential confounders (age and education) were considered.

(*b*) *Exposure to secondhand smoke from the partner*

Table 2.2 shows the relative risk for lung cancer associated with exposure to secondhand smoke from the spouse. Taking the crude relative risks, or the adjusted estimates when the crude ones are not available (in any event, the crude and adjusted estimates are similar) 25 of the 40 case–control studies of nonsmoking women showed an increased risk; the results of seven of the 25 studies were statistically significant (Trichopolous *et al.*, 1983; Lam, 1985; Lam *et al.*, 1987; Geng *et al.*, 1988; Fontham *et al.*, 1994; Zaridze *et al.*, 1998; Lee *et al.*, 2000). In studies of nonsmoking men, five of the nine studies showed an increased risk, although none were statistically significant.

Exposure–response relationships

Several studies reported the risk of lung cancer associated with increasing levels of exposure, in particular, the number of cigarettes smoked by the spouse per day, the number of years of living with a smoker and pack–years; these studies are listed in Table 2.4. Because most of these studies were relatively small, they would not have had sufficient statistical power to find an exposure–response relationship. Eight studies found a statistically significant trend (p value < 0.05) between lung cancer risk and the number of cigarettes smoked by the spouse (Trichopolous *et al.*, 1983; Hirayama, 1984; Garfinkel *et al.*, 1985; Lam *et al.*, 1987; Geng *et al.*, 1988; Inoue & Hirayama, 1988; Liu *et al.*, 1993; Cardenas *et al.*, 1997) and one other found an almost statistically significant trend (Akiba *et al.*, 1986; $p = 0.06$). Six studies found a statistically significant trend (p value < 0.05) for lung cancer risk and the number of years of marriage to a smoker (Gao *et al.*,

Table 2.4. Relative risk of lung cancer in lifelong nonsmoking women comparing those with the highest exposure to secondhand smoke from a smoking partner to women with nonsmoking partners (the relative risks are ranked in ascending order for each type of exposure)

Reference	Exposure level	Relative risk[a] (95% CI)	
	No. of cigarettes smoked per day by the spouse		
Garfinkel (1981)	≥ 20	1.1	(0.8–1.6)
Kabat *et al.* (1995)	> 10	1.1	(0.5–2.3)
Humble *et al.* (1987)	≥ 21	1.2	(0.3–5.2)
Koo *et al.* (1987)	≥ 21	1.2	(0.5–3.0)
Boffetta *et al.* (1998)	> 18.1	1.3	(0.8–2.2)
Wang *et al*. (1996)	≥ 20	1.4	(0.8–2.6)
Zhong *et al*. (1999)	> 20	1.4	(0.7–2.6)
Jee *et al*. (1999)	≥ 20	1.5	(0.7–3.3)
Du *et al.* (1993)	> 20	1.6[b]	(0.8–3.2)
Kalandidi *et al.* (1990)	≥ 41	1.6	(0.5–4.6)
Hirayama (1984)[c,d]	≥ 20	1.7	(1.1–2.7)
Cardenas *et al.* (1997)	≥ 40	1.9	(1.0–3.6)
Trichopoulos *et al.* (1983)	≥ 31	1.9	(0.7–5.0)
Akiba *et al.* (1986)[d]	≥ 30	2.1	(1.7–2.6)
Garfinkel *et al.* (1985)	≥ 20	2.1	(1.1–4.0)
Lam *et al.* (1987)	≥ 21	2.1	(1.1–4.0)
Geng *et al.* (1988)	≥ 20	2.8	(1.9–4.1)
Liu *et al.* (1993)	≥ 20	2.9	(1.2–7.3)
Pershagen *et al.* (1987)	≥ 16[e]	3.2	(1.0–9.5)
Inoue & Hirayama (1988)	≥ 20	3.4	(1.2–9.7)
	No. of years of marriage to a smoker		
Buffler *et al*. (1984)	≥ 33	0.9	(0.4–2.3)
Sun *et al*. (1996)	≥ 35	0.9	(0.5–1.7)
Boffetta *et al.* (1998)	≥ 43	1.0	(0.7–1.7)
Cardenas *et al.* (1997)	≥ 30	1.1	(0.6–2.1)
Wang *et al*. (1996)	≥ 41	1.1	(0.4–3.1)
Zhong *et al*. (1999)	≥ 36	1.1	(0.7–1.8)
Du *et al.* (1993)	≥ 30	1.2	(0.6–2.3)
Fontham *et al.* (1994)	≥ 31	1.2	(0.9–1.7)
Akiba *et al.* (1986)[d]	≥ 40	1.3	(0.6–2.8)
Zaridze *et al.* (1998)	> 15	1.4	(1.0–2.1)
Gao *et al.* (1987)	≥ 40	1.7	(1.0–2.9)
Kalandidi *et al.* (1990)	≥ 40	1.9	(0.8–4.3)
Wu *et al.* (1985)	≥ 31[f]	2.0	NA[g]
Humble *et al.* (1987)	≥ 27	2.1	(0.7–6.9)

Table 2.4 (contd)

Reference	Exposure level	Relative risk[a] (95% CI)	
Choi *et al.* (1989)	≥ 41	2.3	(1.0–5.6)
Stockwell *et al.* (1992)	≥ 40	2.4	(1.1–5.3)
Jee *et al*. (1999)	≥ 30	3.1	(1.4–6.6)
Geng *et al.* (1988)	≥ 40	3.3	(2.1–5.2)
	No. of pack–years of exposure[h]		
Rapiti *et al*. (1999)	> 128	0.4	(0.1–1.8)
Kreuzer *et al*. (2000)[i]	> 23	0.8	(0.2–3.1)
Brownson *et al.* (1992)	≥ 40	1.3	(1.0–1.7)
Boffetta *et al.* (1998)	≥ 23	1.5	(1.0–2.4)
Cardenas *et al.* (1997)	≥ 36	1.5	(0.8–2.6)
Fontham *et al.* (1994)	≥ 80	1.8	(1.0–3.3)
Lee *et al*. (2000)	> 40	3.3	(1.7–6.2)
Correa *et al.* (1983)	≥ 41	3.5	[1.2–10.2][j]

[a] Rate ratios for cohort studies (Garfinkel (1981), Hirayama (1984), Cardenas (1997) & Jee (1999)); odds ratios for case–control studies (all the other studies); adjusted relative risk, where not available crude relative risk

[b] Results are from an analysis using non-tumour controls. The paper also presents results using controls with tumours of sites other than lung (odds ratio, 1.4; 95% CI, 0.7–2.5).

[c] The results are from Table 2 of Hirayama (1984), which were adjusted by the wife's age.

[d] The report presented 90% CIs; 95% CIs were estimated for this table.

[e] For ≥ 30 years of marriage

[f] Years of exposure for adults (from partner and at workplace)

[g] Not available or estimatable from data presented in the paper

[h] Pack–years = number of packs of cigarettes smoked daily by the partner × years of smoking

[i] Some of the cases and controls reported on in Kreuzer *et al*. (2000) were part of another study included in this table (Boffetta *et al*., 1998). The results given here for the study by Kreuzer are based on those cases and controls that were not part of the study by Boffetta (personal communication M. Kreuzer).

[j] Confidence intervals in brackets were not given in the original report and were estimated for this table using an approximate method.

1987; Geng *et al.*, 1988; Stockwell *et al.*, 1992; Fontham *et al.*, 1994; Cardenas *et al.*, 1997; Jee *et al.*, 1999) and the results of two others were almost significant (Kalandidi *et al.*, 1990; Zaridze *et al.*, 1998; p value = 0.07 in both).

Table 2.4 shows the increase in risk in nonsmoking women who have the highest level of exposure according to each measure. All 20 of the studies that reported on the number of cigarettes smoked showed an increased risk in the highest exposure group, and seven of the studies reported a doubling of risk or more. Similarly, of the 18 studies that looked

at the number of years of marriage to a smoker, all but three showed an increased risk in the highest exposure group; six reported a relative risk of at least 2.0.

In summary, there is evidence of an exposure–response relationship, thus providing further support for a causal relationship between the development of lung cancer and exposure to secondhand smoke from partners.

(*c*) *Exposure to secondhand smoke at the workplace*

In total, 23 studies have been published on exposure to secondhand smoke at the workplace (Table 2.5). The results from these studies are mixed with some showing a positive association and others not. Only one study reported a statistically significant association between exposure to secondhand smoke at the workplace and risk for lung cancer (Reynolds *et al*., 1996). Many of the studies assessed only recent workplace exposure to secondhand smoke; this is likely to result in a serious misclassification of exposure because past exposure is more likely to be etiologically relevant.

Exposure–response relationships

Two studies found no statistically significant exposure–response relationship (Kalandidi *et al.*, 1990; Kabat *et al.*, 1995).

In the study by Reynolds *et al*. (1996) in the USA, the risk for lung cancer in women who were exposed to secondhand smoke at work was significantly increased to 1.6 (95% CI, 1.2–2.0). For women who had been exposed to secondhand smoke for 1–15, 16–30 or > 30 years, the relative risk for developing lung cancer increased significantly ($p < 0.001$) with the length of the exposure period: 1.5 (95% CI, 1.1–1.9), 1.6 (95% CI, 1.1–2.2) and 2.1 (95% CI, 1.4–3.2), respectively.

In the European multicentre study (Boffetta *et al.* 1998), the relative risk for lung cancer after exposure to secondhand smoke at work was 1.2 (95% CI, 0.9–1.5). No exposure–response relationship was seen when the data were analysed according to duration of exposure but a significant trend was observed after analysis of weighted exposure, which is most likely a better index of exposure than duration. A significant relative risk of 2.1 (95% CI, 1.3–3.2) was observed in the group with the highest weighted exposure.

Two studies from Germany which are included in part in Boffetta *et al.* (1998) also showed an increased risk in the highest exposure group of 1.9 (95% CI, 1.1–3.6) and 2.5 (women only, 95% CI, 1.1–5.7) (Jöckel *et al*., 1998b; Kreuzer *et al*., 2000).

The study of Rapiti *et al*. (1999) reported increasing relative risks with increasing duration of exposure, but the trend did not reach statistical significance.

In the study of Zhong *et al*. (1999), women ever exposed to secondhand smoke at work showed an odds ratio of 1.7 (95% CI, 1.3–2.3). There was a statistically significant ($p < 0.001$) increase in risk associated with the number of hours of exposure per day at work with odds ratios of 1.0 (95% CI, 0.6–1.7), 1.6 (95% CI, 1.0–2.5) and 2.9 (95% CI, 1.8–4.7) for 1–2, 3–4 and > 4 h per day. When the number of co-workers who smoked was considered there was again a statistically significant trend ($p < 0.001$) with odds ratios of 1.0 (95% CI, 0.6–1.6), 1.7 (95% CI, 1.1–2.8) and 3.0 (95% CI, 1.8–4.9) for 1–2,

NR, not reported

[a] Results shown are for exposure over the preceding 25 years

[b] Results are for adenocarcinoma. There were too few cases in this study to permit an analysis for squamous-cell carcinoma or other histological types.

[c] The 95% CI was not reported. It was estimated using the average standard error taken from Kalandidi *et al*. (1990) and Nyberg *et al*. (1998), because all three studies included similar numbers of cases of lung cancer.

[d] The reported result was 1.1 (95% CI, 0.9–1.6); the authors reported the correct estimates in Wells *et al*. (1998).

[e] Some of the cases and controls in the study by Kreuzer *et al*. (2000) were also part of another study included in this table (Boffetta *et al*., 1998). The results given here are based on those cases and controls that were not part of the study by Boffetta *et al.* [personal communication M. Kreuzer].

3–4 and > 4 co-workers who smoked, whereas there was no increase in relative risk with increasing numbers of years of exposure to secondhand smoke. Risk estimates were not affected when analyses were restricted to personal interviews excluding proxy interviews.

In summary, the studies in which exposure–response relationships were analysed generally revealed an increase in the relative risk for lung cancer associated with exposure to secondhand smoke at work and statistically significant increases in relative risk in those groups with the highest level of exposure. The associations are stronger in studies with better assessment of exposure and other aspects of study design.

(*d*) *Exposure during childhood*

The studies on exposure to secondhand smoke during childhood are summarized in Table 2.6. The results of these studies have been somewhat contradictory. Out of 23 studies, only three studies of exposure from the mother reported a significantly increased relative risk (Brownson *et al*., 1992; Sun *et al*., 1996; Rapiti *et al*., 1999) and two studies reported a significant increase in relative risk related to exposure from the father or either parent (Sun *et al*., 1996; Rapiti *et al*., 1999). One study found a significant inverse association with exposure from the father or either parent (Boffetta *et al*., 1998).

Exposure–response relationships

The study of Wang *et al*. (2000) observed a significant trend ($p < 0.01$) with increasing pack–years of childhood exposure to secondhand smoke with odds ratios for men and women combined of 1.0, 1.4 (95% CI, 1.0–2.1), 1.8 (95% CI, 1.0–3.3) and 3.0 (95% CI, 1.0–8.9) for < 1, 1–9, 10–19 and ≥ 20 pack–years. In contrast, the study of Boffetta *et al*. (1998) suggested a negative trend for cumulative exposure, which was statitistically significant for all subjects combined ($p = 0.02$).

In summary, there is no clear indication that lung cancer risk in later life is associated with exposure to secondhand smoke in childhood. However, an important problem in interpreting these studies is the very poor quality of the assessment of exposure that occurred 50 or more years in the past.

(*e*) *Exposure from other sources*

Few studies have addressed exposure to secondhand smoke from other sources. Kreuzer *et al*. (2000) reported a significantly increased relative risk of 2.6 (95% CI, 1.3–5.4) for exposure in vehicles in the highest category of weighted duration of exposure.

Other studies have either not addressed these other sources of exposure or have considered them only as part of a cumulative exposure from all sources.

In summary, insufficient data are available to evaluate the risk from exposure to secondhand smoke from other sources.

NR, not reported

[a] The crude results are given in the table and where these were not available, the adjusted ones are given.

[b] Only the p value was reported ($p < 0.05$ mother; $p > 0.05$ father); the standard error used to estimate the 95% CI was taken to be the same as in Nyberg *et al*. (1998) because both studies have a similar number of cases.

[c] There were no exposed cases and controls, and thus the odds ratio is undefined.

[d] Results from an analysis that excluded cases and controls that were included in Boffetta *et al*. (1998)

[e] The adjusted results are for children whose parents smoked in their presence whereas the crude results are for having a parent who was a smoker which is consistent with the definition used in the other studies.

(*f*) *Bias and confounding*

There are two sources of bias (misclassification bias and bias resulting from exposure to secondhand smoke in the reference group) and several potential confounders (e.g. dietary confounding) that can result in the relative risk being overestimated or underestimated in the studies of the association between lung cancer and exposure to secondhand smoke described above.

(i) *Misclassification bias*

Misclassification bias occurs when some of the subjects recorded as never-smokers who are included in the studies are in fact current or former smokers who have misreported their smoking status. Their true smoking status makes these subjects more likely to develop lung cancer and because smokers tend to live with smokers, this bias will overestimate the true risk for lung cancer from exposure to secondhand smoke from the spouse. There has been much discussion in the literature on this bias, and it is the main factor proposed as partly or fully explaining the increased risk for lung cancer observed in epidemiological studies. The bias has four determinants:

- *The prevalence of smoking in a particular population*. This can be obtained directly from some of the studies or from national statistics.
- *The aggregation ratio (the extent to which a smoker is more likely to live with another smoker rather than a nonsmoker)*. It is generally accepted to be between 2 and 4 (Wald *et al*., 1986; US Environmental Protection Agency, 1992; Lee, 1992; Hackshaw *et al*., 1997).
- *The relative risk for lung cancer in current and former smokers misclassified as never-smokers*. Some meta-analyses have assumed that the risk for lung cancer in misclassified smokers is the same as that in all reported smokers (US Environmental Protection Agency, 1992; Lee, 1992, 1998). However, misclassified current smokers tend to be light smokers and misclassified former smokers have usually given up smoking many years before the study, so the risk in both groups will be less than the average risk in all current or former smokers. The overall relative risk for lung cancer in misclassified ever smokers has been estimated to be about 3 (Hackshaw *et al*., 1997).
- *The percentage of current and former smokers misclassified as never-smokers*. The percentage of misclassified current smokers can be estimated by comparing self-reported smoking status with serum, urine or salivary cotinine levels; current smokers who report themselves to be never-smokers would tend to have high concentrations (for example, a urinary cotinine concentration > 50 ng/mg creatinine). Wells *et al*. (1998) combined the results of 13 studies, seven of which were used in the US Environmental Protection Agency (1992) report, and concluded that the rates of misclassification of smokers are low; 1.6% of Caucasian women who were current smokers reported themselves as never-smokers. The estimate was higher, though still low, for women from a minority background (4.9%). Similar conclusions had been drawn from a review of six studies on cotinine and nicotine (two of which were included in the review by Wells *et al*., 1998) in which it was estimated that 3.1% of ever smokers were current smokers who reported themselves as never-smokers (Hackshaw *et al*., 1997). Two of the case–control studies on secondhand smoke and risk of lung cancer in female never-smokers (Table 2.2) measured urinary cotinine in the subjects and compared this with their reported smoking status. The percentage of reported never-smoking women with urinary cotinine concentrations > 50 ng/mg creatinine was 3.5% in the study by

Riboli *et al*. (1995) (included in Boffetta *et al.*, 1998 in Table 2.2) and 3.1% of patients with lung cancer and 5.0% of controls in the study by Fontham *et al*. (1994).

(ii) *Bias resulting from exposure to secondhand smoke in the reference group*

Studies of the risk for lung cancer and exposure to secondhand smoke have defined the reference group as never-smoking women with husbands who are nonsmokers. However, these women, although not exposed at home, may be exposed to secondhand smoke outside the home. This bias will tend to underestimate the true relative risk.

(iii) *Dietary confounding*

Several potential confounders have been proposed that may partly or fully explain the increased risk of lung cancer associated with exposure to secondhand smoke from the spouse. None of these potential confounders have been established as having a causal link with lung cancer. For example, dietary confounding (perhaps the main potential confounder) may arise because (i) nonsmokers who live with smokers tend to have similar diets, (ii) the diets of smokers tend to be poorer than those of nonsmokers (i.e. lower consumption of fruits and vegetables) and (iii) people who consume less fruits and vegetables may be more likely to develop lung cancer. Several of the observational studies listed in Table 2.2 had attempted to adjust for consumption of fruits and vegetables or other dietary factors (Dalager *et al.*, 1986 [used data from Correa *et al.* (1983) and Buffler *et al.* (1984) in Table 2.2]; Hirayama, 1989 [used data from Hirayama (1984)]; Kalandidi *et al.*, 1990; Alavanja *et al*., 1993 [used data from Brownson *et al.* (1992)]; Fontham *et al*., 1994; Mayne *et al.*, 1994 [used data from Janerich *et al.* (1990)]; Cardenas *et al.*, 1997; Boffetta *et al.*, 1998; Zhong *et al.*, 1999; Brennan *et al*., 2000; Johnson *et al.*, 2001); they showed that the effect of dietary confounding was negligible.

2.1.3 *Meta-analyses of observational studies of exposure to secondhand smoke and lung cancer in adults*

(*a*) *Introduction*

Since the publication of the first epidemiological studies that reported directly on the association between exposure to secondhand smoke and the risk of lung cancer in nonsmokers (Garfinkel, 1981; Hirayama, 1981), there have been several other cohort studies and case–control studies. Most of these studies were based on a relatively small number of lung cancer cases and did not, therefore, have enough power to show a statistically significant association on their own. Meta-analyses have therefore been performed with the aim of pooling the available data and thus providing a more precise estimate of the risk. A meta-analysis is a formal statistical technique used to combine the estimates of relative risk across studies into a single estimate. Originally developed for clinical trials, it has also been applied to observational studies (see Peto, 1992, for a brief

discussion of some aspects of meta-analyses of case–control and cohort studies on cancer). In spite of some concerns over the application of meta-analysis to studies of secondhand smoke and lung cancer, it is an appropriate approach for interpreting the published data collectively.

(*b*) *Published meta-analyses*

This section presents the results of selected published reports.

(i) *Exposure to secondhand smoke from the spouse*

Table 2.7 shows the main results of published meta-analyses on the risk for lung cancer in never-smokers associated with exposure to secondhand smoke from the spouse, including an indication of whether any adjustment was made for bias and confounding. All the pooled estimates show an increased risk (relative risks of 1.1–1.6), despite using different combinations of studies and methodology.

Some meta-analyses adjusted for the misclassification of ever-smokers as never-smokers (which will tend to overestimate risk). For example, in the analysis by Hackshaw *et al.* (1997) the relative risk was reduced from 1.24 to 1.18 after allowing for misclassification bias in 37 studies of nonsmoking women. In the analysis by Lee *et al.* (2001), which was based on 47 studies and used a different methodology, after allowing for misclassification bias the relative risk was reduced from 1.23 to 1.17. The effect is small.

Few meta-analyses have adjusted for background exposure to secondhand smoke from sources other than the spouse in the reference group (which will tend to underestimate risk). Hackshaw *et al.* (1997) reported that the effect of such an adjustment was to increase the observed relative risk from 1.24 to 1.42.

Few reviews have attempted to adjust for diet as a potential confounder. Hackshaw *et al*. (1997) used pooled data from nine studies of the risk of lung cancer associated with fruit and vegetable consumption in nonsmokers and pooled data from three studies on the difference in diet between nonsmokers who did and did not live with a smoker; the relative risk for lung cancer due to exposure to secondhand smoke from the spouse was reduced from 1.24 (as observed) to 1.21 after adjusting for fruit and vegetable consumption. A similarly small effect was reported by Lee *et al.* (2001), after adjusting for consumption of dietary fat and education as well as consumption of fruits and vegetables, and using different methodology and a larger set of studies (for the risk of lung cancer associated with each confounder: 17 studies on consumption of fruits and vegetables, seven on dietary fat and 12 on education; for the difference between nonsmokers who do and do not live with a smoker: nine studies on consumption of fruits and vegetables, seven on dietary fat and nine on education). The relative risk for lung cancer when the husband smoked 10 cigarettes/day was reduced from 1.10 (observed) to 1.09, after allowing for these three confounders (Lee *et al.*, 2001). In both analyses the effect of allowing for confounding was small.

Table 2.7. Summary results of selected published meta-analyses of the risk for lung cancer in never-smokers exposed to secondhand smoke from the spouse

Reference	No. of studies	Sex of subjects	Pooled relative risk (95% CI)	Pooled estimate adjusted for			Adjusted pooled relative risk
				Misclassification bias	Exposure to secondhand smoke other than from the spouse	Dietary confounding	
National Research Council (1986)	13	Men and women	1.34 (1.18–1.53)	Yes	Yes	No	1.42
	13	Women	1.32 (1.16–1.53)	No	No	No	
Wald *et al*. (1986)	13	Men and women	1.35 (1.19–1.54)	Yes	Yes	No	1.53
Fleiss & Gross (1991)	9 (USA only)	Women	1.12 (0.95–1.30)	No	No	No	
Lee (1992)	28	Men and women	1.20 (1.09–1.31)	No	No	No	
	28	Women	1.18 (1.07–1.30)	No	No	No	
	11	Men	1.39 (0.97–1.99)	No	No	No	
Tweedie & Mengersen (1992)	26	Women	1.17 (1.06–1.28)	Yes	Yes	No	1.08
US Environmental Protection Agency (1992)	11 (USA only)	Women	1.19 (1.04–1.35)	Yes	Yes	No	1.59
Hackshaw (1998)	37	Women	1.24 (1.13–1.36)	Yes	Yes	Yes	1.26
	9	Men	1.34 (0.97–1.84)	No	No	No	
Zhong *et al*. (2000)	40	Women	1.20 (1.12–1.29)	No	No	No	
Lee *et al.* (2001)	47	Women	1.23 (1.12–1.36)	Yes	No	No	1.17
Boffetta *et al*. (2002)	45	Women	1.25 (1.14–1.38)	No	No	No	
	9	Men	1.25 (0.95–1.65)				

Generally, the overestimation due to misclassification bias and potential confounding seems to be balanced by the underestimation due to exposure to secondhand smoke in the reference group (Hackshaw *et al.*, 1997).

(ii) *Exposure at the workplace*

Interest in the risk of lung cancer associated with exposure to secondhand smoke at work has increased over the years and several meta-analyses have been published. These are listed in Table 2.8; some report no association, for example, Lee (1992) and Levois and Layard (1994), whereas others do report an association (Biggerstaff *et al.*, 1994; Wells, 1998; Zhong *et al*., 2000). However, the results of some of the studies may be unreliable because they used levels of exposure reported by next of kin (who may not know the true exposure status of the case or control), and because some studies evaluated only recent exposure to secondhand smoke in the workplace. Wells *et al*. (1998) excluded studies that documented only recent exposure and also studies that (i) included more than 50% surrogate responses for cases, (ii) had only minimal exposure, (iii) included exposure to other respiratory carcinogens, (iv) included subjects who had smoked, and (v) did not report appropriate data to allow the confidence intervals to be checked. Based on these criteria, Wells *et al*. (1998) identified the following studies for inclusion in their meta-analysis: Wu *et al*. (1985), Shimizu *et al*. (1988), Kalandidi *et al*. (1990), Kabat *et al*. (1995) and Reynolds *et al*. (1996); the pooled risk estimate was 1.4 (1.2–1.7). Overall, there seems to be an increased risk of lung cancer in subjects exposed to secondhand smoke at the workplace.

Table 2.8. Summary of results from published meta-analyses of exposure to secondhand smoke and lung cancer in never-smokers exposed at the workplace

Reference	No. of studies included	Sex	Pooled relative risk (95% CI)
Lee (1992)	9	Men and women	0.98 (0.84–1.08)
Biggerstaff *et al*. (1994)	8	Women	1.12 (0.93–1.34)
Levois & Layard (1994)	14	Men and women	1.01 (0.92–1.11)
Chappell & Gratt (1996)	8	Men and women	0.99 (0.91–1.08)
Wells *et al*. (1998)	5[a]	Men and women	1.39 (1.15–1.68)
Zhong *et al*. (2000)	14	Men and women	1.16 (1.05–1.28)

[a] Restricted to studies that were based on self-reported exposure

(iii) *Exposure during childhood*

There have been few meta-analyses on the risk of lung cancer in adulthood following exposure to secondhand smoke during childhood; the results of three of these meta-analyses are given in Table 2.9. None suggested an association, although no stratification

Table 2.9. Results from published meta-analyses of exposure to secondhand smoke and lung cancer in adult never-smokers exposed during childhood

Reference	No. of studies included	Sex	Pooled relative risk (95% CI)
Lee *et al*. (1992)	10	Men and women	0.98 (0.86–1.12)
Boffetta *et al*. (2000)	11	Men and women	
		Men and women	0.91 (0.80–1.05)
		From father	0.83 (0.72–0.95)
		From mother	0.99 (0.78–1.26)
Zhong *et al*. (2000)	18	Men and women	0.91 (0.83–1.00)

according to gender or exposure from the mother or father was carried out. Overall, published meta-analyses have found no evidence for an increased risk for lung cancer associated with childhood exposure to secondhand smoke.

(iv) *Statistical methods and other considerations*

Pooling relative risks

Different methods of combining relative risk estimates from individual studies have generally tended to give similar results. For example, in 37 studies of the risk for lung cancer of never-smoking women exposed or unexposed to secondhand smoke from the spouse, the relative risks (95% CI) using the fixed or random effects model were 1.21 (1.12–1.30) and 1.24 (1.13–1.36), respectively (Hackshaw *et al*., 1997) (the random effects model allows for heterogeneity between the risk estimates).

More complex approaches, such as Bayesian analysis, also do not yield materially different results. The difference between the pooled estimates obtained using a Bayesian model and those obtained using a simpler random effects model was small. Tweedie *et al.* (1996) pooled 40 studies of male or female never-smokers exposed to secondhand smoke from the spouse, the pooled relative risk for lung cancer was 1.20 (95% CI, 1.07–1.34) using the random effects model and 1.22 (95% CI, 1.08–1.37) using a Bayesian model (Tweedie *et al*., 1996).

Pooling results relating to exposure–response relationships

Several studies on the effects of exposure to secondhand smoke in never-smokers have reported the relative risk for lung cancer according to the number of cigarettes smoked by the spouse or the number of years that the nonsmoker has lived with a spouse who smokes. A few researchers, using various combinations of studies and methodology, have attempted to pool the results of epidemiological studies of exposure–response in never-smoking women. For an increase of 10 cigarettes per day smoked by the husband, the excess relative risk for lung cancer compared with never-smoking husbands was esti-

mated to be 23% (95% CI, 14–32) by Hackshaw *et al*. (1997), 17% (95% CI, 12–22) by Brown (1999) and 10% (95% CI, 5–15) by Lee *et al.* (2000). The excess relative risk that resulted from living for 10 years with a husband who smokes compared with one who does not was estimated to be 11% (95% CI, 4–17) by Hackshaw *et al*. (1997) and 7% (95% CI, 4–11) by Lee *et al.* (2000). The estimates are reasonably consistent between different reports and all found a statistically significant increase in risk associated with increasing exposure.

Heterogeneity between the estimates of relative risk

Performing a meta-analysis when there are statistically significant differences between the estimates of relative risk may yield an incorrect pooled estimate. If heterogeneity exists, an attempt should be made to explain it. If it can be explained by a single factor (or factors), then estimates should be stratified according to that factor. The authors of several reviews of the association between exposure to secondhand smoke and lung cancer have allowed for the existence of heterogeneity between geographical regions or found evidence of it and therefore stratified the relative risk estimates according to region (for example, US Environmental Protection Agency, 1992; Lee, 1998). Lee (1998) assessed heterogeneity related to several factors including geographical region, study publication date, study type and study size and concluded that there were statistically significant differences between the relative risk estimates by almost all factors. However, this was shown to be due to a single large discrepant study that unduly influenced the assessment of heterogeneity; this may be a problem especially when there are relatively few studies in the meta-analysis. In the meta-analysis by Hackshaw *et al*. (1997), the test for heterogeneity based on 37 studies on nonsmoking women was almost significant (p = 0.10), although when one study was excluded the p value became 0.46. The discrepant study, from China, was large (417 cases of lung cancer) and reported an almost statistically significant *reduction* in the risk of lung cancer associated with exposure to secondhand smoke from the spouse (relative risk, 0.8; 95% CI, 0.6–1.0), making its results inconsistent with those of the other studies. When this study was excluded, no evidence of heterogeneity was found for several factors (Hackshaw *et al*., 1997; Hackshaw, 1998; Zhong *et al*., 2000).

Publication bias

In meta-analyses of studies of the relationship between secondhand smoke and lung cancer there is a possibility of publication bias if studies with positive results (those that show an increased risk of lung cancer) are more likely to be published than studies with negative ones (those that show a decreased risk or no difference in risk). The pooled estimate of risk would then be biased upwards. Simple methods to ascertain whether much publication bias exists suggest that there is little evidence of this, for example funnel plots (Lubin, 1999) or estimating the number of negative unpublished studies that would be required to explain the increased risk observed from epidemiological studies — about 300 (Hackshaw *et al*., 1997; Lee, 1998); it is implausible that there would be so many

unpublished negative studies. Copas and Shi (2000) used a complex method to adjust the observed relative risk for lung cancer (reported in Hackshaw *et al*., 1997) for publication bias; the pooled estimate was reduced from 1.24 to 1.15, but Copas and Shi assumed that 40% of all studies are unpublished. Even with such an extreme assumption, the adjusted estimate is consistent with the reported relative risk adjusted for bias and confounding (1.26; 95% CI, 1.06–1.47). The problem with assessing publication bias is that it is difficult to determine empirically how many studies are unpublished (Bero *et al*., 1994).

(*c*) *Updated meta-analyses*

Several individual studies on secondhand smoke and the risk of lung cancer in nonsmokers have been published since one of the last detailed meta-analyses on the subject (Hackshaw *et al*., 1997). This section presents updated meta-analyses using currently available results. The selection of studies to be included is as described by Hackshaw *et al*. (1997), and the method of pooling the relative risk estimates is that described by Dersimonian and Laird (1986), which allows for any heterogeneity between the estimates. Some case–control studies reported only crude estimates of relative risk, some reported only adjusted estimates (adjusted for various factors such as age and diet) and others reported both crude and adjusted estimates. Consideration therefore needed to be given to which should be used in the meta-analyses. Pooled estimates were obtained based on the crude relative risks and, where these were not available, the adjusted relative risks. This reduces the effect of those studies that adjusted for factors that are not established confounders. The pooled estimate was also obtained based on the adjusted relative risks, and where these were not available, the crude relative risks to show that the two approaches yielded similar results.

Table 2.10 shows the results of the updated meta-analyses according to type of exposure to secondhand smoke and gender of the subject (for the estimates from the individual studies, see Tables 2.2, 2.5 and 2.6).

(i) *Exposure from the spouse*

Among nonsmoking women who lived with a spouse who smoked, the risk of lung cancer was increased by 24% (relative risk, 1.24; 95% CI, 1.14–1.3; Table 2.10). This estimate was based on the crude estimates of relative risk found in the studies and, where these were not available, the adjusted estimates. Use of the adjusted estimates and, where these were not available, the crude estimates yielded a similar relative risk of 1.27 (95% CI, 1.15–1.41). The studies came from several countries, and the test for heterogeneity between the relative risk estimates across all 46 studies just misses statistical significance (p value = 0.08). However, if the discrepant study from China by Wu-Williams *et al*. (1990) that reported an almost statistically significant decrease in risk due to exposure to secondhand smoke is excluded, the pooled relative risk is not materially changed (1.25; 95% CI, 1.17–1.33), but the test for heterogeneity yields a p value of 0.34. Among nonsmoking men who lived with a smoker, the risk of lung cancer was increased by 37%. The risk estimates for both nonsmoking men and women are statistically significant.

Table 2.10. Summary of the updated meta-analyses of the relative risk for lung cancer in never-smokers exposed to specified sources of secondhand smoke

Source of exposure	No. of studies (total no. of lung cancer cases)	Sex of subject	Pooled relative risk (95% CI)[a]	*p* value	Evidence of significant heterogeneity between the studies
Spouse	46 (6257)	Women	1.24 (1.14–1.34)	< 0.001	No, $p = 0.08$[b]
	11 (442)	Men	1.37 (1.02–1.83)	0.03	No, $p = 0.80$
Workplace	19 (3588)	Women	1.19 (1.09–1.30)	< 0.001	No, $p = 0.87$
	6 (246)	Men	1.12 (0.80–1.56)	0.51	No, $p = 0.38$
	7 (1582)	Women and men combined	1.03 (0.86–1.23)	0.74	No, $p = 0.10$
Childhood					
Mother	9 (2085)	Women	1.50 (1.04–2.14)	0.03	Yes, $p = 0.004$
Father	10 (2274)		1.25 (0.94–1.68)	0.13	Yes, $p < 0.001$
Either parent	14 (2576)		1.11 (0.87–1.42)	0.41	Yes, $p < 0.001$
Either parent	5 (252)	Men	0.86 (0.62–1.20)	0.38	No, $p = 0.35$
Either parent	6 (1306)	Women and men combined	1.14 (0.77–1.70)	0.51	Yes, $p < 0.001$

[a] Based on the crude relative risks from the individual reports and where these were not available, the adjusted estimates

[b] When the study by Wu-Williams *et al*. (1990) from China is excluded (it reported an almost statistically significant decrease in risk for lung cancer associated with exposure to secondhand smoke), the pooled relative risk is similar 1.25 (1.17–1.33), but the test for heterogeneity yields a *p* value of 0.34.

(ii) *Exposure at the workplace*

The increase in risk for lung cancer in nonsmoking women is about 20% (relative risk, 1.19; 95% CI, 1.09–1.30; Table 2.10). If the pooled estimate was based on the adjusted relative risks reported in the studies and, where these were not available, the crude estimates, the result was similar (relative risk, 1.21; 95% CI, 1.09–1.35). There was also an increase in risk in men (12%) though this result was not statistically significant (probably because of the smaller number of studies and fewer cases of lung cancer in the meta-analysis). There was no evidence of heterogeneity between the individual risk estimates.

(iii) *Exposure during childhood*

There is a statistically significant increase in risk among women exposed to secondhand smoke from the mother during childhood (50% increase in risk, but the confidence interval is wide, 4–114%). There is a lower, and non-significant increase in risk for exposure to secondhand smoke from the father (25%). However, there is significant heterogeneity between the estimates of relative risk. The results on exposure during childhood are less clear than those on exposure from the spouse or at the workplace.

Overall, the evidence from the meta-analyses is clear; adult nonsmokers exposed to secondhand smoke have a higher risk for lung cancer. Although the precise quantitative estimate of risk may vary between different measures of exposure, it is consistently raised. The data on exposure to secondhand smoke from the spouse also show that risk increases with increasing exposure. The evidence for an association between lung cancer and childhood exposure to secondhand smoke is less consistent than that for exposure in adulthood.

2.2 Breast cancer

Five prospective cohort studies (Hirayama, 1984; Jee *et al*., 1999; Wartenberg *et al*., 2000; Nishino *et al*., 2001; Egan *et al*., 2002) and 12 reports of 10 case–control studies (Sandler *et al*., 1985a,b; Smith *et al*., 1994; Morabia *et al*., 1996; Millikan *et al*., 1998; Lash & Aschengrau, 1999; Delfino *et al*., 2000; Johnson *et al*., 2000; Marcus *et al*., 2000; Morabia *et al*., 2000; Chang-Claude *et al.*, 2002; Kropp & Chang-Claude, 2002) have examined the role of secondhand smoke in breast cancer. The cohort studies are summarized in Table 2.11 and the reports from the case–control studies are summarized in Table 2.12.

2.2.1 *Cohort studies*

The first cohort study that suggested a possible association of exposure to secondhand smoke with breast cancer was reported by Hirayama in 1984. Specific details of how risk estimates for breast cancer were calculated were provided by Wells (1991). A total of 115 deaths from breast cancer were identified after 15 years of follow-up (1966–81) of over

91 000 married nonsmoking Japanese women. Women whose husbands had ever smoked had a small non-significantly increased risk of breast cancer (relative risk, 1.26; 95% CI, 0.8–2.0*)*. [The Working Group noted this was a first prospective report with a number of limitations. For example, it reported mortality rather than incidence; there was limited assessment of risk specific to breast cancer (spouse only); there was no adjustment for potential confounders; exposure was assessed at only one time-point.]

In a study in the Republic of Korea, Jee *et al*. (1999) also found small non-significantly increased risks of breast cancer associated with husbands' smoking status: for former smokers the relative risk was 1.2 (95% CI, 0.8–1.8) and for current smokers the relative risk was 1.3 (95% CI, 0.9–1.8). Relative risks were adjusted for age of husbands and wives, socioeconomic status, residence, vegetable consumption and occupation of the husband. These findings were based on 138 incident and prevalent breast cancer cases in 3.5 years of follow-up (July 1994–December 1997) of a cohort of 157 436 nonsmoking Korean women. A higher risk, of borderline significance, was observed for women married to current smokers who had smoked for more than 30 years (relative risk, 1.7; 95% CI, 1.0–2.8). [The Working Group noted that this study had several limitations, i.e. prevalent cases were not excluded; limited adjustment was made for potential confounders, and the adjustment did not include reproductive or hormonal factors; assessment of exposure included only secondhand smoke from the spouse.]

Wartenberg *et al*. (2000) reported findings from the large American Cancer Society Cancer Prevention Study II cohort based on 12 years of follow-up (1982–94) of never-smoking women who had been married once. A total of 669 deaths from breast cancer were included and risk estimates were adjusted for year of age at baseline, race, number of years of education, history of breast cancer in mother or sister, personal history of breast cysts, age at first live birth, age at menopause, number of spontaneous abortions, use of oral contraceptives, use of estrogen replacement therapy, body mass index, alcohol intake, fat consumption, vegetable consumption, occupation and occupation of spouse. No increased risks were found for women married to current smokers (relative risk, 1.0; 95% CI, 0.8–1.2) or former smokers (relative risk, 1.0; 95% CI, 0.8–1.2) when compared with never-smokers married to nonsmoking husbands. No association was found by type of tobacco. No trend in risk was observed by years, packs per day or pack–years of spousal smoking. No significant associations were noted between breast cancer and all exposures at home (relative risk, 1.1; 95% CI, 0.9–1.3), at work (relative risk, 0.8; 95% CI; 0.6–1.0), or in other places (relative risk, 0.9; 95% CI, 0.7–1.2). When reported exposures from all sources were combined and examined according to daily hours of exposure using no exposure from any source as referent (0 hour), no trend was observed. [The Working Group considered that the strengths of this study included the large number of cases, the excellent follow-up, the thorough statistical adjustment for potential confounders and that the spouse directly reported his own tobacco use. The limitations include the use of mortality rather than incidence as the outcome and that the assessment of spousal smoking was made at only one time-point.]

A smaller cohort study that included 9675 Japanese female never-smokers over the age of 40 years accrued 67 incident cases over a 9-year follow-up period (1984–92) (Nishino *et al*., 2001). Relative risks were adjusted for age, study area, alcohol consumption, intake of green and yellow vegetables, intake of fruit, age at first birth, number of live births, age at menarche and body mass index. The age-adjusted relative risk for breast cancer was 0.6 (95% CI, 0.3–1.0) among women whose husbands smoked when compared to that in women married to nonsmokers. The age-adjusted risk associated with living in a household with other smokers was also below unity (relative risk, 0.4; 95% CI, 0.2–0.8) when compared with women living in households where there were no smokers. Further adjustment of these relative risks for the potential confounders listed above did not appreciably change the risk estimates, but the relative risks were no longer statistically significant after full adjustment: exposure from spouse, 0.6 (95% CI, 0.3–1.1), and other household members, 0.8 (95% CI, 0.4–1.5*)*. [The Working Group considered that the strengths of this study include adjustment for some reproductive or hormonal and dietary factors; its limitations include the very small sample size, lack of information on marital status at baseline and inclusion of unmarried women at high risk of breast cancer as unexposed which may have reduced point estimates of relative risk.]

The Nurses' Health Study in the USA has provided the largest number of prospectively accrued breast cancer cases in never-smoking women (Egan *et al*., 2002). After 14 years of follow-up (1982–96), 1359 cases of invasive breast cancer were diagnosed among 35 193 never-smokers. Exposure to secondhand smoke was assessed as exposure during childhood as well as during adult life at home, at work and in other settings. Relative risks were adjusted for many variables including age, parity, age at first birth, menopausal status, age at menopause, change in weight (i.e. weight at age 18 years compared to the most recent reported weight), age at menarche, history of benign breast disease, family history of breast cancer, post-menopausal hormone treatment, alcohol intake and carotenoid intake. No statistically significant associations were found for exposure between breast cancer and exposure to secondhand smoke in adult life or in childhood, and most relative risks were near unity. No trends were apparent either for number of years lived with a smoker as an adult (p for trend = 0.87) or for a categorized index of adult exposures (p for trend = 0.97). Women who reported the highest levels of exposure to secondhand smoke during adulthood had a rate of breast cancer similar to that of women who reported no current exposure to secondhand smoke (relative risk, 1.0; 95% CI, 0.8–1.3). The findings were similar for pre- and postmenopausal women. [The Working Group noted that this study's main strength is that it is the largest and most methodologically rigorous prospective study to date. Other strengths were that exposure assessments were updated over time, incident cases rather than mortality were studied and comprehensive adjustment was made for potential confounders.]

2.2.2 *Case–control studies*

The first two reports (Sandler *et al*., 1985a,b) on involuntary smoking and breast cancer were based on a case–control study conducted in North Carolina, USA. Cases were selected from a single hospital tumour registry and included patients diagnosed between 1 July 1979 and 31 March 1981, who were between the ages of 15 and 59 years at the time of diagnosis. Approximately 60% of the controls were friends or acquaintances identified by cases and the remaining 40% were selected by systematic telephone sampling. The two control groups were combined after separate analyses of the two groups indicated similar results. The risk for breast cancer in nonsmoking women was not associated with exposure to secondhand smoke during childhood from either mother (relative risk, 0.9) or father (relative risk, 0.9) (Sandler *et al*., 1985a). Exposure to secondhand smoke in nonsmoking women based on husband's smoking was associated with a two-fold, nonsignificant increase in risk (relative risk, 2.0; 95% CI, 0.9–4.3) (Sandler *et al*., 1985b). Risk estimates of childhood exposure were adjusted for age and education, and risk estimates of exposure during adulthood were adjusted for age, race and education. Both reports included only a few lifetime nonsmokers with breast cancer (29 and 32 cases, respectively). [The Working Group noted that the limitations of this study include small sample size, lack of adjustment for reproductive factors and the potentially inappropriate control group (i.e. friends and neighbours of cases supplemented with controls selected by random digit dialling.]

Smith *et al*. (1994) investigated the relationship between exposure to secondhand smoke and risk for breast cancer in a sample of nonsmokers including 94 incident cases and 99 controls drawn from a larger study of breast cancer diagnosed in young women below the age of 36 years between 1982 and 1985. This study was conducted in the United Kingdom and information on exposure to secondhand smoke was collected by postal questionnaire in a sample of participants from the main study. Controls were selected randomly from the list of the case's general practitioner and matched to the case on age. Risk estimates were adjusted for age, residence, age at menarche, family history of breast cancer, history of biopsy for benign breast disease, oral contraceptive use and history of breastfeeding. Although most of the risk estimates exceeded unity as shown in Table 2.12, none were statistically significant and there was no evidence of a positive trend in risk associated with increasing exposure. When total lifetime exposure as measured in cigarette–years was considered, elevations in risk were found for all levels above zero (referent). However, the trend was not statistically significant. No effect of active smoking was found in this study. [The Working Group considered this study to have limited generalizability (cases < 36 years of age) and noted that no exposure–response relationship was observed despite comparatively high point estimates of risk.]

A population-based case–control study conducted in Switzerland by Morabia *et al*. (1996) was designed specifically to evaluate the role of exposure to secondhand smoke in risk of breast cancer. It included 126 cases and 620 controls who were lifetime never-smokers. Never-smokers were defined as having smoked fewer than 100 cigarettes in a

lifetime. Eligible cases were women less than 75 years of age who had been diagnosed with invasive breast cancer between 1 January 1992 and 31 October 1993. Population controls were selected from the official registers of residents of Geneva and were 30–74 years of age. This study included a detailed assessment of exposure to secondhand smoke and risk estimates were adjusted for the following potential confounders: age, education, body mass index, age at menarche, age at first live birth, oral contraceptive use, breast cancer in mother or sister, history of breast biopsy, alcohol intake and saturated fat intake. The referent unexposed group in this study included women who were never regularly exposed (< 1 (h/day) × years) to either active or passive smoking (28/244 cases and 241/1032 controls). Estimates of relative risk associated with any exposure to secondhand smoke, duration of exposure to secondhand smoke, exposure to spousal secondhand smoke only and duration of spousal smoking were all approximately three and were statistically significant; however, risk estimates stratified by duration (1–50 or > 50 (h/day) × years) were virtually identical and there was no suggestion of an exposure–response relationship. [The Working Group considered that the strengths of the study were its comprehensive assessment of exposure, being population-based and the large number of potential confounders included in the analysis. Concerns included the following: magnitude of the association between cancer and passive smoking is the same as that for active smoking in same study, no exposure–response relationship was found for secondhand smoke and the very restrictive reference category used may have biased the results.]

Morabia *et al*. (2000) next conducted a sub-study from the above-mentioned case–control study. It was designed to evaluate the role of *N*-acetyltransferase 2 (NAT2) in the relationship between breast cancer and active and passive smoking. Cases believed to be alive and living in Geneva in 1996–97 were re-contacted, as were a subset of controls, and asked to provide a buccal swab for DNA extraction and NAT2 genotyping for subsequent classification as slow or fast acetylators. This sub-study included 84 cases who were never-smokers and 99 controls who were never-smokers. As in the parent study, a three-fold increase in risk of breast cancer was associated with any reported exposure to secondhand smoke (relative risk, 3.1; 95% CI, 1.5–6.0). The association between exposure to secondhand smoke and breast cancer appeared to be modified by acetylation status; breast cancer risk was higher in persons with the fast acetylation genotype (relative risk, 5.9; 95% CI, 2.0–17.4) than in slow acetylators (relative risk, 1.9; 95% CI, 0.7–4.6). [The Working Group's comments on the parent study also applied to this sub-study.]

Millikan *et al*. (1998) conducted a population-based case–control study in North Carolina, USA, that also examined the effect of *N*-acetylation genotypes (NAT1 and NAT2), exposure to secondhand smoke and breast cancer risk. Cases included women between 20 and 74 years of age who were diagnosed with invasive primary breast cancer between May 1993 and December 1996. Controls less than 65 years of age were selected from files of the North Carolina Division of Motor Vehicles and those from 65 to 74 years of age from the United States Health Care Financing Administration (HCFA) files. All African–American cases and a sample of white cases were selected. This report was based

on cases and controls who provided a blood sample. Cases and controls were broadly frequency-matched on race (African–American and white) and age (age less than 50 years and 50 years and above). Relative risk estimates were adjusted for age, race, age at menarche, age at first full-term pregnancy, parity, family history of breast cancer, breast biopsies showing benign tumours and alcohol consumption. Statistically non-significant increases in risk were associated with exposure to secondhand smoke after the age of 18 years in never-smokers (relative risk, 1.3; 95% CI, 0.9–1.9). The point estimates for premenopausal (relative risk, 1.5; 95% CI, 0.8–2.8) and postmenopausal women (relative risk, 1.2; 95% CI, 0.7–2.2) were not substantially different. Stratification by menopausal status and NAT1 and NAT2 genotypes resulted in statistically non-significant relative risks for all subgroups. The point estimates for exposure to secondhand smoke after the age of 18 years were highest for pre-menopausal never-smoking women for NAT1*10 (relative risk, 1.7; 95% CI, 0.7–4.3) and NAT2rapid (relative risk, 2.3; 95% CI, 0.9–6.2).

Marcus *et al*. (2000) included additional cases from this North Carolina study without the requirement for a blood sample and addressed the issue of exposure to secondhand smoke before the age of 18 years. Exposure to secondhand smoke at home during childhood showed no statistically significant association with risk of breast cancer in this study (relative risk, 0.8; 95% CI, 0.6–1.1). [The Working Group considered that the strengths of this study included the large number of never-smoking cases and controls; the multiethnic study population (although no ethnicity-specific risk estimates for exposure to secondhand smoke were reported and that the study investigated possible high-risk subgroups.]

Lash and Aschengrau (1999) reported the findings of a case–control study conducted in five towns in Massachusetts, USA. The incident cases of breast cancer were diagnosed from 1983–1986. Population controls from these towns for living cases under 65 years of age were selected using random-digit dialling and for women 65 years and older from the US Health Care Financing Administration (HCFA) files. Because deceased cases were also eligible for this study, deceased controls were selected from Massachusetts Department of Vital Statistics and Research. A total of 120 cases and 406 controls were never-smokers. About one-third of the interviews relating to cases and 45% of the interviews relating to controls were with proxy respondents. Age, parity, history of breast cancer other than index diagnosis, family history of breast cancer, history of benign breast disease, and history of radiation therapy were adjusted for in the analyses. A twofold increase in risk (relative risk, 2.0; 95% CI, 1.1–3.7) was associated with any exposure to secondhand smoke; however, increasing duration was not associated with increasing risk. The relative risk estimates for exposure to secondhand smoke and for active smoking also determined in this study were similar. [The Working Group noted that the limitations of the study were that the original study was not designed to evaluate exposure to secondhand smoke; it was unclear whether controls from the parent study which included three types of cancer cases were matched to breast cancer cases in this substudy, and that this substudy included a large number of proxy respondents.]

Findings from a small clinic-based case–control study, conducted in Orange County, California, USA, were reported by Delfino *et al*. (2000). Three breast cancer centres were

included in the study. Subjects diagnosed with a suspicious breast mass detected either clinically or radiographically who were over the age of 39 years were considered to be eligible. Information on exposure was obtained from a self-administered questionnaire completed prior to biopsy in order to minimize recall bias and interviewer bias. Among women who were never-smokers, 64 were subsequently found to have malignant tumours and comprised the case series, and 149 never-smokers with benign breast disease were classified as controls. Risk estimates for exposure to secondhand smoke in the home were adjusted for age, menopausal status, age at menarche, age at first full-term pregnancy, total months of pregnancy, lactation history, education, race/ethnicity, body mass index and family history of breast cancer. NAT2 genotype was also determined, but was not associated with risk for breast cancer in this study. No statistically significant association was found between exposure to secondhand smoke and breast cancer risk in these never-smokers (relative risk, 1.3; 95% CI, 0.7–2.5) for any exposure to secondhand smoke in the home. [The Working Group considered that the strengths of this study included the fact that exposure data were collected prior to determination of case–control status. Its limitations were that it was a small study and that information on exposure to secondhand smoke was limited to exposure in the household.]

A large Canadian study (Johnson *et al*., 2000) identified population-based incident cases of breast cancer aged 25–74 years at diagnosis from the National Enhanced Cancer Surveillance System beginning in April 1994 in some provinces (later in others) and continuing until July 1997. The study included 378 premenopausal and 700 postmenopausal never-smoking cases and 369 pre- and 845 postmenopausal population-based never-smoking controls. Exposure to secondhand smoke in the household during childhood and adult life as well as in the workplace were assessed. Relative risk estimates were adjusted for age, province, education, body mass index, alcohol use, physical activity, age at menarche, age at the end of first pregnancy lasting 5 months or longer, number of live births, months of breastfeeding and height. There was no evidence of an association between breast cancer and exposure to secondhand smoke during childhood or adulthood in postmenopausal women (relative risk estimates ranged from 0.9 to 1.3, none were statistically significant). However, premenopausal women had significantly elevated risks for breast cancer associated with any exposure to secondhand smoke (relative risk, 2.3; 95% CI, 1.2–4.6), exposure to secondhand smoke during adulthood (relative risk, 2.6; 95% CI, 1.1–6.0), and exposure to secondhand smoke during both childhood and adulthood (relative risk, 2.6; 95% CI, 1.2–5.5). There was evidence of a strong dose–response relationship in premenopausal women associated with duration of residential and occupational exposure (p for trend = 0.0007). [The Working Group noted that the risk associated with passive smoking was similar in magnitude to that in former active smokers (relative risk, 2.6) and was higher than that for current active smokers (relative risk, 1.9) in the same study. The limitations of the study were that information was missing on a large number of cases and controls who were excluded from this study and information on exposure to secondhand smoke was available for only 59% of never-smokers.]

Two recent reports from a case–control study of breast cancer in German women aged 50 years and younger have used as the referent for assessing the risks of both active and involuntary smoking those women who have experienced no active and no passive exposure to tobacco smoke (lifetime non-exposed: < 1 (h/day) × year) (Kropp & Chang-Claude, 2002; Chang-Claude *et al.*, 2002). The study included 706 cases (response rate, 70.1%) and 1381 controls (response rate, 61.2%). Data were initially collected by self-administered questionnaires for active smoking, and later, living cases and controls were re-contacted for information on involuntary exposure to tobacco smoke. Of the original participants, approximately 66% of the cases and 79% of the controls completed this part of the study. Risk estimates were adjusted for daily alcohol intake, total number of months of breastfeeding, education, first-degree family history of breast cancer, menopausal status and body mass index. For active smoking, a relative risk of 1.1 (95% CI, 0.6–2.0) was recorded, whereas never-smokers exposed to involuntary smoking had a statistically increased risk of about 60% (Kropp & Chang-Claude, 2002). In a subgroup analysis of 422 cases and 887 controls, the effect of NAT2 on the association between tobacco and breast cancer was considered (Chang-Claude *et al.*, 2002). When compared to women who had never been exposed to any tobacco smoke, no association with active smoking was seen in rapid acetylators and a modest statistically non-significant increase in risk was observed in slow acetylators. In contrast, passive smoking was associated with a statistically non-significant risk that was higher in rapid than in slow acetylators (relative risk, 2.0; 95% CI, 1.0–4.1; and 1.2; 95% CI, 0.7–2.0, respectively). [The Working Group noted that this study has included many subgroup analyses, had reported incongruent findings related to active and involuntary smoking in the same study AND had obtained passive smoking data for only about 50% of study subjects. However, the strength of this study was the inclusion of a referent group of subjects who had not been exposed to any tobacco smoke during their lifetimes by self-report.]

2.3 Childhood cancers

Many studies have evaluated the association of cancer risk in childhood with exposure to parental smoking since this issue was considered previously in the *IARC Monograph* Volume 38 (IARC, 1986). These associations will be evaluated below for all cancers combined and separately, for brain tumours, leukaemias and lymphomas, and other childhood cancers.

Few studies distinguish times of exposure to tobacco smoke from parents, i.e. whether the exposure was preconception, *in utero* or postnatal. Exposure may have occurred in all three periods even when a study reports on only one, or exposure may also be reported as ‘ever’. Involuntary smoking during each of these time periods tends to be correlated, in particular exposure to secondhand smoke from the father because father’s smoking habits are less likely to change.

2.3.1 *All sites combined*

Four cohort studies (Neutel & Buck, 1971; Golding *et al*., 1990; Pershagen *et al*., 1992; Klebanoff *et al*., 1996) and ten case–control studies (Buckley *et al*., 1986; McKinney *et al*., 1986; Stjernfeldt *et al*., 1986; Forsberg & Kallen, 1990; John *et al*., 1991; Golding *et al*., 1992; Sorahan *et al*., 1995; Ji *et al*., 1997; Sorahan *et al*., 1997a,b) (Table 2.13) have examined the role of involuntary exposure to tobacco smoke in risk for childhood cancers in general.

All four cohort studies specifically reported on the risk associated with cancer related to mothers' smoking during pregnancy. Neutel and Buck (1971) identified 97 deaths from childhood cancer in a cohort of 89 302 births from Ontario (Canada), and England and Wales followed from 7 to 10 years. Children with a mother who had smoked during pregnancy had a relative risk of 1.3 (95% CI, 0.8–2.2). No exposure–response relationship was apparent. [The Working Group noted several limitations of this study: no control for potential confounders; completeness of follow-up unknown, and limited assessment of exposure to secondhand smoke.]

Golding *et al*. (1990) followed a cohort of 16 193 births for 10 years (1970–80) and a total of 33 cancers were diagnosed. After adjustment for social class, exposure to X-rays during pregnancy, term delivery, administration of pethidine in labour and of drugs during infancy, a statistically significant increase in risk was found for children whose mothers smoked five or more cigarettes per day during the index pregnancy (relative risk, 2.5; 95% CI, 1.2–5.1). [The Working Group noted that the strength of this study was that the effect of exposure to secondhand smoke was independent of other risk factors found in this study. Its limitations were that the completeness of follow-up was unknown and that there was limited assessment of exposure to secondhand smoke.]

Pershagen *et al*. (1992), in Sweden, followed a large cohort of 497 051 births. In 5 years of follow-up, a total of 327 cancers that could be linked to data on maternal smoking were diagnosed. Relative risks were adjusted for year and county of birth, birth order and maternal age. No association was found for any maternal smoking during pregnancy (relative risk, 1.0; 95% CI, 0.8–1.3) and no exposure–response relationship was seen for number of cigarettes smoked during pregnancy (< 10 cigarettes per day, relative risk, 1.0; ≥ 10 cigarettes per day, relative risk, 0.9). No cancer at any of the sites evaluated individually was associated with maternal smoking. [The Working Group noted that the strengths of this study were that it was the largest cohort study, some statistical adjustment of risk estimates had been made and there was a high rate of follow-up. Its limitation was that there had been limited assessment of exposure to secondhand smoke.]

The most recent prospective study to evaluate the association between maternal smoking during pregnancy and childhood cancer is the US Collaborative Perinatal Project that included 54 795 children born from 1959–66 who were followed until the age of seven or eight years (Klebanoff *et al*., 1996). The hazard ratio for cancer in children whose mother smoked during pregnancy compared to those whose mother did not was 0.7 (95% CI, 0.4–1.2). Adjustment of the hazard ratio for maternal race, age, education,

socioeconomic status, height and pre-pregnancy weight as well as previous pregnancies, exposure to diagnostic radiation during pregnancy, feeding of infant in hospital, sex of infant and date of delivery had only a minimal effect on the point estimates, all of which remained in the range of 0.6. [The Working Group noted that the limitations of this study were that the completeness of follow-up was unknown, but the estimates of expected incidence suggest that few cases were missed, and that assessment of exposure to secondhand smoke was limited.]

Buckley *et al*. (1986) conducted a case–control analysis using data from the US/Canada Children's Cancer Study Group. These investigators compared smoking by mothers and fathers of 1814 childhood cancer cases with that of parents of 720 controls selected at random from approximately the same geographical regions as cases. Smoking in the periods before and during pregnancy was assessed. No association was found between maternal smoking during pregnancy (< 10 cigarettes per day, relative risk, 1.3; 95% CI, 0.9–1.9; ≥ 10 cigarettes per day, relative risk, 1.0; 95% CI, 0.8–1.2) and no association with paternal smoking was found [relative risk not reported]. Adjustment for potential confounders such as year of birth, age of mother, illnesses during pregnancy and socioeconomic factors, did not alter findings. [The Working Group noted that the strength of this study was the large sample size and its limitations were that the report lacked details of the study and the control group was not well described.]

In a case–control study based on the Inter-Regional Epidemiological Study of Childhood Cancer in the United Kingdom, 555 cases of cancer in children < 15 years of age and 1110 controls matched for age and sex were compared for exposure to maternal smoking during pregnancy (McKinney *et al*., 1986). There was no evidence of an association between maternal smoking and risk for childhood cancer (1–10 cigarettes per day, relative risk, 1.1; 95% CI, 0.9–1.5; > 11 cigarettes per day, relative risk, 0.8; 95% CI, 0.7–1.1). [The Working Group noted that the strength of this study was the large sample size. The limitations were that the report provided few study details; other than matching for age and sex there was no adjustment for potential confounders, and there was limited assessment of exposure to secondhand smoke.] This dataset was recently re-evaluated (Sorahan *et al*., 2001). Microfilmed interview records of all study subjects were reviewed and information on parental cigarette smoking habits was re-abstracted. There was a statistically significant positive trend ($p = 0.02$) associated with daily paternal cigarette consumption before pregnancy for all cancers combined when cases were compared with controls selected from General Practitioners' (GPs') lists ($n = 555$), but no significant association was observed when cases were compared with hospital controls ($n = 555$). The opposite was seen for maternal smoking before pregnancy: an inverse trend ($p < 0.001$) was noted between daily cigarette consumption when cases were compared with hospital controls, but not when compared with GP controls. Risk estimates were adjusted for socioeconomic status, ethnicity, parental age at child's birth and other parent's smoking. [The Working Group noted that the two sets of controls produced very different results that are not easily explained.]

Stjernfeldt *et al*. (1986) reported the findings of a nationwide case–control study in Sweden that included 305 cases of cancer in children ≤ 16 years of age and 340 children with insulin-dependent diabetes mellitus who served as controls. Estimates of relative risk were adjusted for year of child's birth and maternal age, illness during pregnancy, occupation and place of residence. A 50% ($p < 0.01$) increase in risk for cancer was associated with in-utero exposure to maternal smoking. [The Working Group noted that the strengths of the study included the good response rate and the attempt to control for response bias by using children with diabetes mellitus as controls; its limitation was that the appropriateness of the control group was unknown.]

A case–control study from Sweden by Forsberg and Kallen (1990) found no association between childhood cancers and maternal smoking (relative risk, 1.1; 95% CI, 0.6–2.0) based on 69 cases and 139 controls for whom maternal smoking status was known. [The Working Group noted that the limitations of this study included the small sample size, uncertainty as to whether original case–control matching also applied to the substudy sample and the limited assessment of exposure.]

John *et al*. (1991) evaluated both maternal and paternal prenatal smoking histories in relation to risk for childhood cancer. The study included 223 incident cases < 15 years of age diagnosed from 1976 to 1983 in Denver, CO, USA. Controls were selected using random digit dialling and were matched to cases on age, sex and telephone exchange, and 196 controls were included in the analysis. Mothers' and fathers' smoking was highly correlated. Of the 109 children exposed to mother's smoking during the first trimester, 81% were also exposed to father's tobacco smoking while an additional 105 children were exposed to father's smoking alone. Mother's smoking during the first trimester was associated with a modest statistically nonsignificant increase in risk for childhood cancer after adjustment for father's education (relative risk, 1.3; 95% CI, 0.7–2.1). Children whose mothers did not smoke who were exposed to father's smoking also had a modest, statistically non-significant increase in risk (relative risk, 1.2; 95% CI, 0.8–2.1). [The Working Group noted that this study included a more detailed assessment of exposure to secondhand smoke than did earlier studies.]

Golding *et al*. (1992) conducted a case–control study in the United Kingdom to assess the association of childhood cancer with administration of intramuscular vitamin K and pethidine during labour. Data on mothers' smoking during pregnancy as a potential confounder were collected. A twofold increase in risk (relative risk, 2.0; 95% CI, 1.3–3.2) adjusted for year of delivery was found. [The Working Group noted that this study was not designed to investigate exposure to secondhand smoke, that only maternal smoking during pregnancy was recorded and that there was only minimal control for potential confounders.]

Three reports from the Oxford Survey of Childhood Cancer (OSCC) provided data from large case–control studies of childhood cancer deaths during different time periods: 1977–81 (Sorahan *et al*., 1995), 1953–55 (Sorahan *et al*., 1997a) and 1971–76 (Sorahan *et al*., 1997b). The first report in 1995 included 1641 cases and an equal number of controls. There was no association with prenatal maternal cigarette smoking; however,

paternal smoking was associated with a statistically significant positive trend (p for trend = 0.003). When cigarette use by one or both parents was adjusted for social class, maternal age at birth and use of alcohol, the relative risk was 1.4 (95% CI, 1.1–1.7) for father's use of cigarettes and 1.4 (95% CI, 1.1–1.7) for cigarette use by both parents, whereas cigarette use by mother was not statistically significantly associated with an increased risk (relative risk, 1.2; 95% CI, 1.0–1.6). A total of 1549 deaths from childhood cancer between 1953 and 1955 and 1549 matched healthy controls were used to further investigate the earlier findings from the OSCC (Sorahan *et al.*, 1997a). After adjustment for smoking by the spouse, social class, age of father, age of mother, birth order, and exposure to obstetric radiography, no statistically significant dose–response trend was found to be associated with maternal smoking, but maternal smoking only was associated with a 30% increased risk for childhood cancer (relative risk, 1.3; 95% CI, 1.1–1.5). At the highest level of paternal smoking (> 20 cigarettes per day), a clear trend was noted (p for trend < 0.001) with a relative risk of 1.4 (95% CI, 1.1–1.9); paternal smoking only was also associated with increased risk (relative risk, 1.7; 95% CI, 1.3–2.2). The third report (Sorahan *et al.*, 1997b) which examined deaths from 1971 to 1976 provided very similar results to those in the first two reports, i.e. no clear association with childhood cancer was evident for maternal smoking and there was a statistically significant positive trend for paternal smoking. [The Working Group noted the very large sample sizes, the consistent findings over time, the adjustment for potential confounders and the assessment of exposure from mothers and fathers with data for trends.]

A large case–control study in China by Ji *et al*. (1997) also examined paternal smoking and risk for cancer in children (< 15 years of age) of nonsmoking mothers. Relative risks were adjusted for birth weight, income, paternal age, education and alcohol drinking. For all sites combined, the relative risk for 'ever smoking' by the father was 1.3 (95% CI, 1.0–1.7). Statistically significant trends were found for duration of paternal smoking (p for trend = 0.007) and pack–years (p for trend = 0.01), but not age of starting smoking (p for trend = 0.28) or cigarettes per day (p for trend = 0.07). [The Working Group noted the large sample size, the minimization of exposure misclassification by including only children of nonsmoking mothers, the adjustment for potential confounders and the extensive exposure assessment for fathers.]

Boffetta *et al*. (2000) conducted a meta-analysis of childhood cancers associated with passive exposure to smoke based on the random effects model. The relative risk estimate for maternal smoking during pregnancy for all cancers combined included all cohort studies and eight of the ten case–control studies listed in Table 2.13 (Sorahan *et al*. 1997b; Ji *et al*. 1997; were not included). The results suggest a small increase in risk for all cancers for maternal smoking during pregnancy (relative risk, 1.1; 95% CI, 1.0–1.2), but not for specific cancer sites. Results on exposure before and after pregnancy were too sparse for any conclusion to be drawn. Studies of exposure to paternal tobacco smoke and risk for all cancers combined are fewer than those addressing maternal smoking and no relative risk was reported in this meta-analysis.

2.3.2 *Brain and central nervous system*

Table 2.14 lists one cohort study (Pershagen *et al*. 1992) and 15 case–control studies (Gold *et al*., 1979; Preston-Martin *et al*., 1982; Stjernfeldt *et al*., 1986; Howe *et al*., 1989; Kuijten *et al*., 1990; Gold *et al*., 1993; Bunin *et al*., 1994; Cordier *et al*., 1994; Filippini *et al*., 1994; McCredie *et al*., 1994; Norman *et al*., 1996; Ji *et al*., 1997; Sorahan *et al*., 1997a,b; Filippini *et al*., 2000) that have examined parental smoking and risk for brain tumours or for all tumours of the central nervous system combined.

Only the cohort study of Pershagen *et al*. (1992) (see section 2.3.1) has published a relative risk for tumours of the central nervous system. No association was found between maternal smoking in pregnancy and risk for tumours of the central nervous system.

The first case–control study to examine risk for brain tumour and maternal smoking was reported by Gold *et al*. (1979). This study was conducted in the USA and included 84 children with brain tumours and two control groups. One control group comprised 78 children with other malignancies matched on sex, race, date and age at diagnosis, and the other, 73 children selected from the state birth certificate file and matched on sex, date of birth and race. Risk associated with maternal smoking before and during pregnancy was associated with large non-statistically significant risks for childhood brain tumour that were based on a small sample size.

Preston-Martin *et al.* (1982) reported the findings from a larger case–control study in the USA designed to evaluate the risk for brain tumour associated with childhood exposure to *N*-nitroso compounds, including those from tobacco smoke. No increased risk was associated with maternal smoking, but a relative risk of 1.5 ($p = 0.03$) was found for children of mothers living with a smoker during pregnancy. The small Swedish case–control study by Stjernfeldt *et al*. (1986) (see section 2.3.1) found no increased risk for tumours of the central nervous system associated with maternal smoking in pregnancy.

An exploratory case–control study of brain tumours in Canadian children diagnosed in Ontario between 1977 and 1983 included 74 cases and 138 age- and sex-matched controls. The study found neither maternal nor paternal smoking during pregnancy to be statistically significantly associated with risk for brain tumours (Howe *et al*., 1989). Similarly, a population-based case–control study in the USA of childhood astrocytomas that included 163 case–control pairs found no increased risk associated with any smoking by either mother or father (Kuijten *et al.*, 1990).

A large population-based case–control study in the USA of childhood brain tumours examined smoking by both parents in some detail. The study included exposure assessments for the preconception period as well as the pre- and postnatal period (year of birth of child) and dose–response estimates (Gold *et al*., 1993). There was no statistically significant association between risk for brain tumours and any indicator of parental smoking. [The Working Group noted that this was a well-conducted study designed to examine parental smoking in detail, and having sufficient statistical power.]

Bunin *et al.* (1994) studied the two most common types of brain tumour, astrocytoma and primitive neuroectodermal tumour, in children less than six years of age. Controls,

Filippini *et al*. (2000) (Italy)	244 CNS tumours, 502 controls	Telephone interview	5 years diagnosis of children < 16 years old; 85% case response rate; 88% control response rate	*Maternal smoking* Before pregnancy Before she knew she was pregnant *Maternal exposure to secondhand smoke* During early pregnancy During late pregnancy	 1.2 (0.9–1.7) 1.5 (1.0–2.3) 1.8 (1.2–2.6) 1.7 (1.2–2.5)

CNS, central nervous system

selected by random-digit dialling, were matched to cases on race, year of birth, and telephone area code and prefix. Estimates of relative risk for astrocytoma were adjusted for income level, but primitive neuroectodermal tumour estimates were unadjusted. No association was found between either of these types of tumour and maternal active (ever and/or during pregnancy) or passive smoking (during pregnancy) or paternal smoking (ever and/or during pregnancy).

A non-statistically significant increase in risk for brain tumours (relative risk, 1.6; 95% CI, 0.7–3.5) associated with any smoking by the mother was found in a small case–control study in France (Cordier *et al*. 1994). Filippini *et al.* (1994) in Italy assessed the risk associated with active and passive smoking by mothers during pregnancy in a case–control study with 91 cases. Active smoking by the mother during pregnancy was associated with a relative risk of 1.7 (95% CI, 0.8–3.8); no dose–response relationship was observed. Relative risks were adjusted for education level. Among nonsmoking mothers, the relative risks for light and heavy exposure to secondhand smoke were 1.7 (95% CI, 0.8–3.6) and 2.2 (95% CI, 1.1–4.5; p trend = 0.02). McCredie *et al*. (1994) conducted another small, population-based case–control study of brain tumours in Australia. Two controls were matched to each case by age and sex. No association was found with exposure to tobacco smoke from another member of the household, but no risk estimates were provided. [The Working Group noted that the limitations of these studies were that they lacked statistical power; there was limited adjustment for potential confounders and limited assessment of exposure.]

The findings from a large, population-based case–control study of brain tumours in children < 15 years of age diagnosed from 1984 to 1991 provided no support for an association between brain tumour risk and maternal or paternal smoking before pregnancy or maternal smoking during pregnancy (Norman *et al*. 1996). Risk estimates were at or below unity and there was no evidence of a relationship between risk for brain tumours and amount or timing of exposure. [The Working Group noted that the strengths of this study were that it was large and included a relatively detailed assessment of exposure.]

Three studies discussed previously (Ji *et al*. 1997; Sorahan *et al*. 1997a,b) found no increased risk for brain tumours associated with father's smoking (Ji *et al*., 1997) or of tumours of the central nervous system associated with maternal or paternal smoking (Sorahan *et al*., 1997a,b; 2001).

Filippini *et al*. (2000) in northern Italy, conducted a population-based case–control study of childhood tumours of the central nervous system with cases diagnosed from 1988 to 1993. Cases from their previous study (Filippini *et al*., 1994) were excluded. Active smoking by parents before pregnancy was not associated with increased risk. Active smoking by mothers in early pregnancy was associated with a small increase in risk (relative risk, 1.5; 95% CI, 1.0–2.3). An increase in risk was also associated with passive smoking by nonsmoking mothers in early pregnancy (relative risk, 1.8; 95% CI, 1.2–2.6) and late pregnancy (relative risk, 1.7; 95% CI, 1.2–2.5).

The results of the meta-analysis by Boffetta *et al*. (2000) indicated no significant increase in risk for tumours of the central nervous system associated with maternal

smoking during pregnancy (relative risk, 1.0; 95% CI, 0.9–1.2), but exposure to paternal smoking suggested an increased risk for brain tumours (relative risk, 1.1; 95% CI, 1.1–1.4). [The Working Group noted that this meta-analysis included two studies of neuroblastoma and one study of retinoblastoma with tumours of the central nervous system.]

2.3.3 *Leukaemias and lymphomas*

The only cohort study to report specifically on lymphatic and haematopoietic cancers (Pershagen *et al.*, 1992) and 16 case–control studies with data on one or more of these types of malignancy are included in Table 2.15 (Manning & Carroll, 1957; Stewart *et al*., 1958; Van Steensel-Moll *et al*., 1985; Buckley *et al*., 1986; McKinney *et al*., 1986; Stjernfeldt *et al*., 1986; Magnani *et al*., 1990; John *et al*., 1991; Roman *et al*., 1993; Severson *et al*., 1993; Shu *et al*., 1996; Ji *et al*., 1997; Sorahan *et al*., 1997a,b; Brondum *et al*., 1999; Infante-Rivard *et al*., 2000).

A total of 129 lymphatic and haematopoietic cancers were diagnosed during 5 years of follow-up in the Swedish cohort (Pershagen *et al*., 1992). No association was observed between the development of these cancers and smoking during pregnancy or any amount of smoking by the mother.

Manning and Carroll (1957) found no difference in the proportion of mothers of children with leukaemia who smoked 10 or more cigarettes per day at the time of interview when compared to control mothers (39% versus 38%) and a somewhat lower proportion of mothers of children with lymphoma (31%) who smoked at that level. A second early study (Stewart *et al.*, 1958) reported a very small but statistically significant increase in risk for death from leukaemia among children of mothers who had ever smoked (relative risk, 1.1; $p < 0.04$). [The Working Group noted that neither study was designed specifically to study the effects of involuntary smoking; only unadjusted proportions were reported.]

Van Steensel-Moll *et al*. (1985) found no association between maternal smoking in the year before pregnancy and risk for acute lymphocytic leukaemia in a study in the Netherlands designed to assess maternal fertility problems and this risk. [The Working Group noted that the strength of this study was the large number of cases. Its limitations are the limited assessment of exposure and the questionable time period.] The case–control study in Sweden by Stjernfeldt *et al*. (1986) included 157 cases of acute lymphoblastic leukaemia, 16 cases of non-Hodgkin lymphoma and 15 cases of Hodgkin disease. A statistically significant positive trend (p trend < 0.01) was found for number of cigarettes smoked per day by the mother during pregnancy and risk for acute lymphoblastic leukaemia. No statistically significant association with smoking was observed for either non-Hodgkin lymphoma or Hodgkin disease based on a very small number of cases.

McKinney *et al*. (1986) found no association between maternal smoking during pregnancy and risk for childhood leukaemia or lymphoma. Buckley *et al.* (1986) also failed to find an association between maternal smoking during pregnancy in their large

ALL, acute lymphocytic leukaemia; NHL, non-Hodgkin lymphoma; HD, Hodgkin disease; AML, acute myeloblastic leukaemia

study that included 742 cases of acute lymphocytic leukaemia and 169 cases of non-Hodgkin lymphoma.

Magnani *et al.* (1990) found no association between acute lymphocytic leukaemia, other leukaemias or non-Hodgkin lymphoma during childhood and the mother's smoking up to the time of the child's birth. The father's history of smoking was associated with a risk for non-Hodgkin lymphoma (relative risk, 6.7; 95% CI, 1.0–43.4), but not for acute lymphocytic leukaemia or other leukaemias. This Italian hospital-based case–control study included 142 cases of acute lymphocytic leukaemia, but only a small number of non-Hodgkin lymphoma (n = 19) and other types of leukaemia (n = 22). Risk estimates were adjusted for socioeconomic status only.

The case–control study in the USA reported by John *et al*. (1991) included 73 cases of leukaemia and 26 cases of lymphoma. Statistically significant increases in risk were associated with maternal smoking 3 months before conception for acute lymphocytic leukaemia; with smoking during the first trimester for acute lymphocytic leukaemia; and during all three trimesters for acute lymphocytic leukaemia (relative risk, 2.5; 95% CI, 1.2–5.4) and lymphoma (relative risk, 2.7; 95% CI, 1.0–7.6).

A US–Canadian case–control study of acute myeloid leukaemia found no association between risk for acute myeloid leukaemia and maternal smoking before, during or after pregnancy (Severson *et al*. 1993). No association was observed with smoking by the father, but this was not quantified. [The Working Group noted the reasonably detailed exposure assessment, but although relative risks were adjusted for potential confounders, the factors were not named.]

A small case–control study of leukaemia and non-Hodgkin lymphoma in the United Kingdom examined maternal smoking based on obstetric notes and by interview (Roman *et al*., 1993). Both relative risks were below unity. [The Working Group noted that very little information was provided, that no adjustment was made for confounders, and the small size of the sample.]

Shu *et al*. (1996) found that maternal smoking during pregnancy was negatively associated with risk for leukaemia (all leukaemias, acute lymphocytic leukaemia or acute myeloblastic leukaemia) in infants. Paternal smoking one month prior to pregnancy was related to an elevated risk for acute lymphocytic leukaemia (relative risk, 1.6; 95% CI, 1.0–2.4), but not acute myeloblastic leukaemia and smoking by the father during pregnancy did not lead to a statistically significant increase in risk for any type of leukaemia. [The Working Group noted that the strengths of this study included the relatively detailed exposure from mothers' and fathers' smoking, and the adjustment for some potential confounders (sex, parental age, education and alcohol consumption by the mother during pregnancy).]

The case–control study of paternal smoking and childhood cancer in China reported by Ji *et al*. (1997) included 166 cases of acute leukaemia and 87 of lymphoma. No statistically significant association with paternal smoking was found for leukaemia, although a borderline positive trend was found for the father's number of pack–years of smoking (trend, p = 0.06). The father's smoking was associated with a fourfold increase in risk for

lymphoma (relative risk, 4.0; 95% CI, 1.3–12.5) and statistically significant positive dose–response trends for lymphoma were observed for number of years smoked preconception and pack–year history, but not for number of cigarettes smoked per day.

Sorahan *et al.* (1997a) reported a modest association between risk for acute lymphocytic leukaemia and maternal smoking (relative risk, 1.2; 95% CI, 1.0–1.5), but no increased risk was found for myeloid, monocytic or other types of leukaemia or lymphoma. This study found no relationship between paternal smoking and any type of leukaemia, but the risk estimate for lymphoma was 1.4 (95% CI, 1.0–1.8). No increased risks associated with parental smoking were found when cases and controls from a later time period, 1971–76, were examined (Sorahan *et al*. 1997b).

A large case–control study in the USA of parental cigarette smoking and risk for acute leukaemia collected detailed information on exposure to smoke from the mothers and fathers of 1842 children with acute lymphocytic leukaemia and 517 with acute myeloblastic leukaemia and controls matched on age, race, and telephone area code/exchange (Brondum *et al*., 1999). There was no association between risk for acute lymphocytic leukaemia and ever smoking by the father (relative risk, 1.0; 95% CI, 0.9–1.2) or mother (relative risk, 1.0; 95% CI, 0.9–1.2); similarly, no associations were observed between acute myeloblastic leukaemia and ever smoking by the father (relative risk, 0.9; 95% CI, 0.7–1.2) or the mother (relative risk, 1.0; 95% CI, 0.7–1.2). Parental smoking during or around the time of the index pregnancy was not related to risk, nor were the number of cigarettes smoked, years of smoking or pack–years. Risk estimates were adjusted for household income, mother's race and education and father's race and education. [The Working Group noted the good statistical power and the detailed histories of both parents and also that some adjustment has been made for potential confounders.]

A case–control study in Canada of acute lymphocytic leukaemia assessed the role of parental smoking and *CYP1A1* genetic polymorphisms (Infante-Rivard *et al*., 2000). There was no statistically significant association between parents' smoking and leukaemia overall. However, a substudy that included 158 of the 491 cases suggested that the effect of parental smoking may be modified by variant alleles in the *CYP1A1*. *CYP1A1*2B* tended to decrease risks and *CYP1A1*2A* and *CYP1A1*4* increased the risks associated with smoking in the second and third trimesters. [The Working Group noted that this was the first study to look at the interaction between parental smoking, *CYP1A1* and leukaemia.]

Sorahan *et al*. (2001) (see Section 2.3.1) found a statistically non-significant positive association between risk for acute lymphocytic leukaemia and daily cigarette consumption by fathers before pregnancy and a statistically non-significant inverse association between risk for acute lymphocytic leukaemia and daily smoking by mothers before pregnancy.

The results of the meta-analysis for maternal smoking during pregnancy indicated that there were no statistically significant associations for all lymphatic and haematopoietic neoplasms (relative risk, 1.0; 95% CI, 0.9–1.2), for non-Hodgkin lymphoma or total lymphomas (relative risk, 1.1; 95% CI, 0.9–1.5) or for all leukaemias, acute leukaemia or

acute lymphocytic leukaemia (relative risk, 1.1; 95% CI, 0.8–1.3) (Boffetta *et al*., 2000). The authors found evidence of publication bias for the data available on lymphomas ($p = 0.04$). Published studies with a small number of cases reported positive associations between exposure to tobacco smoke and childhood leukaemia, whereas larger studies showed no association. This suggests that small studies that had found no association or a negative association failed to be published. The meta-analysis for paternal smoking indicated no statistically significant association with acute lymphocytic leukaemia, but a twofold increase in risk for non-Hodgkin lymphoma (relative risk, 2.1; 95% CI, 1.1–4.0).

2.3.4 *Other childhood cancers*

Several other types of childhood cancer have been studied in relation to parental smoking in epidemiological investigations.

The cohort study by Pershagen *et al*. (1992) reported no statistically significant associations between mother's smoking during pregnancy and kidney cancer (30 cases; relative risk, 0.6; 95% CI, 0.2–1.5), eye tumours (28 cases; relative risk, 1.4; 95% CI, 0.6–2.8), endocrine tumours (13 cases; relative risk, 1.9; 95% CI, 0.6–6.0) or tumours of the connective tissue and muscle (15 cases; relative risk, 1.2; 95% CI, 0.4–3.6).

Magnani *et al*. (1989) conducted a hospital-based case–control study of soft-tissue sarcomas in Italy during 1983–84. The cases included 36 children with rhabdomyosarcoma and 16 cases of other soft-tissue sarcomas who were compared with 326 controls from the same hospitals. No associations were found between soft-tissue sarcoma or rhabdomyosarcoma and either mother's or father's smoking (all point estimates of relative risks were below unity). Smoking during several time periods, before, during and after birth was then looked at separately and the results were the same as for any smoking by the parents. [The Working Group noted that this was a small study, but that the exposure assessment included different time periods.]

Two studies in the USA (Holly *et al*., 1992; Winn *et al*., 1992) examined risk factors for Ewing's sarcoma. In their population-based study, Holly *et al*. (1992) looked at 43 cases and 193 controls selected by random digit dialling and matched to cases by sex and age. This tumour was not associated with smoking by the mother during pregnancy (relative risk, 1.1; 95% CI, 0.5–2.4) or by the father (relative risk, 0.9; 95% CI, 0.4–1.9). Risk estimates were adjusted for agricultural occupation of the father, poison or overdose of medication, area of residence, year of child's birth and income. [The Working Group noted that this was a small study that had made a detailed assessment of many factors, but less for parental smoking.] Winn *et al*. (1992) reported the findings of a larger case–control study that included 208 cases throughout the USA and two control groups with equal numbers of controls (sibling controls and regional controls). When cases were compared to regional controls, no significant risk estimates were found for smoking by either parent; however, parents were more likely to have smoked during pregnancy with the child with Ewing's sarcoma than during the pregnancy with the unaffected sibling; if only the mother smoked, the relative risk was 1.5 (95% CI, 0.3–9.0); if only the father

smoked, the relative risk was 3.1 (95% CI, 0.7–14.0); if both parents smoked, the relative risk was 7.3 (95% CI, 1.3–41.6).

Two case–control studies in the USA evaluated prenatal drug consumption by the mother and risk for neuroblastoma (Kramer *et al*., 1987; Schwartzbaum, 1992). The first study was population-based and included 104 cases diagnosed from 1970 to 1979, a first group of 104 controls matched on date of birth, race and the first five digits of case's telephone number and a second group of controls comprising siblings of the index case. No significant increase in risk was associated with maternal smoking during pregnancy when cases were compared to either control group. The second study compared 101 newly diagnosed cases of neuroblastoma and 690 controls diagnosed with other types of childhood cancer at St Jude Children's Research Hospital. Cigarette smoking by the mother during pregnancy was found to increase the risk for neuroblastoma (relative risk, 1.9; 95% CI, 1.1–3.2). [The Working Group noted the questionable appropriateness of the control group in the study by Schwartzbaum and the limited exposure assessments in both studies.]

Olshan *et al*. (1993) reported findings from the National Wilms Tumour Study, a case–control study from a national collaborative clinical trial group in the USA. The study was conducted using interviews with 200 cases and 233 matched controls identified by random-digit dialling. No association was found for mother's smoking during pregnancy and risk for Wilms tumour (relative risk for smoking ten or more cigarettes per day, 0.7; 95% CI, 0.4–1.3).

2.4 Other cancers

2.4.1 *All cancer sites combined*

Hirayama (1984) reported a statistically significant association (p for trend < 0.001) between husband's smoking and cancer mortality in wives for all sites combined in the Japanese cohort (relative risk for former smoker: 1–19 cigarettes per day, 1.1; 95% CI, 1.0–1.2; relative risk for ≥ 20 cigarettes per day, 1.2; 95% CI, 1.1–1.4).

Sandler *et al*. (1985b), in their study previously described in detail (Section 2.2.2), found an increased risk of all cancers combined among nonsmokers passively exposed to cigarette smoke in adulthood (relative risk, 2.1; 95% CI, 1.4–3.0). Risk did not differ according to race (white or non-white), but was statistically significant only among women aged 30–49 years.

Miller (1990) reported the findings from a case–control study in the USA of cancer deaths among nonsmoking women in which next-of-kins were interviewed by telephone. Data on 906 nonsmoking wives were included in this report. The cases were women who had died of any type of cancer and the controls were nonsmoking wives who had died of cardiovascular, respiratory, kidney and other non-cancer diseases, excluding trauma. A nonsmoker was defined as a person who had smoked fewer than 20 packs of cigarettes during her lifetime. The percentage of deaths from cancer among non-exposed, non-

employed wives was 2.2%; for exposed, non-employed wives, 18.9%, and for employed wives, 34.3% ($p < 0.001$). [The Working Group noted that the study used a questionable comparison group and a non-standard definition of a nonsmoker.]

2.4.2 *Cervical cancer*

Three Asian cohort studies described in Section 2.1 also reported on involuntary smoking and risk for cancer of the cervix. Risk for cervical cancer associated with involuntary exposure to smoking in nonsmokers was examined in a Japanese cohort study that found no significant increase in risk associated with husbands' smoking (Hirayama, 1984). A second cohort study also considered exposure to husbands' smoking and risk for cervical cancer in nonsmoking Korean women (Jee *et al*., 1999). The relative risk based on 203 cases of cervical cancer in nonsmokers was 0.9 (95% CI, 0.6–1.3) for women married to former and 0.9 (95% CI, 0.6–1.2) for women married to current smokers when compared with women married to nonsmokers. The cohort study by Nishino *et al*. (2001) included 11 incident cases of cervical cancer. Again, no association with husband's smoking status was observed (relative risk, 1.1; 95% CI, 0.3–4.5). [The Working Group noted that these cohort studies consistently indicated no association between exposure to secondhand smoke and cervical cancer.]

The case–control study from the USA reported by Sandler *et al*. (1985b; see Section 2.2.2) found an increased risk of cervical cancer associated with spousal smoking (relative risk, 2.1; 95% CI, 1.2–3.9). A second case–control study in the USA was conducted from 1984 to 1987 in Utah where a large percentage of the population are members of the Church of Jesus Christ of the Latter-day Saints which proscribes tobacco smoking (Slattery *et al*., 1989). The cases were population-based and controls were selected by random-digit dialling and matched to cases on age and county of residence. The response rates for cases and controls were 66% and 76%, respectively. Nonsmokers involuntarily exposed for 3 hours or more per day to secondhand smoke were found to have an increased risk for cervical cancer (relative risk, 3.4; 95% CI, 1.2–9.5). Self-characterized exposure to 'a lot' of secondhand smoke was also associated with increased risk (in-home relative risk, 2.9; 95% CI, 1.1–7.9; outside the home relative risk, 1.6; 95% CI, 0.6–4.5). [The Working Group noted that a statistically non-significant increase in risk was also observed in active smokers exposed to smoking by others.]

Coker *et al*. (1992) examined the risk of exposure to secondhand smoke in a case–control study of cervical intraepithelial neoplasma (CIN) of grades II ($n = 40$) and III ($n = 63$) in the USA. No statistically significant association was found between exposure to secondhand smoke and CIN II/III in nonsmokers, after adjustment for age, race, education, number of partners, contraceptive use, history of sexually transmitted disease and history of Pap smear. Another case–control study conducted in the USA compared 582 women with abnormal Pap smears (class 2–4) with 1866 controls with normal cytology (Scholes *et al*., 1999). Nonsmokers exposed to secondhand smoke from spouses, partners or other household members were found to have a borderline increase in risk for abnormal

cervical cytology compared to nonsmokers who were not exposed to these sources of secondhand smoke (relative risk, 1.4; 95% CI, 1.0–2.0). Risk estimates were adjusted for age, age at first sexual intercourse, and number of sexual partners during lifetime.

2.4.3 *Gastrointestinal cancers*

The incidence of colorectal cancer in relation to passive exposure to smoke, which was defined as having lived with a person who smoked, was examined in a 12-year prospective cohort study in Washington County, MD, USA (Sandler *et al*., 1988). A statistically significant reduction in risk for colorectal cancer was observed for nonsmoking women who were involuntarily exposed to smoking (relative risk, 0.7; 95% CI, 0.6–1.0), but an increased risk for this cancer was found for nonsmoking men exposed to secondhand smoke in the household (relative risk, 3.0; 95% CI, 1.8–5.0).

In a Swedish population-based case–control study, Gerhardsson de Verdier *et al*. (1992) found an increased risk for colon cancer in women (relative risk, 1.8; 95% CI, 1.2–2.8) and rectal cancer in men (relative risk, 1.9; 95% CI, 1.0–3.6) in association with passive smoking after adjustment for numerous potential confounders. [The Working Group noted that it is unclear whether the analysis was restricted to never-smokers.]

A large Canadian case–control study of 1171 patients newly diagnosed with histologically confirmed stomach cancer and 2207 population controls evaluated the risk associated with active and passive smoking (Mao *et al*., 2002). Response rates of approximately 65% were obtained for both cases and controls. The analysis of passive smoking was conducted in male never-smokers (132 cases, 343 controls). Questionnaires were mailed to respondents and provided information on lifetime exposure to secondhand smoke through residential and occupational histories and also looked at source, intensity, and duration of exposure. Risk estimates for passive smoking were adjusted for 10-year age group, province of residence, education, social class, total consumption of meat and total consumption of vegetables, fruits and juices. A positive trend ($p = 0.03$) in risk for cancer of the gastric cardia was associated with lifetime exposure to secondhand smoke (sum of years of residential plus occupational exposure) in male never-smokers. At the highest level of exposure (≥ 43 years), the relative risk was 5.8 (95% CI, 1.2–27.5). No increased risks or trends were associated with risk for distal gastric cancer. Risks assessed by subsite (cardia and distal), were similar for active and passive smoking.

2.4.4 *Nasopharyngeal and nasal sinus cavity cancer*

The relationship between involuntary exposure of nonsmokers to secondhand smoke and risk for these rare cancers of the upper respiratory tract has been examined in one cohort study (Hirayama, 1984) and four case–controls studies (Fukuda & Shibata, 1990; Zheng *et al*., 1993; Cheng *et al*., 1999; Yuan *et al*., 2000). A positive association was found in most of these studies.

Hirayama (1984) found an increased risk of nasal sinus cancer in women (histology not noted) associated with increasing numbers of cigarettes smoked by husbands of non-smoking women. When compared with nonsmoking women married to nonsmokers, wives whose husbands smoked had a relative risk of 1.7 (95% CI, 0.7–4.2) for 1–14 cigarettes per day, 2.0 (95% CI, 0.6–6.3) for 15–19 cigarettes per day and 2.55 (95% CI, 1.0–6.3) for ≥ 20 cigarettes per day (p for trend = 0.03).

Fukuda and Shibata (1990) reported the results of the first Japanese case–control study based on 169 cases of squamous-cell carcinoma of the maxillary sinus and 338 controls matched on sex, age and residence in Hokkaido, Japan. Among nonsmoking women, a relative risk of 5.4 ($p < 0.05$) was associated with exposure in the household to secondhand smoke from one or more smokers. Active smoking was associated with an increased risk for squamous-cell carcinoma in men in the same study.

Zheng *et al*. (1993) used data from the 1986 US National Mortality Followback Survey to assess risk for cancer of the nasal cavity and sinuses in relation to exposure to secondhand smoke in white men. A total of 147 deaths from cancer of the nasal cavity and sinuses were compared to 449 controls who had died from one of a variety of causes (excluding any causes strongly linked to alcohol and/or tobacco use). Data were obtained from postal questionnaires completed by next-of-kins. Among nonsmokers, patients with nasal cancer were more likely to have a spouse who smoked cigarettes (relative risk, 3.0; 95% CI, 1.0–8.9) after adjustment for age and alcohol use. When the analysis of cases was restricted to those with cancer of the maxillary sinus, the risk was somewhat higher (relative risk, 4.8; 95% CI, 0.9–24.7). The risks reported for active and for involuntary smoking were of similar magnitude in this study.

Neither involuntary exposure to tobacco smoke during childhood nor exposure during adult life were positively associated with an increased risk for nasopharyngeal cancer in a study in China (Province of Taiwan) (Cheng *et al*., 1999). Although histological type was not specified, all cases were histologically confirmed. Among never-smokers, the risk estimates for cumulative exposure to passive smoking (pack–person–years) in childhood declined as exposure increased (p for trend = 0.05); a similar but non-significant inverse relationship was found for exposure during adulthood. Significant elevations in risk of nasopharyngeal cancer were observed for active smokers in this study. [The Working Group noted that the exposure assessment was relatively detailed and that the estimates of relative risk were adjusted for age, sex, education and family history of nasopharyngeal cancer.]

A large population-based case–control study conducted in Shanghai, China, included 935 cases of nasopharyngeal carcinoma and 1032 population controls randomly selected from a population-registry and frequency-matched by sex and 5-year age group (Yuan *et al*., 2000). All cases were histologically confirmed, but the cell type was not specified. The study subjects were interviewed face to face, and the response rates were 84% for cases and 99% for controls. In female never-smokers, a consistent increase in risk related to exposure to secondhand smoke during childhood was noted. If the mother smoked, the relative risk was 3.4 (95% CI, 1.4–8.1); if the father smoked, the relative risk was 3.0

(95% CI, 1.4–6.2); if another household member smoked, the relative risk was 2.7 (95% CI, 1.1–6.9), and if any household member smoked, the relative risk was 3.0 (95% CI, 1.4–6.2). Risks associated with exposure to secondhand smoke during adulthood in women were also statistically significantly increased. For male never-smokers, the associations were weaker and were not statistically significant for exposure during childhood and adulthood. Gender-specific risk estimates were adjusted for age, level of education, consumption of preserved foods, oranges and tangerines, exposure to rapeseed oil, exposure to burning coal during cooking, occupational exposure to chemical fumes, history of chronic ear and nose conditions and family history of nasopharyngeal cancer. [The Working Group noted that this was a large, well-conducted study that included a detailed exposure assessment and adjustment for numerous potential confounders.]

2.4.5 *Tumours of the brain and central nervous system*

A population-based case–control study of patients with incident primary brain tumours diagnosed from 1987 through 1990 in Adelaide, Australia, was reported by Ryan *et al.* (1992). Controls were selected from the Australian electoral rolls which cover 95% of the population. Response rates of 90% and 63% were obtained for cases and controls, respectively. The study included 110 histologically confirmed cases of glioma, 60 meningioma cases and 417 controls. An increased risk of meningioma was associated with involuntary exposure to tobacco from the spouse, particularly among women (relative risk, 2.7; 95% CI, 1.2–6.1). No statistically significant association was found between active smoking and either glioma or meningioma in this study.

3. Studies of Cancer in Experimental Animals

3.1 Inhalation exposure: simulated environmental tobacco smoke

Since the previous *IARC Monograph* on tobacco smoking (IARC, 1986), studies that include exposure to sidestream cigarette smoke or to simulated environmental tobacco smoke from cigarettes have been conducted. For experimental purposes, many of the studies employed a mixture of 89% sidestream and 11% mainstream tobacco smoke prepared by smoking machines from standard reference cigarettes, referred to in the published literature and in this section as simulated environmental tobacco smoke (Teague *et al*., 1994). Although this experimental exposure system was designed to mimic human exposure, it provides an exposure pattern that differs from that encountered by humans exposed to secondhand smoke. No studies were available on sidestream smoke or simulated environmental smoke from other tobacco products.

The mice used in the studies described below were of the specially inbred strain A/J and outbred strain Swiss, both of which are highly susceptible to lung tumour development (Shimkin & Stoner, 1975). Both strains carry the pulmonary adenoma susceptibility-1 genetic locus (*Pas1*), a locus affecting genetic predisposition to lung tumours in mice (Manenti *et al.*, 1997). Strain A/J mice carry the *Eco*RI-generated 0.55 Kb DNA fragment of the K-*ras* oncogene which is associated with high susceptibility to lung tumour development (Malkinson, 1992). Both strains are highly susceptible to chemical induction of peripheral lung tumours that originate primarily from type II pneumocytes. It should be noted that type II pneumocytes are precursors for a relatively small fraction (~5–10%) of human adenocarcinomas (i.e. bronchiolo-alveolar carcinomas). Most adenocarcinoma cells are derived from bronchiolar cells and not from type II pneumocytes.

Mouse

Male strain A/J mice (6–8 weeks old) were exposed in chambers to sidestream smoke generated from Kentucky 1R4F reference cigarettes. Mice were exposed for 6 h/day, 5 days/week at chamber concentrations of 4 mg/m^3 total suspended respirable particulate matter. The experiment was terminated after 6 months. The fraction of animals bearing lung tumours was the same in those exposed to smoke (33%; 12/36) as in those exposed to filtered air (33%; 12/36). The average number of tumours per lung (0.42 tumours/smoke-exposed mouse; 0.39 tumours/control mouse) was also similar (Witschi *et al.*,

1995). [The Working Group noted the low concentration of tobacco smoke used and the short duration of the study.]

Male strain A/J mice (6–8 weeks old) were exposed to simulated environmental tobacco smoke that consisted of a mixture of 89% sidestream and 11% mainstream smoke from Kentucky 1R4F reference cigarettes, at a chamber concentration of 87 mg/m^3 total suspended particulate matter. Mice were exposed in 0.44 m^3 stainless steel inhalation chambers for 6 h/day, 5 days/week for 5 months and then killed for assessment of lung tumour incidence and multiplicity (see Table 3.1). The incidence of lung tumours in mice exposed to simulated environmental tobacco smoke (25%; 6/24) was not significantly different from that in controls (8.3%; 2/24). There was no significant difference between lung tumour multiplicities (total number of lung tumours per total number of animals) in exposed and control animals (0.3 ± 0.1 and 0.1 ± 0.1 tumour/mouse, respectively [mean ± SE]). A second group of mice exposed for 5 months to simulated environmental tobacco smoke was allowed to recover for a further 4 months in filtered air before being killed for analysis of lung tumour incidence and multiplicity. Tumour incidence was significantly greater in mice exposed to smoke (83.3%; 20/24) than in controls kept in air (37.5%; 9/24; $p < 0.05$, Fisher's

Table 3.1. Lung tumours in strain A/J mice exposed to filtered and unfiltered simulated environmental tobacco smoke

Exposure conditions	Parameter	Filtered air controls	Animals exposed to ETS
5 months in simulated ETS (87 mg TSP/m^3), 6 h/day, 5 days/week	Tumour incidence[a] Tumour multiplicity[b]	8.3% (2/24) 0.1 ± 0.1	25.0% (6/24) 0.3 ± 0.1
5 months in simulated ETS (87 mg TSP/m^3), 6 h/day, 5 days/week, then 4 months recovery in air	Tumour incidence Tumour multiplicity	37.5% (9/24) 0.5 ± 0.2	83.3% (20/24)[c] 1.4 ± 0.2[d]
5 months in unfiltered simulated ETS (78.5 mg TSP/m^3) and 4 months recovery in air	Tumour incidence Tumour multiplicity	41.6% (10/24) 0.5 ± 0.1	57.7% (15/26) 1.3 ± 0.3[d]
5 months in filtered simulated ETS (0.1 mg TSP/m^3) and 4 months recovery in air	Tumour incidence Tumour multiplicity	37.5% (9/24) 0.5 ± 0.1	66.7% (16/24) 1.2 ± 0.3[d]
5 months in filtered simulated ETS (0.1 mg TSP/m^3)	Tumour incidence Tumour multiplicity	20% (4/20) 0.3 ± 0.1	50% (12/24) 0.7 ± 0.2

Modified from Witschi *et al*. (1997a,b)
ETS, simulated environmental tobacco smoke; TSP, total suspended particulate matter
[a] Percentage of animals with lung tumours (incidence)
[b] Total number of lung tumours/total number of mice in the group (mean ± SE)
[c] $p < 0.05$, Fisher's exact test
[d] $p < 0.05$, Welch's alternate *t*-test

exact test) and tumour multiplicities were significantly higher in the group exposed to smoke (1.4 ± 0.2 versus 0.5 ± 0.2, $p < 0.05$, Welch's alternate *t*-test). More than 80% of all tumours were adenomas and the remainder were adenocarcinomas (Witschi *et al*., 1997a).

Female strain A/J mice (10 weeks old) were exposed to unfiltered (one group of 26 animals) or high efficiency particulate air (HEPA)-filtered simulated environmental tobacco smoke (two groups of 24 animals) which consisted of a mixture of 89% sidestream and 11% mainstream smoke from Kentucky 1R4F reference cigarettes. The concentration of total suspended particulates was 78.5 mg/m^3 in the unfiltered smoke exposure chamber and 0.1 mg/m^3 in the filtered smoke chamber (see Table 3.1). In addition, three groups of 24 control animals were exposed to filtered air. Lung tumour incidence and multiplicity in animals exposed to filtered smoke for 6 h/day, 5 days/week, and killed after 5 months were not significantly greater than those in controls kept in filtered air. Mice exposed as above to filtered tobacco smoke and then allowed to recover in air for 4 months had a lung tumour incidence of 16/24 (67%) and an average lung tumour multiplicity of 1.2 ± 0.3, compared with an incidence of 9/24 (37.5%) and a lung tumour multiplicity of 0.5 ± 0.1 in control mice breathing filtered air. Lung tumour multiplicity was significantly higher in mice exposed to filtered smoke than in controls ($p < 0.05$). Mice exposed to unfiltered smoke had a lung tumour incidence of 15/26 (57.5%) and a lung tumour multiplicity of 1.3 ± 0.3, whereas controls kept in filtered air had a tumour incidence of 10/24 (41.6%) and a lung tumour multiplicity of 0.5 ± 0.1 (multiplicity greater in treated mice, $p < 0.05$ than in controls kept in filtered air, Welch's alternate *t*-test). The authors concluded that the gas phase of simulated environmental tobacco smoke is as carcinogenic as unfiltered environmental tobacco smoke (Witschi *et al*., 1997b).

In a study of the effects of the experimental chemopreventive agents, phenethyl isothiocyanate and *N*-acetylcysteine, on the occurrence of lung tumours, male and female strain A/J mice (6–8 weeks old) were exposed to simulated environmental tobacco smoke that consisted of a mixture of 89% sidestream and 11% mainstream smoke from Kentucky 1R4F reference cigarettes. Mice were exposed for 6 h/day, 5 days/week for 5 months in 0.4 m^3 stainless steel inhalation chambers in which the concentration of total airborne suspended particulates was 82.5 mg/m^3. Controls were placed, within their cages, into chambers of the same size as the inhalation chambers. At the conclusion of the exposure period, the mice were transferred to a conventional animal holding facility. Nine months after the beginning of the experiment, the animals were killed and the lungs prepared for tumour analysis and histopathological examination. Lung tumour multiplicity, but not incidence, was increased in mice exposed to simulated environmental tobacco smoke. Lung tumours occurred in 20/29 (69%) of the controls with a multiplicity of 0.9 ± 0.2, and in 24/33 (73%) of the mice exposed to smoke with a multiplicity of 1.3 ± 0.2 (mean ± SEM, $p < 0.05$ by two-way ANOVA) (Witschi *et al*., 1998).

As part of a study on chemoprevention of tobacco smoke-induced lung tumours by dietary supplements of *myo*-inositol/dexamethasone, male strain A/J mice (8–10 weeks old) were exposed for 5 months to a mixture of 89% sidestream and 11% mainstream cigarette smoke. The animals were placed, within their cages, in stainless steel inhalation

chambers ventilated with tobacco smoke or filtered air (controls). Exposure to simulated environmental tobacco smoke took place for 6 h/day, 5 days/week. Exposure during the first 2 weeks was to an average of 71 mg total suspended particles/m^3; this was followed by exposure for 3 weeks to 86 mg/m^3 and finally to an average of 132 mg/m^3 for the remainder of the exposure period. After 5 months, all mice were removed from the inhalation chambers and transferred to a conventional animal holding facility with controlled temperature and humidity. Mice were killed 9 months after the beginning of the experiment. The incidence of lung tumours in control mice was 15/30 (50%) and the lung tumour multiplicity was 0.6 ± 0.1; the incidence of tumours in mice exposed to simulated environmental tobacco smoke was 30/35 (86%) and the multiplicity was 2.1 ± 0.3. The difference in lung tumour multiplicity between exposed and control mice was statistically significant ($p < 0.05$) (Witschi *et al.*, 1999).

As part of a study on chemoprevention of lung tumours induced by exposure to tobacco smoke, male strain A/J mice (10 weeks old) were exposed in stainless steel inhalation chambers for 6 h/day, 5 days/week to a mixture of 89% sidestream cigarette smoke and 11% mainstream smoke prepared from Kentucky 1R4F reference cigarettes. The total suspended particulate concentration was 137 mg/m^3. Inhalation exposure took place for 5 months and was followed by a recovery period of 4 months in filtered air in a conventional animal facility. Control mice were kept in chambers of the same size as the inhalation chambers, but ventilated with filtered air, for the first 5 months of the study. Mice were killed 9 months after the beginning of exposure. In the first of two studies, the lung tumour incidence in control mice was 35/54 (65%) and lung tumour multiplicity was 1.0 ± 0.1. In mice exposed to smoke, the tumour incidence was 25/28 (89%; i.e. significantly different from controls, $p < 0.05$, Fisher's exact test) and tumour multiplicity was 2.4 ± 0.3 (i.e. significantly different from controls, $p < 0.01$ by parametric or non-parametric ANOVA). In the second experiment, conducted under the same conditions of exposure, lung tumour incidence in control mice was 18/30 mice and the incidence in mice exposed to smoke was 38/38 ($p < 0.01$, Fisher's exact test). Lung tumour multiplicity was 0.9 ± 0.2 in control mice and 2.8 ± 0.2 in animals exposed to smoke ($p < 0.01$, ANOVA) (Witschi *et al*., 2000).

In a third study conducted using the same experimental design, strain A/J mice [sex not specified] were exposed continuously to simulated environmental tobacco smoke for 9 months. There was no statistically significant increase in lung tumour incidence (85% [23/27] versus 63% [53/84]) or lung tumour multiplicity (1.5 ± 0.2 versus 1.0 ± 0.1) (Witschi, 2000).

Female strain A/J mice (4 weeks of age) were exposed to simulated environmental tobacco smoke (89% sidestream and 11% mainstream smoke) from Kentucky 2R1 reference cigarettes. Exposure continued for 5 months for 6 h/day, 5 days/week. The concentration of total suspended particulates was 120 mg/m^3 air. Control mice were kept in chambers ventilated with filtered air. Mice were then kept for a 4-month recovery period in filtered air, after which they were killed and lungs tumours were counted. The lung tumour incidence in mice exposed to smoke was 15/20 (75%); the incidence in sham-exposed controls was 5/20 (25%; $p < 0.01$). Lung tumour multiplicity in mice exposed to

smoke was 1.05 ± 0.17 and that in control mice was 0.25 ± 0.10 ($p < 0.01$). In a third group of mice exposed to simulated environmental tobacco smoke under the same conditions for 9 months and killed immediately at the end of the exposure period, the lung tumour incidence (6/20; 30%) and multiplicity (0.4 ± 0.15) were not significantly different from the tumour incidence and multiplicity in control mice. In a fourth group of mice exposed to simulated tobacco smoke under the same conditions for 2 months, followed by a recovery period of 7 months, lung tumour incidence (8/20; 40%) and multiplicity (0.50 ± 0.15) were also not significantly greater than in control mice. These data are in agreement with the results of Witschi *et al*. (1997a,b, 1998 and 1999) which indicate that strain A/J mice require a 4-month recovery period following a smoke exposure for 5 months to demonstrate a positive carcinogenic effect of environmental tobacco smoke (D'Agostini *et al*., 2001).

Witschi *et al*. (2002) exposed male Swiss albino mice to simulated environmental tobacco smoke for 5 months, followed by 4 months of recovery in air. The lung tumour incidence was 1/26 (4%) in sham-exposed mice and 6/31 (20%) in mice exposed to simulated environmental tobacco smoke, with a fivefold increase ($p = 0.075$). Lung tumour multiplicity was 0.04 ± 0.04 in sham-exposed mice and 0.35 ± 0.14 in mice exposed to environmental tobacco smoke ($p < 0.05$). When BALB/c mice were exposed to simulated environmental tobacco smoke under identical conditions, the incidence of lung tumours was increased (33%, 9/27 versus 20%, 6/30), but the multiplicity was not (0.4 versus 0.2).

As part of a series of pilot experiments on chemoprevention of cancer induced by environmental tobacco smoke, De Flora *et al*. (2003) reported studies of the effects of environmental tobacco smoke in Swiss albino mice. However, these studies were published in a review, and the reporting of study details was incomplete.

Groups of gestating female Swiss albino mice were exposed for 20 days to simulated environmental tobacco smoke. The exposure conditions were similar to those described by D'Agostini *et al*. (2001). The exposure of gestating mice to environmental tobacco smoke decreased the body weights of dams during the 3 months following delivery [details not given]. Similarly, in the female progeny of dams exposed to smoke, the body weight 10 days after birth was slightly, but significantly lower than that of female progeny from sham-exposed dams [details not given]. Dams exposed to tobacco smoke during gestation had significantly higher yields of lung tumours than sham-exposed dams. The lung tumour incidence at 8.5 months of age was increased from 1/22 (4.5%) in sham-exposed dams to 4/14 (28.6%) in dams exposed to tobacco smoke. The lung tumour multiplicity at 8.5 months of age was increased from 0.05 ± 0.5 in sham-exposed dams to 0.36 ± 0.17 (mean ± SE; $p < 0.05$) in dams exposed to tobacco smoke. The progeny of sham-exposed dams and dams exposed to environmental tobacco smoke, kept either 8.5 or 15 months after birth in filtered air, had identical yields of lung tumours. The incidence of lung tumours in the progeny at 8.5 months was 10% (1/10) and the lung tumour multiplicity was 0.1 ± 0.1. At 15 months, the lung tumour incidence in the progeny was 20% (2/10) and the lung tumour multiplicity was 0.3 ± 0.21 (De Flora *et al*., 2003).

In a second experiment (see Table 3.2), De Flora *et al*. (2003) investigated the effects of gestation and length of the exposure period on lung tumours induced by environmental tobacco smoke in Swiss mice. The exposure to environmental tobacco smoke during gestation (for 20 days) increased the tumour incidence from 4.4% (1/23) in sham-exposed dams to 23.8% (10/42; $p < 0.05$) in dams exposed to smoke. The lung tumour multiplicity in sham-exposed dams (0.09 ± 0.09) was significantly lower than that in the mice exposed to smoke (0.38 ± 0.13; $p < 0.05$). A similar trend was seen in non-gestating Swiss albino mice exposed for an equivalent period (20 days), but the increases in tumour incidence and lung tumour multiplicity were not significant. When non-gestating mice were exposed to environmental tobacco smoke for 5 months, followed by 4 months of recovery in filtered air, there was an increase in lung tumour incidence from 9.1% (2/22) in sham-exposed mice to 42.9% (9/21; $p < 0.01$) in mice exposed to tobacco smoke and in lung tumour multiplicity from 0.14 to 0.57 ($p < 0.01$) in sham-exposed compared to smoke-exposed mice. The increases were more pronounced if the animals were exposed to environmental tobacco smoke for 9 consecutive months.

In summary, when strain A/J mice of either sex are exposed to sufficiently high concentrations of simulated environmental tobacco smoke for a period of 5 months and are then kept in filtered air for a further 4 months, lung tumour multiplicities are consistently and significantly higher in mice exposed to tobacco smoke than in concomitant controls.

Table 3.2. Lung tumour yield in female Swiss albino mice, either gestating or non-gestating, exposed to simulated environmental tobacco smoke for varying time periods

Exposure to simulated ETS (time)	Gestating	Percentage of animals with lung tumour (incidence)	Lung tumour multiplicity[a]
0[b]	–	9.1% (2/22)	0.14 ± 0.10
0[b]	+	4.4% (1/23)	0.09 ± 0.09
20 days[c]	–	20.9% (9/43)	0.28 ± 0.09
20 days[c]	+	23.8% (10/42)[e]	0.38 ± 0.13[e]
5 months[d]	–	42.9% (9/21)[f]	0.57 ± 0.16[f]
9 months	–	50.0% (11/22)[f]	0.68 ± 0.17[f]

From De Flora *et al*. (2003)
ETS, environmental tobacco smoke
[a] Total number of lung tumours/total number of mice in the group (mean ± SE)
[b] Sham-exposed mice kept in filtered air for 9 months
[c] Exposed to ETS throughout gestation, or for an equivalent period in non-gestating mice, followed by 8 months and 10 days of recovery in filtered air
[d] Followed by 4 months of recovery in filtered air
[e] $p < 0.05$
[f] $p < 0.01$, compared with the corresponding sham-exposed mice, assessed by χ^2 analysis (incidence data) or Student's *t* test for unpaired data (multiplicity data)

In one experiment, filtered simulated environmental tobacco smoke induced lung tumours as effectively as whole simulated environmental tobacco smoke. At the higher levels of exposure, the incidences of lung tumour were also significantly higher in mice exposed to simulated environmental tobacco smoke than in controls. Similarly, the exposure of Swiss mice to environmental tobacco smoke for 5 months followed by a 4-month recovery period resulted in a significant increase in lung tumour response. In contrast to the findings in A/J mice, however, treatment of Swiss mice with environmental tobacco smoke for 9 consecutive months also resulted in a significant increase in the lung tumour response. Moreover, the short-term exposure of Swiss mice to environmental tobacco smoke led to an increased occurrence of lung tumours after 9 months.

3.2 Administration of condensates of sidestream smoke

3.2.1 *Mouse*

The comparative carcinogenicity of cigarette sidestream and mainstream smoke condensates was tested on the skin of female NMRI mice. Commercial brand German blond tobacco cigarettes were smoked to a defined butt length on a smoking machine using a puff duration of 2 s/min. Sidestream and mainstream smoke condensates were collected separately, dissolved in acetone, and administered on the shaved skin of the animal's lower back. Mice received half a dose twice a week for 3 months to give total weekly doses of 5, 10 and 15 mg. The animals were kept until natural death. No cutaneous or subcutaneous tumours developed in any of three control groups (42, 44 and 43 mice). In animals given mainstream smoke condensate, there were four malignant and three benign tumours in seven of 177 treated mice: two mammary adenocarcinomas, one haemangiosarcoma and one schwannoma in 58 mice that received the 5-mg dose; no tumours in any of the 61 mice that received the 10-mg dose, and three squamous-cell papillomas of the skin in 58 mice that received the 15-mg weekly dose. In the mice given sidestream smoke condensate, there were 16 malignant and 14 benign tumours in 30 of 182 treated mice: one mammary adenocarcinoma, three squamous-cell carcinomas and one squamous-cell papilloma of the skin in 60 mice that received the 5-mg dose; two mammary adenocarcinomas, one squamous-cell carcinoma and two squamous-cell papillomas of the skin in 61 mice that received the 10-mg dose; and two mammary adenocarcinomas, one mixed mammary tumour, six squamous-cell carcinomas and 11 squamous-cell papillomas in 61 mice that received the 15-mg dose. The overall carcinogenic effect of sidestream smoke condensate was significantly higher than that of mainstream smoke condensate ($p < 0.001$) (Mohtashamipur *et al*., 1990).

3.2.2 *Rat*

The carcinogenicity of sidestream cigarette smoke condensate was studied by collecting particles and semivolatiles from commercial German cigarettes smoked on a smoking machine and implanting the condensed material in a mixture of trioctanoin and

beeswax into the lungs of female Osborne-Mendel rats at a dose corresponding to the products of a single cigarette. The fraction containing PAHs with four and more rings (dose, 1.06 mg/rat) induced five lung carcinomas in 35 treated rats. A sixfold higher dose (6.4 mg/rat) induced two lung carcinomas in five treated rats. The combined fractions containing no PAHs and PAHs of two and three rings (16 mg/rat) caused one lung carcinoma in 35 treated rats, and the semivolatiles (11.8 mg/rat) gave rise to no carcinoma in 35 treated rats (Grimmer *et al*., 1988).

3.3 Observational studies of cancer in companion animals

Many species of animals are kept as pets, or companion animals, and these animals commonly share the environments of their owners. In consequence they are also exposed to toxic agents that may be present in the shared environment. The use of epidemiological methods to investigate environmental carcinogens through analysis of the occurrence of tumours in companion animals has been reviewed by Bukowski and Wartenberg (1997). Such data have been used in previous *IARC Monographs*, notably in the evaluation of carcinogenic risks associated with surgical implants and other foreign bodies (IARC, 1999).

3.3.1 *Case reports*

Case reports of lung cancer in the household pets of smokers are useful for generating hypotheses, but usually contain insufficient details to allow useful analysis (Cummins, 1994).

3.3.2 *Case–control studies*

(*a*) *Dog*

Lung: A case–control study was conducted using 51 pet dogs with confirmed primary lung cancer from two veterinary teaching hospitals in the USA during 1985–87. Dogs with cancers at sites other than the lung (i.e. breast, soft connective tissues, skin, gastrointestinal tract, thyroid, bone, lymphoid and others) and not suspected of being related to cigarette smoking were chosen as controls (n = 83). Types of exposure to secondhand smoke that were assessed for both case and control dogs included the number of smokers who resided in the household, the number of packs of cigarettes smoked per day by the heaviest smoker and the time per day spent by the dog inside the home. Age, sex, body size and skull shape were included in a stratified analysis. A weak, statistically non-significant association was found between exposure to secondhand tobacco smoke and the risk of canine lung cancer. The crude odds ratio for exposure to environmental tobacco smoke was 1.5 (95% CI, 0.7–3.0). After adjustment for age, sex, skull shape, time spent indoors, and hospital of origin, the odds ratio rose slightly to 1.6 (95% CI, 0.7–3.7). The risk estimate for dogs aged 10 years or less was 2.7 (95% CI, 1.0–7.2); that for older dogs

was 0.8 (95% CI, 0.3–2.2). A suggestion that skull shape exerted a modifying effect on risk for lung cancer was noted: the odds ratio was non-significantly increased in dogs of breeds with short (brachycephalic) and medium length (mesocephalic) noses (odds ratio, 2.4; 95% CI, 0.7–7.8), but not in dogs with long noses. It was noted that primary canine lung cancer is rare (approximately 4 cases per 100 000 hospitalizations) (Reif *et al*., 1992).

Nasal cavity and paranasal sinuses: Sinonasal cancer is estimated to be tenfold more prevalent in dogs than lung cancer (Bukowski *et al.*, 1998).

A case–control study of nasal cancer in pet dogs treated at the veterinary teaching hospital at Colorado State University, USA, included 103 dogs with cancer of the nasal cavity and paranasal sinuses. Dogs with cancers at other sites (chiefly lymphoma, melanoma, haemangiosarcoma, and breast, bone and oral cavity) served as controls. The controls were similar to cases with respect to age, sex, breed and time spent outdoors. Telephone interviews were conducted with the owners of the pets to obtain data on exposure to environmental tobacco smoke. These data included the number of smokers in the household, the number of packs of cigarettes smoked per day at home by each smoker, the number of years that each person had smoked during the dog's lifetime and the time spent by the dog inside the home. The crude odds ratio for the presence of a smoker in the home and risk of nasal cancer was 1.1 (95% CI, 0.7–1.8). After stratification by anatomical features, the risk appeared to be restricted to long-nosed (dolichocephalic) dogs (odds ratio, 2.0; 95% CI, 1.0–4.1) (Reif *et al.*, 1998).

A case–control study was conducted to investigate the environmental causes of sinonasal cancers among pet dogs. Data on indoor environmental exposure including the presence of smokers in the household were collected for 129 dogs with histologically confirmed sinonasal cancer diagnosed during 1989–93 at the University of Pennsylvania School of Veterinary Medicine, USA. These were compared with 176 control dogs diagnosed with primary stomach, bowel, omental or liver cancers during the same period. Long-nosed dogs were significantly more likely to present with sinonasal cancer than dogs with short or medium-length noses (odds ratio, 3.2; 95% CI, 1.1–10). Elevated odds ratios were reported for dogs living in households that used coal fires or kerosene heaters for indoor heating (2.7; 95% CI, 1.4–5.4) and in which household chemicals were stored in the living area (5.5; 95% CI, 1.2–29). There was no excess risk associated with smokers living in the home (odds ratio, 0.70; 95% CI, 0.41–1.2) (Bukowski *et al.*, 1998).

Urinary bladder: A case–control study of household dogs was conducted to determine whether exposure to sidestream cigarette smoke, chemicals in the home, use of topical insecticides or obesity are associated with the occurrence of bladder cancer in canines. Information was obtained by interviewing the owners of 59 dogs with transitional cell carcinoma of the urinary bladder, diagnosed histologically at the University of Pennsylvania School of Veterinary Medicine, USA, between January 1982 and June 1985. Dogs matched on age and size of breed (n = 71) with other chronic diseases or neoplasms, excluding diseases of the urinary tract, served as controls. The risk of bladder cancer was correlated with use of topical insecticide and was enhanced in overweight dogs. The risk of bladder

cancer was not found to be related to exposure to household chemicals or to sidestream cigarette smoke at the levels of 1–3000 lifetime pack–years (odds ratio, 1.3; 95% CI, 0.5–3.1) or > 3000 lifetime pack–years (odds ratio, 0.8; 95% CI, 0.3–2.0) (Glickman *et al*., 1989). [The Working Group noted that the exposure is most likely expressed as lifetime number of packs.]

(*b*) *Cat*

Malignant lymphoma

A case–control study of domestic cats was conducted to determine whether exposure to household environmental tobacco smoke is associated with the occurrence of feline malignant lymphoma. Information on the level of smoking in the household two years prior to diagnosis was obtained from questionnaires sent to the owners of 80 cats with malignant lymphoma diagnosed during 1993–2000 at the Foster Small Animal Hospital, MA, USA. These cases were compared with 114 control cats diagnosed with renal disease during the same period. The relative risk of malignant lymphoma for cats exposed to any household tobacco smoke was 2.4 (95% CI, 1.2–4.5). The risk increased with both duration and level of exposure, with evidence of a linear trend. Cats exposed to tobacco smoke for five or more years had a relative risk of 3.2 (95% CI, 1.5–6.9; p for trend = 0.003) when compared with cats in nonsmoking households (Bertone *et al.*, 2002).

4. Other Data Relevant to an Evaluation of Carcinogenicity and its Mechanisms

The Working Group attempted to provide comprehensive coverage of the published literature on other data relevant to the evaluation of the carcinogenic hazards of secondhand smoke (since 1985), in some cases referring to recent reviews.

4.1 Absorption, distribution, metabolism and excretion

For a description of the absorption, distribution, metabolism and excretion of components of tobacco smoke, the reader is referred to the monograph on tobacco smoke.

4.1.1 *Humans*

(*a*) *Enzyme activities and metabolism*

In a study of human placental monooxygenase activity, as measured by in-vitro oxidation of 7-ethoxyresorufin, *O*-deethylase activity was significantly inhibited ($p < 0.05$) by 7,8-benzoflavone with placental microsomes from women passively exposed to cigarette smoke, but not with those from women who had not been exposed (Manchester & Jacoby, 1981).

A pharmacokinetic study reported a significantly faster clearance of theophylline in a group of seven nonsmokers exposed to secondhand tobacco smoke, as determined by questionnaire data and cotinine levels, than in a matched group of non-exposed individuals, as determined by clearance rate, terminal elimination half-time and mean residence time ($T_{½}$ = 6.93 h versus 8.69 h, $p < 0.05$) (Matsunga *et al*., 1989). Conversely, no changes in theophylline clearance rate were observed in five male subjects who were heavily exposed to secondhand tobacco smoke for 3 h/day on 5 consecutive days under controlled conditions (Casto *et al*., 1990).

(*b*) *Tobacco smoke carcinogen biomarkers*

(i) *Urinary compounds*

The use of urinary compounds as biomarkers of carcinogen uptake from environmental tobacco smoke was reviewed by Scherer and Richter (1997).

4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) and its glucuronides (NNAL-Gluc) are metabolites of the tobacco-specific lung carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK). The use of the assay for NNAL and NNAL-Gluc in urine for investigations of exposure to secondhand tobacco smoke offers several advantages. Firstly, it has the sensitivity required to measure relatively low concentrations (typically about 0.05 pmol/mL urine). Secondly, because NNK is a tobacco-specific compound, the detection of NNAL and NNAL-Gluc in urine specifically signals exposure to tobacco smoke. All studies reported to date have found significantly higher concentrations of NNAL plus NNAL-Gluc, or NNAL-Gluc alone, in the urine of nonsmokers exposed to secondhand tobacco smoke than in the urine of unexposed controls, and a good correlation between urinary levels of cotinine and NNAL plus NNAL-Gluc (Table 4.1). In one study, the uptake of NNK was more than six times higher in women who lived with smokers than in women who lived with nonsmokers (Anderson *et al*., 2001). In another investigation, widespread uptake of NNK was demonstrated in a group of economically disadvantaged school-children heavily exposed to tobacco smoke at home (Hecht *et al*., 2001). Correlations have been consistently observed between levels of urinary cotinine and NNAL + NNAL-Gluc in people exposed to secondhand tobacco smoke (Hecht, 2002). Because NNAL is a metabolite of the lung carcinogen NNK, these data imply that there is elevated carcinogen uptake in subjects with raised concentrations of urinary cotinine.

Mixed results have been obtained in studies on the relationship between *tt*-muconic acid, a metabolite of benzene, and exposure to secondhand tobacco smoke. Some studies have shown significantly increased concentrations in people exposed to secondhand tobacco smoke (Yu & Weisel, 1996; Taniguchi *et al.*, 1999; Carrer *et al*., 2000) whereas others found no effect (Scherer *et al*., 1995; Weaver *et al*., 1996; Ruppert *et al*., 1997; Scherer *et al*., 1999), the levels being primarily dependent on whether the subject's home is in the city or the suburbs and on dietary intake of sorbic acid rather than on exposure to secondhand tobacco smoke. The levels of 1-hydroxypyrene and hydroxyphenanthrenes in urine are generally not increased by exposure to secondhand tobacco smoke (Hoepfner *et al*., 1987; Scherer *et al*., 1992; Scherer *et al*., 2000), although significant increases have been reported under some high exposure conditions (Van Rooij *et al*., 1994; Siwinska *et al*., 1999).

The concentrations of aromatic amines (Grimmer *et al*., 2000) and 8-hydroxy-2′-deoxyguanosine (8-OHdG) (Pilger *et al*., 2001) in urine were also unaffected by exposure to secondhand tobacco smoke. The concentration of urinary 5-(hydroxymethyl)uracil was significantly elevated in nonsmokers exposed to high levels of secondhand tobacco smoke, in a dose-dependent manner (Bianchini *et al*., 1998). Exposure to secondhand tobacco smoke did not affect urinary concentrations of 3-ethyladenine (Kopplin *et al*., 1995). Elevated concentrations of thioethers, in particular of 3-hydroxypropylmercapturic acid, were observed under controlled, high exposure conditions (Scherer *et al*., 1990, 1992), but not in a field study (Scherer *et al.*, 1996).

Lackmann *et al.* (1999) first reported the presence of NNAL and NNAL-Gluc in the urine of newborns of women who smoked (Table 4.1). The available data indicate that

Table 4.1. Urinary NNAL and its glucuronides (NNAL-Gluc): biomarkers of NNK uptake in studies of involuntary exposure to tobacco smoke

Study group	Main conclusions[a]	Reference
Exposure of adults to secondhand smoke		
5 men exposed to secondhand smoke	Significantly increased levels of NNAL + NNAL-Gluc after exposure in a chamber: 127 ± 74 pmol/day (approx. 0.16 ± 74 pmol/mL urine)	Hecht *et al*. (1993)
5 men, 4 women exposed to secondhand smoke 5 unexposed controls	Significantly increased levels of NNAL-Gluc in exposed workers compared to unexposed controls: 0.059 ± 0.028 pmol/mL urine	Parsons *et al*. (1998)
29 nonsmokers (13 women)	NNAL + NNAL-Gluc levels correlated with nicotine levels from personal samplers. NNAL, 20.3 ± 21.8 pmol/day; NNAL-Gluc, 22.9 ± 28.6 pmol/day in exposed nonsmokers	Meger *et al*. (2000)
45 nonsmoking women, 23 exposed to secondhand smoke in the home, 22 non-exposed	NNAL + NNAL-Gluc significantly higher in exposed women: 0.050 ± 0.068 pmol/mL urine	Anderson *et al*. (2001)
204 nonsmoking elementary school-aged children	34% with total cotinine ≥ 5 ng/mL; 52/54 of these samples had detectable NNAL or NNAL-Gluc, 93-fold range. NNAL + NNAL-Gluc, 0.056 ± 0.076 pmol/mL urine	Hecht *et al*. (2001)
In-utero exposure to mother's smoking		
31 newborns of mothers who smoked; 17 newborns of mothers who did not smoke	NNAL-Gluc detected in 71%, NNAL in 13% of urine samples of newborns of smokers; neither detected in urine of newborns of nonsmokers ($p < 0.001$); NNAL + NNAL-Gluc in urine of newborns of smoking mothers, 0.13 ± 0.15 pmol/mL urine	Lackmann *et al*. (1999)
21 smokers and 30 nonsmokers	NNAL detected in amniotic fluid of 52.4% of smokers and 6.7% of nonsmokers ($p = 0.0006$). NNAL concentration in amniotic fluid of smokers, 0.025 ± 0.029 pmol/mL	Milunsky *et al*. (2000)
12 smokers and 10 nonsmokers	NNAL and NNAL-Gluc not detected in follicular fluid	Matthews *et al*. (2002)

[a] Values represent mean ± SD.

NNAL, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol; NNK, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone

NNK, a transplacental carcinogen, is taken up by the fetus and metabolized to NNAL and NNAL-Gluc by fetal enzymes (Lackmann *et al*., 1999). Consistent with these results, NNAL was detected in the amniotic fluid of pregnant smokers (Milunksy *et al*., 2000). However, neither NNAL nor NNAL-Gluc could be detected in follicular fluid (Matthews *et al*., 2002).

Urinary excretion of 8-OHdG by newborn babies (n = 12) whose mothers were exposed to secondhand tobacco smoke was significantly higher (p = 0.047) than that of babies whose mothers were not exposed (n = 8). In both groups, the concentration of 8-OHdG excreted was also significantly higher for babies whose mothers had the *GSTM1* null genotype (Hong *et al*., 2001).

(ii) *Protein adducts*

To determine whether involuntary smoking increased the levels of aromatic amine-haemoglobin adducts, a group of 14 volunteers who reported negligible exposure to secondhand tobacco smoke was compared with a group of 15 nonsmokers who reported exposure to at least one pack of cigarettes per day smoked by others, and one of 15 non-smokers with unknown levels of exposure to secondhand tobacco smoke. No measurable quantities of cotinine were detected in the blood of members of any of the three groups (see Section 4.1.1.(d) for measurement of cotinine). A further group of 13 nonsmokers, including six bartenders who were heavily exposed to secondhand tobacco smoke, had measurable levels of cotinine in their blood. Background levels of adducts from 4-amino-biphenyl (ABP) and 3-aminobiphenyl were detected in all subjects, but higher levels were found in subjects with detectable cotinine levels (p = 0.05 and 0.027, respectively) (Maclure *et al.*, 1989). In another study, the levels of 4-ABP-haemoglobin adducts in 15 nonsmokers who reported being exposed to secondhand tobacco smoke were not significantly higher than those in 35 nonsmokers who were not exposed to secondhand tobacco smoke (87.9 ± 19 [SE] pg/g haemoglobin and 69.5 ± 7 pg/g, respectively). Only four out of 15 of those subjects who reported exposure to secondhand tobacco smoke and four out of 35 of those who reported no exposure had measurable levels of urinary cotinine (Bartsch *et al.*, 1990). The level of exposure of 40 nonsmoking women to secondhand tobacco smoke was determined by questionnaire, use of a diary and a personal air monitor and was stratified by average nicotine concentration. There was a significant correlation between the concentration of 4-ABP–haemoglobin and exposure category (p = 0.009) (Hammond *et al.*, 1993).

Exposure of pre-school children to secondhand tobacco smoke from their mothers was investigated by measuring plasma cotinine levels and PAH–albumin adducts in peripheral blood, the latter detected by ELISA. The study involved 87 mother–child pairs; 31 mothers smoked and 56 did not. Not only did the mothers who smoked have higher levels of adducts (see monograph on tobacco smoke), but the levels in their children were also significantly higher ($p < 0.05$). There was also a significant correlation between adduct levels in the mothers and in their children (p = 0.014) (Crawford *et al.*, 1994). In a subsequent study, PAH–albumin and 4-ABP–haemoglobin adducts were also found to be

significantly higher in children whose mothers smoked or who lived with other smokers ($p < 0.05$) (Tang *et al.*, 1999). In a study in children from three different-sized cities, levels of 4-ABP adducts and other aromatic amines correlated with the size of the city. Exposure to secondhand tobacco smoke was associated with a non-significant increase in levels of 4-ABP adducts and a significant decrease in adducts of *ortho*- and *m*-toluidine ($p < 0.05$) (Richter *et al*., 2001).

In a study of 69 adults, 27 were smokers, and 19 of the 42 nonsmokers were classified as passive smokers as determined by self-report and cotinine levels. The levels of benzo-[*a*]pyrene adducts with albumin and haemoglobin were similar for nonsmokers and passive smokers (Scherer *et al.*, 2000).

The levels of *N*-hydroxyethylvaline in haemoglobin were reported to be similar in nonsmokers who did not live or work with a smoker ($n = 74$) and in those who did ($n = 28$). Cotinine levels in passive smokers were not higher than in nonsmokers (Bono *et al.*, 1999).

There was a significantly higher level ($p = 0.02$) of nitrated proteins in blood plasma of nonsmokers who were exposed to secondhand tobacco smoke ($n = 30$) than in non-smokers who were unexposed ($n = 23$) (Pignatelli *et al*., 2001).

Measurements of maternal–fetal exchange of 4-ABP in pregnant women who smoked ($n = 14$) and in nonsmoking ($n = 38$) pregnant women (see monograph on tobacco smoke) showed consistently lower levels of haemoglobin adducts in cord blood than in maternal blood, with an average maternal to fetal ratio of 2. A significant correlation was found between maternal and fetal levels for all subjects ($p < 0.001$) and for smokers only ($p = 0.002$), but not for nonsmokers only ($p = 0.06$) (Coghlin *et al.* 1991). Another study also found that adduct levels were lower in fetal blood than in maternal blood and were correlated with the smoking status of the mothers (subjects included 74 smokers and 74 nonsmokers) (Myers *et al.*, 1996). Another study of 73 nonsmoking pregnant women whose cotinine:creatinine ratios correlated with self-reported exposure to secondhand tobacco smoke, found no association with levels of haemoglobin adducts formed by any of nine aromatic amines (Branner *et al*., 1998).

Blood samples from smoking and nonsmoking mothers and cord blood from their newborns were analysed for *N*-hydroxyethylvaline in haemoglobin. The average adduct concentration in newborns of mothers who smoked ($n = 13$; 147 ± 68 [mean ± SD] pmol/g) was significantly higher ($p < 0.01$) than in those from mothers who were nonsmokers ($n = 10$; 42 ± 18 pmol/g). There was also a significant correlation ($p < 0.01$) between adduct levels in the newborns and in their mothers (Tavares *et al.*, 1994). The same samples showed a strong correlation between the concentration of *N*-(2-cyanoethyl)valine (CEVal) adducts in the mothers who smoked and in their newborns ($p < 0.001$). The adduct levels in the babies were also strongly correlated with the numbers of cigarettes smoked per day by their mothers ($p = 0.009$). The levels of CEVal in babies of mothers who did not smoke were below the limit of detection of the assay (1 pmol/g) (Tavares *et al.*, 1996).

(iii) *DNA adducts*

Although many studies have investigated the levels of DNA adducts or other measures of DNA damage in the tissues of smokers, ex-smokers and nonsmokers (see monograph on tobacco smoke), relatively few studies have investigated the use of these biomarkers to monitor the exposure of nonsmokers to secondhand tobacco smoke, probably because they may not distinguish the effects of exposure to secondhand tobacco smoke from those of exposure to other sources of environmental carcinogens.

In a study in which declining DNA adduct levels in the white blood cells of smokers enrolled in a smoking cessation programme were measured by ELISA, the levels of PAH–DNA adducts both at baseline and 10 weeks after cessation were significantly associated with number of hours of exposure to secondhand tobacco smoke at home ($p = 0.009$ and $p = 0.02$, respectively) and were also higher if the subject lived with another smoker ($p = 0.02$). However, there was no observable influence of exposure to secondhand tobacco smoke at the workplace (Mooney *et al.*, 1995).

Using the prevalence of serum antibodies to benzo[*a*]pyrene diol epoxide (BPDE)–DNA adducts as a biomarker of exposure to environmental PAHs in an Italian population, no association between the percentage of subjects with DNA adducts and passive smoking was found (Petruzzelli *et al.*, 1998). In a study in which significant differences were observed between the levels of BPDE–DNA adducts in the peripheral lymphocytes of smokers ($n = 40$) and nonsmokers ($n = 35$), as determined by a flow cytometric method using BPDE–DNA antibodies, the mean value for nonsmokers with no or low exposure to secondhand tobacco smoke ($n = 17$) was marginally *higher* than that of exposed nonsmokers ($n = 18$), but the difference was not statistically significant (Shinozaki *et al.*, 1999). Using antibodies to BPDE–DNA adducts, immunohistochemical staining of ovarian granulosa-lutein cells from women undergoing in-vitro fertilization showed a strong correlation between smoking status and adduct levels in nonsmokers ($n = 11$), passive smokers ($n = 7$) and active smokers ($n = 14$); all pairwise comparisons were highly significant ($p < 0.0001$) (Zenzes *et al.*, 1998).

Oxidative damage caused by exposure to secondhand tobacco smoke was assessed by measuring the concentration of 8-OHdG in the blood of 74 nonsmokers. The levels were, on average, 63% higher in the subjects exposed to secondhand tobacco smoke in the workplace ($n = 27$) than in the unexposed group ($n = 29$) and this difference was statistically significant ($p < 0.05$) (Howard *et al*., 1998a). However, in another study, the levels of 8-OHdG in leukocytes were significantly *lower* in smokers than in nonsmokers (see monograph on tobacco smoke) and no association was observed with exposure to secondhand tobacco smoke (van Zeeland *et al*., 1999).

Five nonsmokers were exposed to secondhand tobacco smoke under controlled conditions (exposure to gas phase only for 8 h, followed by exposure to whole secondhand tobacco smoke for 8 h, 40 h later). When their monocyte DNA was analysed by ^{32}P-post-labelling, no changes in the adduct patterns were seen after either exposure period, when compared with the samples obtained before exposure (Holz *et al.*, 1990). In a study of biomarkers of exposure to air pollution in three Greek populations, one urban, one rural and

one on a university campus, ^{32}P-postlabelling analysis of lymphocyte DNA revealed the presence of DNA adducts that significantly ($p < 0.001$) paralleled the level of exposure to secondhand tobacco smoke, as determined by self-report, plasma cotinine concentrations and profiles of personal exposure to PAHs that were characteristic of secondhand tobacco smoke, rather than other environmental sources (Georgiadis *et al.*, 2001).

DNA adducts of PAHs were detected by ELISA in 6/14 placentas and in 5/12 matched fetal lung samples from spontaneous abortions. None of the samples were from women who reported smoking during pregnancy, suggesting that the adducts are due to some other source of hydrocarbon exposure (Hatch *et al.*, 1990). In another study using ELISA, BPDE–DNA adducts were detected in 13/15 placental samples from smokers and 3/10 from nonsmokers. There was a strong correlation between concentrations of both adducts and urinary cotinine for both placental DNA and umbilical cord DNA, the former tissue having the higher adduct levels (transfer coefficient = 0.37–0.74) (Arnould *et al.*, 1997). When placental DNA was analysed both for bulky DNA adducts by ^{32}P-postlabelling and for 8-OHdG by electrochemical detection, neither method showed a difference between 11 smokers, ten nonsmokers and nine nonsmokers exposed to passive smoking (Daube *et al.*, 1997). Using ^{32}P-postlabelling with nuclease P1 digestion, DNA adducts were detected in placental and umbilical cord DNA regardless of the smoking status of the mothers and were significantly higher in maternal tissue than in fetal tissue (maternal/fetal ratio = 2.0). When considered separately, tissues showed only marginally increased adduct levels in smokers, but total DNA adduct levels in all tissues combined were significantly higher in smokers ($n = 8$) than in nonsmokers ($n = 11$) (Hansen *et al.*, 1992, 1993).

(*c*) *Other biomarkers*

(i) *Breath compounds*

Carbon monoxide

Carbon monoxide (CO) in expired air has been reported to be an indirect measure of passive smoking both in adults and children. Given its very short half-life, CO concentration must be measured shortly after exposure.

After a 9-h period of exposure to secondhand tobacco smoke at the workplace, 100 nonsmoking waiters exhaled on average 5.0 ppm CO (the pre-exposure CO concentration was 2.0 ppm) compared to a concentration of 2.5 ppm CO exhaled by 100 medical students who spent the day in a nonsmoking environment ($p < 0.001$; Laranjeira *et al.*, 2000). A study in Japan found that mean concentrations of exhaled CO in passive smokers were also significantly higher ($p < 0.001$) than those of nonsmokers who were not exposed to secondhand tobacco smoke (Taniguchi *et al.*, 1999).

The concentrations of exhaled CO were also measured in 235 healthy and 54 asthmatic children (Ece *et al.*, 2000). Regardless of the parents' smoking habits, CO concentrations were higher in asthmatic than in healthy children (1.32 ppm versus 0.86 ppm; $p = 0.028$). Significant relationships were found between the number of cigarettes smoked

in the house and concentrations of exhaled CO in both healthy ($p = 0.003$) and asthmatic children ($p = 0.01$).

Both women exposed to secondhand smoke during pregnancy and their newborns exhaled higher concentrations of CO than non-exposed women (1.95 ppm versus 1.33 ppm and 2.51 versus 1.74 ppm, respectively) (Seidman *et al*., 1999).

Nitric oxide

Fifteen nonsmoking subjects were exposed to secondhand tobacco smoke or asked to smoke for 60 min in a ventilated chamber. Within 15 min of exposure, the concentrations of exhaled nitric oxide (NO) had fallen by 23.6% or 30.3%, respectively, and remained low during the entire time of exposure (Yates *et al*., 2001). Similarly, newborns exposed prenatally to cigarette smoke ($n = 7$) exhaled significantly less NO than non-exposed ($n = 13$) newborns (Hall *et al*., 2002).

Benzene

The concentrations of exhaled benzene in children exposed to secondhand tobacco smoke were not significantly related to the smoking status of the household members, but depended primarily on the location of the home (Scherer *et al*., 1999). Passive smokers not exposed at home, but exposed for more than 50% of their time at work had significantly higher levels of benzene, ethylbenzene, *meta*-xylene + *para*-xylene and *ortho*-xylene in their breath than did non-exposed nonsmokers (Wallace *et al*., 1987) .

(ii) *Blood compounds*

Carboxyhaemoglobin

Measurements of the concentration of carboxyhaemaglobin in subjects exposed to secondhand tobacco smoke and in subjects who were not, are consistent with measurements of CO in the environment (Russell *et al.*, 1973; Hugod *et al.*, 1978; Jarvis *et al.*, 1983). However, carboxyhaemoglobin measurements may be largely confounded by endogenous formation and environmental factors, and are thus not a reliable means for monitoring passive smoking (Scherer & Richter, 1997).

Thiocyanate

It is not possible to distinguish between nonsmokers who are exposed to secondhand smoke and those who are not by measuring serum thiocyanate concentrations (Robertson *et al*., 1987; Scherer & Richter, 1997).

(iii) *Particles*

Experimental deposition of particulate matter with a diameter of < 1 μm from secondhand tobacco smoke within the human respiratory tract was evaluated in 15 nonsmokers and three regular smokers (Morawska *et al*., 1999). On average, smokers had a higher rate of deposition than nonsmokers (65.3 ± 24.1% versus 56.0 ± 15.9% for nose breathing and 66.1 ± 17.6 % versus 48.7 ± 11.6% for mouth breathing). The large variations observed

between individuals indicate that deposition of environmental tobacco smoke is governed by an individual's airway anatomy and breathing patterns.

(*d*) *Nicotine and its metabolites as biomarkers*

Many of the biological markers other than nicotine or cotinine that are used as indicators of exposure and uptake in smokers (e.g. carboxyhaemoglobin and thiocyanate; see monograph on tobacco smoke) are not suitable for accurate measurement of exposure to secondhand tobacco smoke because of potential confounding exposure from diet and environment (US National Research Council, 1986; US Environmental Protection Agency, 1992; California Environmental Protection Agency, 1997; Benowitz, 1999).

In addition to nicotine from use of tobacco products, pharmaceutical products for nicotine replacement therapy or exposure from secondhand tobacco smoke, small quantities of nicotine may enter the body from dietary sources, mainly from consumption of tea and some solanaceous plants such as aubergine, potato peel and tomato (Castro & Monji, 1986; Sheen, 1988; Davis *et al*., 1991; Domino *et al*., 1993; reviewed in Leyden *et al*., 1999). The contribution from dietary sources has, however, been estimated to be minimal and is generally thought not to influence the concentrations of nicotine or cotinine in body fluids significantly enough to affect their use as a biomarker for exposure to secondhand tobacco smoke (Tunstall-Pedoe *et al*., 1991; Henningfield, 1993; Benowitz, 1996), although there has been some disagreement on the subject (Davis *et al.*, 1991). It has been calculated that even very high consumption of these nicotine-containing products would equal, at most, about 10% of the amount of nicotine generally taken up by nonsmokers exposed to secondhand tobacco smoke (Jarvis, 1994; Repace, 1994; Pirkle *et al*., 1996).

Measurements of nicotine and/or cotinine in body fluids of smokers have demonstrated that nicotine and cotinine are biomarkers of high sensitivity (96–97%) and specificity (99–100%) of exposure to tobacco smoke (Jarvis *et al*., 1987; see monograph on tobacco smoke). Owing to its longer half-life, cotinine measured in the blood, saliva or urine of nonsmokers is presently the most widely used biomarker for assessment of exposure to secondhand tobacco smoke (IARC, 1986; US National Research Council, 1986; US Environmental Protection Agency, 1992).

(i) *Adults*

Numerous studies have investigated the dependence of concentrations of cotinine in the serum, saliva and urine on exposure to secondhand tobacco smoke (concentration and duration of exposure) in experimental conditions as well as in nonsmokers exposed to secondhand tobacco smoke, as reviewed in the reports of IARC (1986), US National Research Council (1986), the US DHHS (1986), the US Environmental Protection Agency (1992) and the California Environmental Protection Agency (1997). Studies involving several thousands of subjects have demonstrated that cotinine concentrations measured in the blood, saliva or urine of nonsmokers exposed to secondhand tobacco smoke at home or at work are significantly higher than the concentrations in non-exposed

nonsmokers (Coultas *et al*., 1987; Cummings *et al*., 1990; Riboli *et al*., 1990; Tunstall-Pedoe *et al.*, 1991; Pirkle *et al*., 1996; Wagenknecht *et al*., 1993; Fontham *et al*., 1994; Jarvis *et al*., 2001). In nonsmokers exposed to secondhand tobacco smoke, cotinine levels are typically 0.6–2% of those detected in smokers (Hackshaw *et al.*, 1997; Jarvis *et al*., 1987, 2001; Etzel *et al*., 1990; Benowitz, 1999; Etter, 2000), and they correlate well with self-reported exposure (Jarvis *et al*., 1985; Haley *et al*., 1989; Coultas *et al*., 1987; Cummings *et al*., 1990; Riboli *et al*., 1990; Jarvis *et al*., 1991, 2001, and also discussed in the reviews of the US Environmental Protection Agency (1992) and the California Environmental Protection Agency (1997)).

Cut-points have been introduced in these studies to distinguish occasional smokers from nonsmokers exposed to secondhand smoke. The cut-off values used in the various studies are typically in the range of 10–30 ng/mL for salivary cotinine, 10–15 ng/mL for cotinine in serum, 20–40 ng/mL for cotinine in plasma, and 50–90 ng/mL for cotinine in urine (reviewed in Etzel, 1990; Pérez-Stable *et al.*, 1992; California Environmental Protection Agency, 1997), but higher values may sometimes be applied (Riboli *et al*., 1995).

The relationships between exposure to secondhand tobacco smoke and cotinine concentrations in body fluids have been investigated. Cummings and co-workers (1990) found a clear association between concentrations of urinary cotinine and the number of reported exposures to secondhand tobacco smoke in the 4 days before sampling in 663 nonsmokers. Another study that investigated almost 200 nonsmokers who were exposed to secondhand tobacco smoke at home or at work showed that concentrations of urinary cotinine increased with increasing duration of exposure (Thompson *et al*., 1990). Every additional 10-h period of exposure was found to result in an increase in urinary cotinine of 44% (95% CI, 23–67%; $p < 0.001$).

In a large multicentre, multinationality study conducted among 1300 nonsmoking women, a clear linear increase in mean concentrations of urinary cotinine was observed from the group of women not exposed to secondhand smoke either at work or at home (mean, 2.7 ng/mg creatinine) to those exposed both at work and at home (mean, 10.0 ng/mg creatinine) (Riboli *et al*., 1990). Cotinine concentrations have been demonstrated to be dependent both on the duration of exposure and the number of cigarettes smoked by others. When the number of cigarettes was corrected for duration of exposure and room volume, it was estimated that a similar increase in concentration of cotinine (5 ng/mg) is predicted with 7.2 cigarettes smoked at home versus 17.9 cigarettes smoked at the workplace. Based on the measured cotinine concentrations, the number of cigarettes smoked by the spouse was found to be the best estimate for domestic exposure, and duration of exposure provided the best estimate for occupational exposure (Riboli *et al*., 1990).

Cotinine concentrations associated with occupational exposure to secondhand tobacco smoke vary somewhat more than those related to domestic exposure. This is because occupational exposure is subject to larger variations in several variables including the number of smokers present, ventilation conditions and variation in physical workload of the nonsmokers. Studies of flight attendants and workers in restaurants, bars, casinos

and other similar public settings have found that these occupations lead to greater exposure to secondhand tobacco smoke than that of the average population, with cotinine concentrations generally reflecting those of tobacco smoke concentrations measured in the workplace (Mattson *et al*., 1989; Jarvis *et al*., 1992; Siegel, 1993; Dimich-Ward *et al*., 1997; Trout *et al*., 1998; Maskarinec *et al*., 2000). One study showed that in addition to exposure in the workplace, exposure of bartenders to secondhand smoke at home further elevated their cotinine concentrations (Maskarinec *et al*., 2000). Jarvis *et al*. (1992) reported a median salivary cotinine concentration of 7.95 ng/mL and a maximum concentration of 31.3 ng/mL among 42 nonsmoking staff working in a bar. Thus, under certain circumstances of exposure, peak values detected in people exposed to secondhand tobacco smoke may exceed the cut-points used to distinguish smokers from nonsmokers in many studies (Pérez-Stable *et al.*, 1992; California Environmental Protection Agency, 1997).

(ii) *Children*

The reports of the US Environmental Protection Agency (1992) and the California Environmental Protection Agency (1997) summarize studies that have reported increased concentrations of cotinine in children exposed to secondhand tobacco smoke at home. Many more recent studies have also found a significant correlation between cotinine concentrations in children and the amount of smoking by the parent(s) (Jarvis *et al.*, 1985; reviewed in Hovell *et al*., 2000a). A cross-sectional survey of secondary-school children conducted in 1998 found that salivary cotinine concentrations were correlated with parental smoking, but that the concentrations had halved since the late 1980s (Jarvis *et al*., 2000). Counselling, during 3 months, of non-employed mothers who smoked and who had children under school age significantly reduced the children's urine cotinine concentration at 12 months (Hovell *et al.*, 2000b).

(iii) *Newborns*

Higher concentrations of cotinine were found in amniotic fluid than in maternal urine in both smokers and nonsmokers (Jordanov, 1990). Studies of isolated perfused human placental cotyledon indicated that less than 1% of nicotine is metabolized to cotinine by the placenta. Rather, after rapid transfer across the placenta, nicotine is metabolized to cotinine by fetal tissues (Pastrakuljic *et al*., 1998; Sastry *et al*., 1998). The elimination kinetics of nicotine, cotinine, trans-3′-hydroxycotinine and their conjugates in the urine of newborns were first reported by Dempsey *et al*. (2000). The results indicated that the half-life of nicotine in newborns was 3–4 times longer than that in adults, whereas the half-life of cotinine was essentially the same in newborns as in adults. The data indicate that newborns are capable of metabolizing nicotine to cotinine and of conjugating nicotine, cotinine and 3′-OH cotinine. However, it is not known what percentage of cotinine is formed by the fetus and what percentage is acquired transplacentally, and which P450 isozymes are involved in fetal metabolism of nicotine (Dempsey *et al*., 2000).

Etzel *et al*. (1985) used a radio-immunoassay to detect cotinine in the 1-day urine of infants born to self-identified smokers and nonsmokers. The median concentration of urinary cotinine for newborns of smokers was 1233 ng/mg creatinine as opposed to 14.5 ng/mg for newborns whose mothers were nonsmokers.

A study of 31 mothers and their newborns was conducted in Bulgaria (Jordanov, 1990). Analysis of 1-day urine by a direct colorimetric method found a mean urinary cotinine concentration of 13 ± 3 μmol/L for the newborns of nonsmokers not exposed to tobacco smoke, 18 ± 4 μmol/L for the newborns of passive smokers and 44 ± 18 μmol/L for the newborns of active smokers who smoked an average of 15 cigarettes per day; all differences were statistically significant. First-day urine of newborns was analysed in a large study of 429 mothers in Barcelona, Spain (Pichini *et al*., 2000). Concentrations of urinary cotinine higher than the cut-off value of 50 ng/mL were measured in 17% of samples from newborns of nonsmoking mothers exposed to secondhand smoke, versus 2% for nonsmoking mothers who were not exposed to secondhand smoke. The concentrations of cotinine in the urine and cord serum of newborns of nonsmoking women with a calculated daily exposure to nicotine of more than 4 mg were significantly higher than the levels in newborns of nonsmoking mothers who were not exposed (30.9 versus 6.2 ng/mL; $p < 0.05$), after adjustment for creatinine, maternal age and sex. Daily intake of nicotine for active smokers was stratified into ≤ 3.6 mg nicotine per day, 3.6–9 mg per day, and > 9 mg per day. Urinary and cord serum cotinine concentrations were 515 ng/mL for newborns of mothers with intermediate daily nicotine intake and 568 ng/mL for the newborns of mothers with high daily nicotine intake and were statistically different ($p < 0.05$) from the concentrations in newborns of mothers with a low daily nicotine intake (161 ng/mL).

Nicotine has recently been demonstrated to occur in newborn urine. Lackmann *et al*. (1999) used gas chromatography–mass spectrometry with selective ion monitoring to detect nicotine in first voided urine samples in newborns of mothers who smoked an average of 12.4 cigarettes per day. The average concentration of nicotine in 18/31 (58%) samples was 0.63 nmol/mL. Nicotine was not detected in the urine of 17 newborns of women who did not smoke ($p < 0.001$). In the same study, cotinine was detected in 28/31 (90%) of the urine samples from newborns of mothers who were smokers, at a mean concentration of 0.87 nmol/mL. The newborns of women who were nonsmokers had a mean urine cotinine concentration of 0.049 nmol/mL. The difference was statistically significant ($p < 0.001$). Similarly, using high-performance liquid chromatography, Köhler *et al*. (2001) were able to detect nicotine and cotinine in the urine of newborns of active smokers (mean ± SD, 374 ± 765 nmol/L for nicotine and 500 ± 572 nmol/L for cotinine), but not in the urine of the newborns of nonsmokers, whether or not they were exposed to secondhand tobacco smoke ($p < 0.05$ and $p < 0.001$ for nicotine and cotinine, respectively). They also observed a strong correlation between the nicotine and cotinine concentrations in the mothers and in their newborns.

(iv) *Alternative nicotine-related measures of exposure*

The analysis of nicotine in hair has been suggested as an alternative and non-invasive measure of exposure to tobacco smoke, particularly in children. This method may allow past exposure to be measured over a longer time period than is possible using measurements of nicotine in blood, saliva or urine. Several studies have shown a strong correlation between nicotine levels in hair and self-reported exposure to tobacco smoke or exposure in experimental chambers (Zahlsen *et al*., 1996; Nafstad *et al*., 1997; Dimich-Ward *et al*., 1997; Al-Delaimy *et al*., 2000). In fact, this has been proposed to be a more precise indicator of exposure to secondhand tobacco smoke than concentrations of urinary cotinine (Al-Delaimy *et al*., 2002).

The concentrations in the urine of minor nicotine-related tobacco alkaloids not present in nicotine medications, such as anabasine or anatabine, have been proposed as indicators of exposure to tobacco smoke in individuals undergoing nicotine replacement therapy (Jacob *et al*., 1999).

In summary, cotinine and its parent compound nicotine have a very high specificity and sensitivity for exposure to secondhand tobacco smoke, and, as such, cotinine is presently the best suited biomarker for assessing exposure to secondhand smoke and its uptake and metabolism in adults, children and newborns.

4.1.2 *Experimental systems*

The studies in which experimental animals were exposed to sidestream smoke alone or to simulated environmental tobacco smoke are reviewed below (see Section 3.1 for definitions).

In most studies the amount of smoke administered to the animals was monitored by measuring its total particulate matter (TPM), carbon monoxide (CO) and/or nicotine content. Internal dose measurements include those of carboxyhaemoglobin (COHb) adducts and/or cotinine in blood or urine.

(*a*) *Effects of tobacco smoke on enzyme activities*

Studies in animals on the effects of sidestream smoke on enzyme concentrations have evaluated changes in phase I and phase II enzymes in liver, lung and trachea (Table 4.2). A few studies have looked at changes in enzyme activities in brain and heart.

(i) *Phase I enzymes*

The ability of sidestream smoke to induce hepatic P450 activity was investigated in male Wistar rats (Kawamoto *et al*., 1993). Animals were exposed for 8 h/day to the smoke from 1, 3 or 5 cigarettes/h for 5 days (6–500 ppm CO). Total cytochrome P450 and nicotinamide-adenine dinucleotide phosphate (reduced form; NADPH) cytochrome c reductase activities were not affected, but cytochrome b_5 was increased 1.6-fold and aryl hydrocarbon hydroxylase (AHH) activity was significantly decreased in the highest exposure

group. Although total cytochrome P450s did not change, P450 1A1, P450 1A2, and P450 2B1 were elevated by the high exposure regimen.

The effect of sidestream smoke on bronchiolar epithelial cell expression of P450 1A1 was studied in postnatal male Sprague-Dawley rats that were exposed to aged and diluted sidestream smoke (1 mg/m^3 TPM; 6 ppm CO; 350 μg/m^3 nicotine) for 6 h/day, 5 days/week from birth until 7, 14, 21, 50 or 100 days of age. Exposure to sidestream smoke significantly increased the expression of P450 1A1 in Clara cells of the proximal and distal airways and in alveolar Type II cells in the lung parenchyma at all times, with a maximal expression occurring at 50 days of age. NADPH reductase was increased in bronchiolar epithelial cells at 21 and 50 days, but not at 7 or 100 days. Cytochrome P450 2B expression was not affected by sidestream smoke in any airway epithelial cells during this study (Ji *et al.*, 1994).

Sindhu *et al*. (1995) studied hepatic cytochrome P450s after the exposure of ferrets to simulated environmental tobacco smoke. Six-week old male and female European ferrets were exposed to simulated environmental tobacco smoke (38 mg/m^3 TPM (low-dose) and 381 mg/m^3 TPM (high-dose)) for 2 h/day, 5 days/week for 8 weeks. In both male and female animals, there was a significant decrease in P450 content, and in P450 reductase and 7-ethoxycoumarin *O*-deethylase activities after exposure to both high and low concentrations. Immunoblot analysis revealed a decrease in P450 1A in exposed animals compared with controls. In addition, cytochrome b_5 content and the activity of its reductase were decreased in females.

The expression of P450 1A1 and 2B1 was evaluated in newborn male rats which were exposed to aged and diluted sidestream smoke for 6 h/day, 5 days/week (1 mg/m^3 TPM). Sidestream smoke induced pulmonary P450 1A1 activity as early as day 7 after birth, whereas it was not detected in controls. Pulmonary P450 1A1 activity remained significantly (3- to 4-fold) elevated until 100 days, whereas pulmonary P450 2B1 activity did not change at any age. Hepatic P450 1A1 and P450 2B1 were generally unchanged following exposure to sidestream smoke, except that P450 2B1 activity was decreased by 30% at 100 days. The effects of short-term exposure were studied in 47-day-old rats exposed for 6 h/day for 4 days, to either filtered or unfiltered sidestream smoke (0.03 and 1 mg/m^3 TPM, respectively). Whole, but not filtered, sidestream smoke increased pulmonary P450 1A1 more than threefold; P450 2B1 was unchanged by either type of exposure (Gebremichael *et al.*, 1995).

The role of the Ah receptor in response to exposure to sidestream smoke was evaluated (Gebremichael *et al*., 1996). Male C57BL/6N and DBA/2N mice were exposed for 6 h/day for 4 days to aged and diluted sidestream smoke (1 mg/m^3 TPM; 3.4 ppm CO; 703 μg/m^3 nicotine). Sidestream smoke induced ethoxyresorufin-*O*-dealkylase activity in the lungs of C57BL/6N mice, but had no effect in mice of the DBA/2N strain, which has a reduced AhR functionality.

The induction of pulmonary tumours and P450 1A1 after exposure to simulated environmental tobacco smoke was examined in male A/J mice (Witschi *et al*., 1997a). Mice, 12 weeks of age, were exposed to simulated environmental tobacco smoke (87.3 mg/m^3

TPM) for 6 h/day, 5 days/week for 5 months. The expression of P450 1A1 was significantly increased in airway epithelium and lung parenchyma of the smoke-exposed mice after 5 months of exposure; however, after a 4-month recovery period, no expression of P450 1A1 could be detected. P450 2B1 and 2E1 were not affected by exposure to tobacco smoke. No enhanced expression of P450 1A1 was detected in lung tumours. Filtered smoke containing 0.1 mg/m^3 TPM did not induce P450 1A1 expression in female A/J mice under the same conditions (Witschi *et al.*, 1997b).

The effect of sidestream smoke on the expression of pulmonary cytochrome P450 mRNAs in rats has been examined following in-utero and postnatal exposure (Lee *et al*., 2000). Gestating Sprague-Dawley rats were exposed to aged and diluted sidestream smoke (1 mg/m^3 TPM; 7.3 ppm CO; 250 µg/m^3 nicotine) beginning on gestational day 5. None of the P450 isozymes analysed were increased in fetal lungs when evaluated at 17, 19 or 21 days of gestation. In contrast, postnatal exposure to sidestream smoke induced P450 1A1 expression as early as 1 day after birth. No induction of P450 1B1, 2B1 or NADPH cytochrome P450 reductase was observed following continuous in-utero and postnatal exposure to sidestream smoke.

Total liver content of P450 remained unchanged in male Wistar rats following exposure to sidestream smoke for 2 h/day for 25 days [no information on TPM or other measurements of smoke concentration was given] (Kurata *et al.*, 1998).

Spontaneously hypertensive (SH) rats exhibit heritable risk factors similar to those found in patients with chronic obstructive pulmonary disease, and are more susceptible to lung injury and inflammation, to oxidative stress resulting from exposure to combustion by-products and to induction of pulmonary diseases in general. Nadadur *et al*. (2002) used this model to examine the differential gene expression following exposure to sidestream smoke. Male SH rats were exposed to sidestream smoke (90 mg/m^3 TPM) for 6 h/day on 2 consecutive days. Total RNAs were isolated from lungs on the third day and cDNA was examined by gene-expression array filters containing 588 genes. Exposure to sidestream smoke resulted in a differential expression of 16 genes, including P450 1A1.

The effect of sidestream smoke on AHH activity was investigated in different species and strains. Male C57BL mice, Sprague-Dawley rats and Hartley guinea-pigs [ages not stated] were exposed to sidestream smoke once or twice daily, on 7 days/week for 16 weeks. AHH levels were significantly increased in mice and rats (3.7-fold and 2.7-fold, respectively), but remained unchanged in guinea-pigs (Gairola, 1987). In a later study by Gairola *et al.* (1993), female C57BL and DBA mice, 8–9 weeks old, were exposed to sidestream smoke daily [duration of exposure not stated] for 65–70 weeks (average TPM intake, 5.21 and 7.05 mg/kg body weight, respectively). Exposure to sidestream smoke induced pulmonary AHH activity two- to threefold in C57BL mice, but no effect was found in DBA mice. In a later study, male Sprague-Dawley rats were exposed to simulated environmental tobacco smoke (a mixture of 89% sidestream smoke and 11% mainstream smoke) for 6 h/day, 5 days/week for up to 5 weeks (73–93 mg/m^3 TPM; 350 ppm CO). Exposure to simulated environmental tobacco smoke resulted in a significant induction of AHH activity in lung microsomal fractions, which increased over the first 4

weeks of exposure; however, within 1 week after termination of the exposure, AHH activity decreased to the same levels as those measured in sham-treated rats (Izzotti *et al*., 1999).

(ii) *Phase II enzymes*

Male Sprague-Dawley rats were exposed to simulated environmental tobacco smoke for 6 h/day, 5 days/week for up to 5 weeks (73–93 mg/m^3 TPM; 350 ppm CO) (Izzotti *et al.*, 1999). This exposure resulted in the concentrations of GSH in lung post-mitochondrial (S12) fractions undergoing a progressive and consistent decrease, which became significant after 4 weeks. After 5 weeks, GSH levels in exposed animals were 67% of the levels in controls. The activity of glutathione-*S*-transferase (GST) in lung cytosolic fractions from exposed animals increased steadily and became significantly elevated after 5 weeks.

(iii) *Other enzymatic alterations*

The effect of chronic exposure to sidestream smoke on ornithine decarboxylase and *S*-adenosyl-methionine decarboxylase activity was determined in the rat trachea and lung. Male Sprague-Dawley rats were exposed for 10 min daily, 7 days/week, for 4 or 8 weeks to 25% sidestream smoke, or for 20 weeks to either 50%, 25% or 10% sidestream smoke (Olson, 1985). Ornithine decarboxylase activity in the lung was elevated in the group exposed for 8 weeks, but not in the group exposed for 20 weeks at any dose. Ornithine decarboxylase in the trachea was significantly elevated by all concentrations of sidestream smoke at all times. None of the treated rats showed any significant increase in *S*-adenosyl-methionine decarboxylase activity at any concentration or duration of exposure.

In 8-week-old male Wistar rats exposed to sidestream smoke [concentration not reported] for 1-h periods, twice daily, for 8, 12 or 20 weeks, protein kinase C activity in lung was increased by 120% at 8 weeks, and by 86% and 81% at 12 and 20 weeks, respectively (Maehira *et al*., 1999).

The synergistic effects of sidestream smoke and mineral fibres were investigated by Morimoto *et al*. (1999). Ten-week-old male Wistar rats were first given an intratracheal instillation of chrysotile or ceramic fibres and subsequently exposed to sidestream smoke for 4 h/day, 5 days/week for 4 weeks (10 mg/m^3 TPM; 79 ppm CO). Control groups included animals exposed to saline only, chrysotile only, ceramic fibres only and sidestream smoke only. Both exposure to mineral fibres and/or to sidestream smoke increased the number of cells recovered from bronchoalveolar lavage; alveolar macrophages accounted for > 95% of the total cells. Levels of IL-1α mRNA were significantly increased ($p < 0.05$) in all exposed groups (i.e. those exposed to sidestream smoke, mineral fibres, and sidestream smoke plus mineral fibres) in alveolar macrophages, but not in lung (when compared to saline-treated controls). Increased expression of IL-6 mRNA was only seen in the lung when sidestream smoke was combined with chrysotile, but neither exposure alone was sufficient to induce expression of IL-6 mRNA. No such

increase was observed in alveolar macrophages. Similarly, inducible nitric oxide synthase (iNOS) was not increased in the alveolar macrophages of rats treated with mineral fibres or sidestream smoke alone, but was significantly increased in animals that received combination treatments ($p < 0.01$). iNOS was not induced in the lungs by any treatment.

To mimic fetal and childhood exposure to secondhand smoke, gestating Sprague-Dawley rats were exposed to mainstream smoke (29 mg/m^3 TPM; 93 ppm CO; 4.6 mg/m^3 nicotine) for 6 h/day, 7 days/week, from gestational day 5 to day 20. One or two days after parturition, dams and pups were exposed to sidestream smoke (1 mg/m^3 TPM; 5.6 ppm CO; 117 μg/m^3 nicotine) until postnatal day 21. Animals were exposed either prenatally or postnatally or both. Adenylyl cyclase (AC) activity was evaluated under four different conditions in brain and heart tissues: basal AC, after isoproterenol or forskolin stimulation, and after forskolin stimulation followed by carbachol inhibition. In the brain, both prenatal and postnatal exposure were effective in upregulating AC when measured by forskolin response, but not when measured by the other methods. In the heart, AC activity as measured by all methods was significantly elevated after prenatal exposure, postnatal exposure, or both. The authors concluded that postnatal exposure to sidestream smoke elicited changes similar to, or more severe than, those observed during prenatal exposure from maternal smoking (see also Section 4.3.2(iii)) (Slotkin *et al.*, 2001).

Male SH rats were exposed to sidestream smoke (90 mg/m^3 TPM) for 6 h/day for 2 days (Nadadur *et al.*, 2002; see Section 4.1.2(*a*)(i) for details). A two- to threefold increase was observed in expression of macrophage inflammatory protein-2, suggesting the potential for lung inflammation. Over-expression of matrix metalloproteinase-7 was also observed; this may play a role in cell migration and invasion.

(*b*) *Tobacco smoke carcinogen biomarkers*

Animal studies on the formation of carcinogen biomarkers following exposure to sidestream smoke have evaluated protein and DNA adducts, including those in lung and liver. These studies are summarized in Table 4.3; only the main studies are described in detail in the text.

(i) *Urinary compounds*

Urine samples from male and female Fischer 344 rats exposed to sidestream smoke for 15 min four times/day for 5 days elicited DNA adducts in a plasmid assay *in vitro* (Takenawa *et al.*, 1994).

(ii) *DNA adducts*

Lee *et al*. (1992, 1993) evaluated the formation of DNA adducts in various tissues following 14-day and 90-day periods of exposure to sidestream smoke. In these studies, 7-week-old male Sprague-Dawley rats were exposed to aged and diluted sidestream smoke for 6 h/day for 14 or 90 days at target exposure concentrations of 0, 0.1, 1.0 and 10 mg/m^3 TPM. DNA adducts were observed only in the lung and heart of animals that received the highest dose. Adducts in lung were observed after 7 and 14 days and were

still present after 14 days of recovery. Adducts in heart tissue were first seen after 14 days and persisted through the 14-day recovery period. Neither liver nor larynx exhibited exposure-related adducts at any time period or any dose. In the 90-day study, animals were killed at 28 and 90 days, and after a 90-day recovery period. After 28 and 90 days, a significant elevation in adducts in lung, heart and larynx was seen only in the animals exposed to 10 mg/m^3 TPM, and liver and bladder were unaffected by exposure at any time or any dose. After a 90-day recovery period, adduct levels in all organs in which there had been a response to exposure decreased, but were still elevated compared to the levels in controls [no statistical test performed]. These data establish a no-observed-effect-level of at least 1.0 mg/m^3 TPM for DNA adducts.

Sidestream smoke condensate was applied topically on mouse skin and DNA adducts formed from the condensate in several organs were quantified by ^{32}P-postlabelling techniques. When compared with unexposed controls, sidestream smoke condensate was found to induce approximately five- to sevenfold higher levels of adducts in skin, lung and bladder and two- to threefold higher levels in heart and kidney (Carmichael *et al*., 1993).

Long-term studies of exposure of female C57BL and DBA mice to sidestream smoke were conducted by Gairola *et al*. (1993). DNA adducts were assayed in lung and liver after 65–70 consecutive weeks of exposure (average TPM intake, 5.21 and 7.05 mg/kg body weight, respectively). Sidestream smoke enhanced DNA adducts in lung in both strains of mice; the increase was about 16-fold in C57BL mice and 8-fold in DBA mice (the difference between the two strains was not statistically significant. Adduct maps showed no qualitative difference between strains, or between treated and control mice. No increase in adduct levels was observed in the liver.

Male and female Fischer 344 rats were exposed to sidestream smoke for 15 min four times/day for 5 days (Takenawa *et al*., 1994). [No monitoring of exposure was reported.] A significant increase in DNA adducts in bladder and kidney was seen in exposed animals when compared to control samples, but not in testicular tissues; this suggests that the DNA adducts were formed in the tissues along the urinary tract.

Adult female BALB/c mice were exposed to a regimen of 30-min exposures to sidestream smoke followed by a 90-min recovery, for three consecutive cycles. The level of 8-OHdG adducts was increased by exposure to sidestream smoke in heart, lung and liver (about 1.6-fold) and remained elevated in lung and heart after the recovery period [limited statistical analysis was performed] (Howard *et al*., 1998b).

In a study to evaluate the inhibitory effect of indole-3-carbinol on cigarette smoke-related formation of DNA adducts in target organs, Arif *et al*. (2000) found that whole-body exposure of female Sprague-Dawley rats to sidestream smoke (6 h/day, 7 days/week for 4 weeks; 27 mg/m^3 TPM) induced smoke-related adducts in all tissues examined, including (in descending order) lung, heart, trachea and bladder. The adducts were qualitatively similar in all organs, but were present in different proportions.

Male Sprague-Dawley rats were exposed to simulated environmental tobacco smoke for 6 h/day, 5 days/week for up to 5 weeks (73–93 mg/m^3 TPM; 350 ppm CO) (Izzotti *et al.*, 1999, 2001). The exposure continued for 1, 2, 3, 4 or 5 weeks and rats were killed

16 h after the last exposure. Samples of heart, lung, liver, testes, bladder, bronchial alveolar macrophages and tracheal epithelium were analysed for adducts. Examination of the autoradiograph patterns revealed the existence of four major and two minor spots in tracheal epithelium, three major spots in macrophages, and one major and one minor spot in lung, heart and bladder. All organs showed a time-related increase in adducts during the first 4 weeks, and the trachea and macrophages continued to accumulate adducts through the fifth week. When animals were allowed 1 week of recovery after 4 weeks of exposure, levels of adducts decreased significantly in all tissues except heart, but remained significantly higher than in control animals. There was a slight but significant increase in 8-OHdG adducts in lung of animals exposed to smoke for 4 weeks when compared with sham-treated rats (Izzotti *et al.*, 2001).

In a preliminary experiment reported by De Flora *et al*. (2003), SKH-1 hairless mice were exposed to simulated environmental tobacco smoke for 28 days [exposure concentrations not given]. Whole-body exposure resulted in bulky DNA and 8-OHdG-adducts in the skin and lungs of treated animals. A potential synergistic effect was noted between exposure to simulated environmental tobacco smoke and exposure to sunlight-simulating lamps with respect to the induction of bulky DNA adducts in the lung.

(*c*) *Other biomarkers and metabolites*

The results of animal studies that have reported changes in metabolites and carboxyhaemoglobin levels in various tissues are summarized below and in Table 4.3.

(i) *Blood compounds*

Serum concentrations of carboxyhaemoglobin, together with nicotine and/or cotinine, are commonly used as biomarkers of exposure in experimental models as they are strongly correlated with the estimated total particulate matter (von Meyerink *et al.*, 1989; Coggins *et al.*, 1992, 1993; Zhu *et al.*, 1994; Sun *et al.*, 2001).

(ii) *Particles*

A comparison of the deposition of environmental tobacco smoke particles in human and rat tracheobronchial tree and pulmonary region was performed by Oberdörster and Pott (1986). Their calculations showed that the relative deposition of particles (mass median aerodynamic diameter of 0.2 μm) was about the same in the tracheobronchial tree of rats and humans, and was less in the pulmonary region in rats than in humans. However, the rate of deposition in the transitional region of the lung was about twice as high in rats as in humans. These data should be taken into consideration when using the results of experiments in rats to predict the results of human exposure.

(iii) *Urinary compounds including cotinine*

L-Ascorbic acid is a potential scavenger of free radicals under normal conditions and following most carcinogenic insults, including the free radicals contained in and generated by cigarette smoke. To evaluate the effect of sidestream smoke on the metabolism and excretion of L-ascorbic acid, Kurata *et al*. (1998) exposed 7-week-old male Wistar

rats to the sidestream smoke generated by two cigarettes every 30 min, four times/day, for 25 days [concentrations of TPM, CO and nicotine not stated]. The excretion of L-ascorbic acid into urine increased steadily with duration of exposure to sidestream smoke, and became significantly higher than in controls after day 12. At 25 days, L-ascorbic acid in liver, adrenal glands, lungs and kidneys in exposed animals was higher than in controls.

The exposure of rats to sidestream smoke produces a smoke-related oxidative stress, resulting in lipid peroxidation, that can be monitored by the urinary excretion of F_2 isoprostanes (e.g. 8-*iso*-prostaglandin $F_{2\alpha}$), produced from arachidonic acid by free radical-catalysed mechanisms. Visioli *et al*. (2000) evaluated the antioxidant effect of olive oil on the excretion of 8-*iso*-prostaglandin $F_{2\alpha}$. Male Sprague-Dawley rats were exposed to sidestream smoke for 20 min/day for 4 days (2600 ppm CO). The excretion of 8-*iso*-prostaglandin $F_{2\alpha}$ increased from 237 to 319 pg/mg creatinine after 2 days of exposure, an increase of 44%. After four exposures, the excretion of 8-*iso*-prostaglandin $F_{2\alpha}$ was 55% higher than in control rats. Treatment with olive oil reduced the excretion to pre-exposure levels and to a 34% increase over pre-exposure levels, after 2 and 4 days of exposure, respectively.

Oddoze *et al*. (1998) developed a rapid and sensitive assay for measuring urinary metabolites in human nonsmokers and rats. In rats exposed to sidestream smoke for 4 days [strain and sex of rats and conditions of exposure not stated], 24-h urine samples were collected before the exposure began and after the last exposure. No cotinine was found in sham-exposed samples, but the amount of cotinine in the urine of exposed rats (n = 5) ranged from 525 to 675 ng/mL and one sample had a cotinine concentration of 1587 ng/mL.

4.2 Toxic effects

Exposure to secondhand tobacco smoke is a cause of cardiovascular and respiratory disease. The studies reviewed here add to the knowledge of the adverse effects of exposure to secondhand tobacco smoke on the health of adult humans.

4.2.1 *Humans*

(*a*) *Nicotine addiction*

No data on nicotine addiction resulting from involuntary exposure to tobacco smoke were available to the Working Group.

(*b*) *Cardiovascular system*

A causal association between active smoking and coronary heart disease (CHD) is well established (US Department of Health and Human Services, 1983, 1990). Since 1984, some 20 studies have examined the association between exposure to secondhand tobacco smoke and risk of CHD in nonsmokers. The available literature was first reviewed in 1986 in a report from the US National Research Council (US National

Research Council, 1986) and a report of the Surgeon General (US DHHS, 1986). Both reviews concluded that an association between exposure to secondhand tobacco smoke and CHD was biologically plausible, but that the epidemiological evidence was inconclusive. Since then, numerous reviews and reports have become available (Wells, 1988; Wu-Williams & Samet, 1990; Glantz & Parmley, 1991; Steenland, 1992; Wells, 1994; Glantz & Parmley, 1995; Kritz *et al*., 1995; Law *et al*., 1997; Wells, 1998; He *et al*., 1999; Thun *et al*., 1999; US National Cancer Institute, 1999). Nine of these reviews included a meta-analysis to calculate a pooled relative risk for CHD in relation to exposure to secondhand tobacco smoke (Wells, 1988; Glantz & Parmley, 1991; Wells, 1994 ; Glantz & Parmley, 1995; Kritz *et al*., 1995; Law *et al*., 1997; Wells, 1998; He *et al*., 1999; Thun *et al*., 1999).

(i) *Epidemiological studies*

The results of three recent meta-analyses (Law *et al*., 1997; He *et al*., 1999; Thun *et al*., 1999) are summarized in Tables 4.4 and 4.5.

Law *et al.* (1997) carried out five sets of meta-analyses using published data (Table 4.4). In the first analysis, which included 19 studies of exposure to secondhand tobacco smoke and ischaemic heart disease (IHD), it was estimated that never-smokers living with a smoker have a 30% increased risk of IHD. In the second analysis, which included five large cohorts of men, it was estimated that the risk for CHD in nonsmokers living with a smoker was similar to the excess risk from smoking one cigarette per day. The third analysis, which included three cohorts, estimated that almost all the excess risk reversed after cessation of smoking; the residual excess risk was 6%. The fourth analysis was conducted on 18 studies to estimate the potential effect of confounding attributable to differences in diet between passive smokers and nonsmokers. People exposed to secondhand smoke were more likely than nonsmokers not exposed to tobacco smoke to consume diets with few vegetables and fruits and were less likely to take antioxidant vitamin supplements. However, clinical trials have indicated that taking β-carotene and vitamin E supplements does not reduce the risk for CHD in persons with no history of myocardial infarction (Alpha-Tocopherol β Carotene Cancer Prevention Study Group, 1994; Hennekens *et al.*, 1996). It was estimated that nonsmokers living with smokers eat a diet that gives them a 6% increased risk for IHD. The relative risk of exposure to secondhand smoke for ischaemic heart disease adjusted for diet was 1.2 (95% CI, 1.1–1.3). In the fifth analysis, which was based on eight studies, the increase in risk for IHD attributable to secondhand tobacco smoke-related platelet aggregation was estimated. It was concluded that the increase in experimentally produced platelet aggregation caused by exposure to secondhand tobacco smoke would be expected to have acute effects increasing the risk for IHD by 34%.

In the meta-analysis conducted by He *et al.* (1999), passive smoking was consistently associated with an increased relative risk for CHD. This association was observed in cohort studies, in case–control studies, in men, in women and in those exposed to

Table 4.4. Relative risk for coronary (or ischaemic) heart disease (and/or death from coronary heart disease) in never-smokers exposed to secondhand tobacco smoke in meta-analyses

Focus of meta-analysis	Relative risk (95% CI)	Exposure to tobacco smoke	Number of studies included and references
Secondhand tobacco smoke and IHD	1.30 (1.22–1.38; $p < 0.001$)	Never-smokers living with a smoker	Meta-analysis of 19 studies (Garland *et al.*, 1985; Lee *et al.*, 1986; Svendsen *et al.*, 1987; He, 1989; Hole *et al.*, 1989; Sandler *et al.*, 1989; Hirayama, 1990; Humble *et al.*, 1990; Dobson *et al.*, 1991; Lee, 1992; La Vecchia *et al.*, 1993; He *et al.*, 1994; Layard, 1995; LeVois & Layard, 1995; Muscat & Wynder, 1995; Tunstall-Pedoe *et al.*, 1995; Steenland *et al.*, 1996; Kawachi *et al.*, 1997; Ciruzzi *et al.*, 1998)
Smoking at low doses and IHD	1.39 (1.18–1.64) 1.78 (1.31–2.44)	Active smoking of 1 cig/day Active smoking of 20 cig/day	Five large cohorts of men (660 IHD events) (Hammond & Horn, 1958; Doll & Hill, 1964; 1966; Hammond, 1966; Kahn, 1966; Hammond & Garfinkel, 1969; Pooling Project Research Group, 1978)
Smoking cessation and reversibility of excess risk of IHD	1.06 (1.02–1.10)	Former smokers (smoking cessation)	Meta-analysis of 3 studies (Hammond & Garfinkel, 1969; Rogot & Murray, 1980; Doll & Peto, 1976)
Dietary differences between nonsmokers living with a smoker and nonsmokers living with a nonsmoker and IHD	1.06	Diet of nonsmokers living with a smoker	Meta-analysis of 18 studies (Keith & Driskell, 1980; Fehily *et al.*, 1984; Stryker *et al.*, 1988; Sidney *et al.*, 1989; Larkin *et al.*, 1990; Subar *et al.*, 1990; Cade & Margetts, 1991; Le Marchand *et al.*, 1991; Nuttens *et al.*, 1992; Bolton-Smith *et al.*, 1993; Margetts & Jackson, 1993; Midgette *et al.*, 1993; Tribble *et al.*, 1993; Järvinen *et al.*, 1994; McPhillips *et al.*, 1994; Thornton *et al.*, 1994; Emmons *et al.*, 1995; Zondervan *et al.*, 1996)
Secondhand tobacco smoke-related platelet aggregation and risk of IHD	1.34 (1.19–1.50)	Platelets experimentally exposed to second-hand tobacco smoke	Meta-analysis of 8 studies (cohort of 2398 men) (Davis & Davis, 1981; Davis *et al.*, 1982; Schmidt & Rasmussen, 1984; Davis *et al.*, 1985a,b, 1986; 1989; Blache *et al.*, 1992)

CI, confidence interval; IHD, ischaemic heart disease; cig, cigarettes

Table 4.5. Relative risk for coronary heart disease (and/or death from coronary heart disease) in never-smokers exposed to secondhand tobacco smoke in meta-analyses

Meta-analyses	Number of studies analysed	Number of cases of CHD	Relative risk (95% CI)	References
He *et al.* (1999)	10 cohort studies 8 case–control studies	6813	1.25 (1.17–1.32) in all studies 1.21 (1.14–1.30) in cohort studies 1.51 (1.26–1.81) in case–control studies 1.22 (1.10–1.35) in men 1.24 (1.15–1.34) in women 1.17 (1.11–1.24) at home 1.11 (1.00–1.23) at work 1.26 (1.16–1.38) pooled adjusted relative risk[a] *Intensity of exposure to secondhand smoke* 1–19 cig/day, 1.23 (1.13–1.34) ≥ 20 cig/day, 1.31 (1.21–1.42) (*p* for linear trend = 0.006) *Duration of exposure to secondhand smoke* 1–9 years, 1.18 (0.98–1.42) 10–19 years, 1.31 (1.11–1.55) ≥ 20 years, 1.29 (1.16–1.43) (*p* for linear trend = 0.01)	Cohort studies: Hirayama (1984); Garland *et al.* (1985); Svendsen *et al.* (1987); Butler (1988); Hole *et al.* (1989); Sandler *et al.* (1989); Hirayama (1990); Humble *et al.* (1990); Steenland *et al.* (1996); Kawachi *et al.* (1997) Case–control studies: Lee *et al.* (1986); He (1989); Jackson (1989); Dobson *et al.* (1991); La Vecchia *et al.* (1993); He *et al.* (1994); Muscat & Wynder (1995); Ciruzzi *et al.* (1998)
Thun *et al.* (1999)	9 cohort studies 8 case–control studies	7345	1.25 (1.17–1.33) in all studies 1.23 (1.15–1.31) in cohort studies 1.47 (1.19–1.81) in case–control studies 1.24 (1.15–1.32) in men 1.23 (1.15–1.32) in women 1.22 (1.13–1.30) in USA 1.41 (1.21–1.65) in other countries 1.22 (1.14–1.30) for fatal CHD 1.32 (1.04–1.67) for non-CHD	Cohort studies: Hirayama (1984); Garland *et al.* (1985); Svendsen *et al.* (1987); Butler (1988); Hole *et al.* (1989); Sandler *et al.* (1989); Hirayama (1990); Humble *et al.* (1990); Steenland *et al.* (1996); Kawachi *et al.* (1997) Case–control studies: Lee *et al.* (1986); He (1989); Jackson (1989); Dobson *et al.* (1991); La Vecchia *et al.* (1993); He *et al.* (1994); Muscat & Wynder (1995); Lam & He (1997); Ciruzzi *et al.* (1998)

CHD, coronary heart disease; IHD, ischaemic heart disease; CI, confidence interval; cig, cigarettes

[a] Analysis confined to 10 studies that adjusted for age, sex, blood pressure, body weight and serum cholesterol

smoking at home or in the workplace. Positive dose–response relationships for intensity and duration of exposure were observed (Table 4.5).

Thun *et al.* (1999) found that never-smokers married to smokers had an increased relative risk for fatal or non-fatal coronary events when compared with never-smokers married to nonsmokers. The increase in relative risk was similar in men and women, in cohort and case–control studies, in the USA and other countries and in studies of fatal and non-fatal coronary events (Table 4.5).

(ii) *Other human data*

Several mechanisms may increase the risk of CHD in nonsmokers exposed to secondhand tobacco smoke (US DHHS, 1990; Wells, 1994; He *et al*., 1999). The acute effects of passive smoking include alterations in heart rate (Pope *et al*., 2001), blood pressure, concentrations of carboxyhaemoglobin and carbon monoxide in the blood, in the blood's ability to use oxygen in the formation of adenosine triphosphate (ATP), and reduced exercise capability in people breathing secondhand smoke (Glantz & Parmley, 1995). An increase in the ratio of serum total cholesterol to high-density lipoprotein cholesterol (HDL-C), a decrease in the serum level of HDL-C (Feldman *et al*., 1991), an increase in platelet aggregation (Davis *et al*., 1989) and endothelial cell dysfunction (Otsuka *et al*., 2001) have also been described. Exposure to secondhand tobacco smoke may also contribute to atherosclerosis by priming and sensitizing neutrophils, resulting in their activation and subsequent oxidant-mediated tissue damage (Anderson *et al*., 1991).

(*c*) *Respiratory system*

The relationship between exposure to secondhand tobacco smoke and a variety of non-malignant respiratory health endpoints has been examined extensively in epidemiological and experimental studies. When this topic was first raised in the 1972 Report of the Surgeon General (US DHHS, 1972), the handful of studies that had addressed this issue had provided only limited information.

Since then, several reviews of the literature on secondhand tobacco smoke have addressed some aspects of the effects of secondhand tobacco smoke on the risk for non-neoplastic respiratory diseases in adults (Weiss *et al*., 1983; US DHHS, 1984, 1986; US National Research Council, 1986; Crawford, 1988; Eriksen *et al*., 1988; Spitzer *et al*., 1990; Trédaniel *et al*., 1994; Jinot & Bayard, 1996; California Environmental Protection Agency, 1997; Coultas, 1998; Weiss *et al*., 1999; US National Academy of Sciences, 2000).

A variety of adverse respiratory health outcomes in children have been causally linked to exposure to secondhand tobacco smoke or there is suggestive evidence of a causal association (see Table 4.6). For a detailed discussion of the relevant studies, the reader is referred to the recent reviews of the California Environmental Protection Agency (1997) and the US National Academy of Sciences (2000).

In adults, irritation of the eyes and nasal irritation have been causally associated with exposure to secondhand tobacco smoke and other annoyance has been described in

Table 4.6. Respiratory effects associated with exposure to secondhand tobacco smoke in children

Effects causally associated with exposure to secondhand tobacco smoke	Effects for which there is suggestive evidence of a causal association with exposure to secondhand tobacco smoke
Acute infections of the lower respiratory tract (e.g. bronchitis and pneumonia) Induction and exacerbation of asthma Chronic respiratory symptoms Middle-ear infections	Exacerbation of cystic fibrosis Decreased pulmonary function

Modified from California Environmental Protection Agency (1997)

several studies (US DHHS, 1999). For decreased pulmonary function, especially in combination with other exposures (e.g. prior exposure to occupational irritants) and for exacerbation of asthma, there is suggestive evidence of a causal association (California Environmental Protection Agency, 1997; US National Academy of Sciences, 2000). Some of the studies on exposure to secondhand tobacco smoke and respiratory health effects are briefly summarized below; for more comprehensive details, the reader is referred to some recent reviews (California Environmental Protection Agency, 1999; US National Academy of Sciences, 2000).

(i) *Acute effects of sensory irritation and annoyance*

The determination of the acute effects of secondhand tobacco smoke is difficult, because the observed reactions, although immediate, are largely subjective (Speer, 1968). A review of the irritation and annoyance attributable to exposure to secondhand tobacco smoke was published by the California Environmental Protection Agency (1997). The chemical constituents of secondhand tobacco smoke thought to be responsible for sensory irritation include organic acids (acetic acid and propionic acid), aldehydes (formaldehyde and acrolein), nicotine, ammonia, pyridine, toluene, sulfur dioxide and nitrogen oxides, among others (Ayer & Yeager, 1982; Triebig *et al*., 1984; US DHHS, 1986).

Nonsmokers seem to react significantly more than smokers (Weber, 1984a). The most common effect is tissue irritation, especially of the eyes (Speer, 1968; Basu *et al*., 1978; Shephard *et al*., 1979a; Bascom *et al*., 1991; White *et al*., 1991), but also of the nose, throat and airways (Bascom *et al*., 1991; Willes *et al*., 1992, 1998). The complaints are especially marked among aircraft passengers (US National Institute for Occupational Safety and Health, 1971; US National Academy of Sciences, 1986; Mattson *et al*., 1989).

Weber and co-workers (Weber *et al*., 1976; Weber, 1984b; Weber & Grosjean, 1987) and Muramatsu *et al*. (1983) conducted experiments in which volunteers were exposed to progressively increasing concentrations of secondhand tobacco smoke; as duration and intensity of exposure increased, subjects began to report subjective eye irritation, and blink rate also increased.

Lebowitz *et al*. (1992) found an increased prevalence of acute respiratory symptoms as levels of indoor secondhand tobacco smoke increased, especially in the households of subjects with lower socioeconomic status.

(ii) *Chronic respiratory symptoms*

In an early study, 25% of 10 320 nonsmoking office workers reported exacerbation of pre-existing pulmonary conditions when working with a smoker (Barad, 1979).

Other studies have shown no association (or a weak and statistically non-significant association) between the frequency of major respiratory symptoms and exposure to secondhand tobacco smoke from family members or spouse (Lebowitz & Burrows, 1976; Schilling *et al.*, 1977; Comstock *et al.*, 1981; Kauffmann *et al.*, 1983; Gillis *et al.*, 1984; Hole *et al.*, 1989; Kauffmann *et al.*, 1989).

Since 1990, however, several investigations have demonstrated a significant increase in risk for many respiratory symptoms (including cough, phlegm, breathlessness, wheeze, chest illness and dyspnoea) in subjects exposed to secondhand smoke at home and/or at work (Schwartz & Zeger, 1990; White *et al.*, 1991; Ng *et al.*, 1993; Leuenberger *et al.*, 1994; Janson *et al.*, 2001).

(iii) *Lung function testing*

A number of studies have been published that have examined the effects of secondhand tobacco smoke on pulmonary function in adults. These investigations were often initiated within the framework of research projects not primarily concerned with secondhand tobacco smoke; as a result, certain limitations apply regarding the validity of some of the findings, because of the low sensitivity and low power of these studies.

Acute exposure

Many studies have shown that exposure of nonsmoking adults to secondhand tobacco smoke is associated with a decrease in maximum expiratory flow at 25% (MEF25), FVC, FEV_1 and FEF25–75 and a decrease in dynamic lung volume (Pimm *et al.*, 1978; Shephard *et al.*, 1979a,b,c; Bascom *et al.*, 1991; Smith *et al.*, 2001).

Chronic exposure

A number of studies failed to detect any association between exposure to secondhand tobacco smoke and ventilatory parameters of lung function (Schilling *et al*., 1977; Comstock *et al.*, 1981; Jones *et al.*, 1983; Lebowitz, 1984a,b; Kentner *et al.*, 1984; Laurent *et al.*, 1992; Jaakkola *et al.*, 1995; Frette *et al.*, 1996).

Other investigators have reported an association between exposure to secondhand tobacco smoke and pulmonary function determined using different test parameters. In numerous studies, FEV_1 and/or FVC were reported to be significantly decreased (Brunekreef *et al.*, 1985; Svendsen *et al.*, 1987; Hole *et al.*, 1989; Kauffmann *et al.*, 1989; Masjedi *et al.*, 1990; Xu & Li, 1995; Carey *et al.*, 1999; Chen *et al.*, 2001). Other studies reported a significant decrease in the ventilatory parameters FEF25–75, PEF or FEF75–85 (Kauffmann & Perdrizet, 1981; Kauffmann *et al.*, 1983; Salem *et al.*, 1984; Masi *et al.*,

1988; White & Froeb, 1980; Masjedi *et al.*, 1990; Lebowitz *et al.*, 1992). Decreases in MEF50 and/or MEF75 were reported to occur only in nonsmoking men exposed at home (Masi *et al.*, 1988) or nonsmoking women exposed at home (Brunekreef *et al.*, 1985).

(iv) *Chronic obstructive pulmonary disease*

Few studies have examined the possible association between exposure to secondhand tobacco smoke and development of chronic obstructive pulmonary disease (COPD). With the exception of two studies that reported a negative association (Hirayama, 1981; Lee *et al.*, 1986), most of them found an increased risk for COPD including emphysema and bronchitis, airways obstructive disease (AOD) and obstructive respiratory disease associated with exposure to secondhand smoke (Euler *et al.*, 1987; Kalandidi *et al.*, 1987; Sandler *et al.*, 1989; Kalandidi *et al.*, 1990; Robbins *et al.*, 1993; Dayal *et al.*, 1994).

(v) *Asthma*

Many patients regard secondhand tobacco smoke as a major factor in the exacerbation of asthma (Cockcroft, 1988).

Symptoms and lung function. Many studies have shown that patients with allergies and/or asthma experienced more nasal symptoms, headache, cough, wheezing, sore throat, hoarseness (Speer, 1968), eye irritation (Weber & Fisher, 1980), aggravation of the asthma (Dales *et al.*, 1992) and restrictions in activity (Ostro *et al.*, 1994) in response to secondhand smoke. Other studies have reported a statistically significant association between the new onset of asthma, asthma ever diagnosed by a physician or current asthma and exposure to secondhand tobacco smoke at the workplace (Greer *et al.*, 1993), in the home environment and among young adults exposed to parental smoking (Hu *et al.*, 1997; Thorn *et al.*, 2001).

Two studies have found no statistically significant change in dynamic lung volume of asthmatic subjects exposed for 1 or 2 h to tobacco smoke (Shephard *et al.*, 1979b; Wiedeman *et al.*, 1986), whereas other studies have reported a statistically significant decrease in FEV_1, FVC and FEF25–75 in asthmatic subjects exposed to smoke in a chamber study (Dahms *et al.*, 1981), to secondhand tobacco smoke from the spouse and/or other close contacts (Jindal *et al.*, 1994) or in the workplace, particularly in asthmatic women (Künzli *et al.*, 2000).

Chamber studies. Chamber studies have been used to investigate potential relationships between controlled exposure to secondhand smoke and lung function and airway reactivity in asthmatic subjects. The principal advantage of this methodology over epidemiological studies is that the exposure to secondhand tobacco smoke can, in theory, be measured precisely.

Most of the studies of exposure to secondhand tobacco smoke in inhalation chambers reported slight-to-moderate transient effects on lung function in at least some of the study subjects. In several studies, some participants experienced decreases in lung function of more than 20% and a marked increase in bronchial reactivity to inhaled histamine or methacholine. These changes in lung function are considered clinically significant, parti-

cularly when they occur in conjunction with lower respiratory symptoms such as chest tightness, dyspnoea and cough (Dahms *et al.*, 1981; Knight & Breslin, 1985; Stankus *et al.*, 1988; Menon *et al.*, 1991, 1992; Nowak *et al.*, 1997). However, these results were not confirmed by Magnussen and colleagues (Jörres & Magnussen, 1992; Magnussen *et al.*, 1992) who exposed adults with mild and moderate asthma to secondhand tobacco smoke for a short period (1 h) and then conducted a bronchoprovocation test with methacholine.

Suggestion can induce an attack of asthma (Spector *et al.*, 1976). Most of the above-mentioned studies were unable to exclude the possibility that the changes reported in asthmatic subjects were emotionally related to cigarette smoke which might result in psychological suggestion being the cause of the observed symptoms, such as changes in lung function and others (Witorsch, 1992). Urch *et al.* (1988) argued that, if physiological responses were dominant, changes in pulmonary function should show a dose–response relationship to secondhand tobacco smoke, whereas, if psychological reactions were dominant, correlations between functional changes and specific measures of suggestibility would be expected. Sixteen nonsmoking asthmatic subjects were exposed to high or low concentrations of secondhand tobacco smoke or to ambient air for 65 min. Cigarette smoke was generated by a machine located outside the exposure chamber, but visible to the subjects; during sham-exposure, the smoke from the cigarettes was diverted from the study chamber. Subjects with asthma showed significant dose–response relationships for MEF50 at 5 min, and for FVC and FEV_1 at 30 min of exposure; these results support a physiological rather than psychological explanation of the findings. In the study by Danuser *et al.* (1993), the subjects wore noseclips and were exposed to secondhand tobacco smoke administered by a mouthpiece, thus blinding them to the differences in the concentrations of secondhand tobacco smoke delivered. In these conditions subjective airway symptoms were weak, but most of the symptomatic responses of the subjects with airway hyperresponsiveness appeared to be dose-related.

4.2.2 *Experimental systems*

Studies in which experimental animals were exposed to sidestream smoke alone or to simulated environmental tobacco smoke were reviewed, and the results of studies on adult animals are summarized in Tables 4.7 and 4.8 (see also Witschi *et al.*, 1997c) (see Section 3.1 for definitions).

(*a*) *Exposure of adult animals*

(i) *Effects on the respiratory tract*

Rats and hamsters were exposed to sidestream smoke (4 mg/m^3 TPM; 25–30 ppm CO) for 10 h/day, 5 days/week for 90 days. Hyperplasia and metaplasia in the epithelium of the dorsal nasal turbinates were the only changes seen in the rats. The changes partially receded after 30 days and had completely reversed 60 days after exposure. No signs of toxicity were observed in the hamster respiratory tract (Von Meyerinck *et al.*, 1989).

Table 4.7. Toxicity of sidestream or simulated environmental tobacco smoke on respiratory tract in adult animals

Species	Strain/sex	Exposure concentration (mg/m^3 TPM)	Exposure duration; conditions	Effects	Reference
Rat	F344/CrlBr/M+F	4	90 days; 10 h/d; 5 d/wk	Hyperplasia/metaplasia of the dorsal nasal epithelium	von Meyerinck *et al.* (1989)
Hamster	Syrian golden/M+F			No effect	
Rat	SD/M+F	0.1; 1; 10	14 d; 6 h/d	Slight-to-mild hyperplasia and inflammation in rostral nasal cavity at high dose only	Coggins *et al.* (1992)
Rat	SD/M	0.1; 1; 10	4 d; 28 d; 90 d; 6 h/d; 5 d/wk	Slight-to-mild hyperplasia and inflammation in rostral nasal cavity at high dose only	Coggins *et al.* (1993)
Rat	SD/F	1	3 h; 4 d	No effect	Joad *et al.* (1993)
Mouse	A/J/M	1	3 d; 5 d; 6 h/day	Increased cell proliferation in airways	Rajini & Witschi (1994)
Mouse	C57BL/6/M		5 d	No effect	
Hamster	Syrian golden/M	1	1 wk; 6 h/d; 7 d/wk	Increased cell proliferation in respiratory epithelium of nasal septum; increase after 1-week recovery period in terminal bronchioles	Witschi & Rajini (1994)
Rat	Wistar/M+F	35 ppm CO	3 mths; 90 min/d; 5 d/wk	Emphysema in lungs	Escolar *et al.* (1995)
Mouse	A/J/M	83.5	20 wks; 6 h/d; 5 d/wk	Increased cell proliferation in airways during the first 2 wks. No changes in lung parameters (volume and cell number)	Witschi *et al.* (1997a)

TPM, total particulate matter; M, male; F, female; h, hour; d, day; wk, week; mths, months; SD, Sprague-Dawley

Table 4.8. Toxicity of sidestream or simulated environmental tobacco smoke on cardiovascular system in adult animals

Species	Strain/sex	Exposure concentration (mg/m^3 TPM)	Exposure duration; conditions	Effects	Reference
Cockerel	–	8	16 wks; 6 h/d; 5 d/wk	Increase in size of arteriosclerotic plaques, but not in number or distribution	Penn & Snyder (1993)
Rabbit	New Zealand/M	4 or 33	10 wks; 6 h/d; 5 d/wk	Dose-dependent increase in formation of arteriosclerotic plaques in cholesterol-fed animals	Zhu *et al.* (1993)
Cockerel	–	2.5	16 wks; 6 h/d; 5 d/wk	Increase in size of arteriosclerotic plaques, but not in number or distribution	Penn *et al.* (1994)
Rat	SD/not given	60	3 d; 3 wks; 6 wks; 6 h/d; 7 d/wk	Time-dependent increase in infarct size	Zhu *et al.* (1994)
Mouse	Apolipoprotein $E^{-/-}$/F	25	7, 10, 14 wks; 6 h/d; 5 d/wk	Increased percentage of atherosclerotic lesions in aortic intimal surface	Gairola *et al.* (2001)
Rabbit	New Zealand White/M	24	10 wk; 6 h/d; 5 d/wk	Increased percentage of surface lipid lesions in aorta and pulmonary artery	Sun *et al.* (2001)

TPM, total particulate matter; h, hour; d, day; wk, week; M, male; F, female; SD, Sprague-Dawley

Rats were exposed, nose-only, for 6 h/day for 4, 14, 28 or 90 days to sidestream smoke at concentrations of 0.1, 1 or 10 mg/m^3 TPM. The only pathological response observed was slight to mild epithelial hyperplasia and chronic active inflammation in the most rostral part of the nasal cavity, in the group exposed to the high dose (10 mg/m^3 TPM). No time-dependent increase in the severity of the lesions was observed. After a 14-day recovery period, the changes had completely reversed (Coggins *et al*., 1992, 1993).

Male A/J and C57BL/6 mice were exposed for 6 h/day for up to 5 days to aged and diluted sidestream smoke (1 mg/m^3 TPM; 5.9 ppm CO; 549 μg/m^3 nicotine). Labelling indices in the epithelium of the large intrapulmonary airways and terminal bronchioles, but not in the alveoli, were significantly increased after 3 and 5 days of exposure in A/J mice. No signs of increased cell proliferation in the respiratory tract were seen in C57BL/6 mice (Rajini & Witschi, 1994).

Hamsters were exposed to aged and diluted sidestream smoke containing 1 mg/m^3 TPM for 6 h/day for 1–3 weeks, after which some subgroups were allowed a 1-week recovery period. Increased cell proliferation was observed in the respiratory epithelium of nasal septum after 1 week of exposure, but not at later time points. After 1 week of exposure and 1 week of recovery, cell proliferation in the terminal bronchioles was significantly increased when compared to concomitant controls and to the levels observed before recovery (Witschi & Rajini, 1994).

A similar initial increase in cell proliferation was seen in alveoli and terminal bronchioles in male A/J mice during the first 2 weeks of exposure to simulated environmental tobacco smoke (83.5 mg/m^3 TPM; 233 ppm CO; 18.9 mg/m^3 nicotine) (Witschi *et al.*, 1997a).

Wistar rats were exposed for 90 min/day, 5 days/week, for 3 months to sidestream smoke containing 35 ppm CO. Emphysematous changes (decreased number of distal airspaces and increase in alveolar chord) were observed in the lungs. These changes were accompanied by decreases in tissue density, internal alveolar perimeter, wall thickness and density and perimeter of elastic fibres (Escolar *et al.*, 1995).

Exposure of female rats to sidestream smoke (1 mg/m^3 TPM; 6.5 ppm CO) either on 1 day for 3 h or for 6 h/day on 4 days had no effect on dynamic compliance, lung resistance, lung weight/body weight, pulmonary artery pressure, or airway reactivity to methacholine (all $p > 0.4$) (Joad *et al.*, 1993).

(ii) *Cardiovascular effects*

Cardiovascular changes resulting from exposure to sidestream smoke have been demonstrated in several animal models.

Male New Zealand rabbits, fed a cholesterol-rich diet, were exposed to low-dose or high-dose sidestream smoke (4 and 33 mg/m^3 TPM, respectively) for 6 h/day, 5 days/week for 10 weeks. A dose-dependent significant increase in the size of arteriosclerotic plaques was found in the aorta and the pulmonary artery when compared with control rabbits receiving the same diet but exposed to clean air (Zhu *et al*., 1993).

Sprague-Dawley rats were exposed to sidestream smoke (60 mg/m^3 TPM; 92 ppm CO; 1103 µg/m^3 nicotine) 6 h/day, 5 days/week for 3 days, 3 weeks or 6 weeks. Infarct sizes increased in a time-dependent manner ($p = 0.023$) (Zhu *et al.*, 1994).

Exposure of 6-week old cockerels for 6 h/day, 5 days/week to sidestream smoke containing 8 mg/m^3 TPM (Penn & Snyder, 1993) or 2.5 mg/m^3 TPM (Penn *et al.*, 1994) resulted in a significant increase in the size of arteriosclerotic plaques in the aorta.

Roberts *et al.* (1996) developed a model to measure the rate of accumulation of low-density lipoproteins (LDL) in rat carotid arteries. First, rats were exposed to simulated environmental tobacco smoke for 4 h (3.3 mg/m^3 TPM; 18 ppm CO; 615 µg/m^3 nicotine) to obtain simulated tobacco smoke-plasma). Second, carotid arteries from unexposed rats were perfused with control plasma containing fluorescently labelled LDL and subsequently with tobacco smoke-plasma containing fluorescently labelled LDL. Photometric measurements were made during perfusion with labelled LDL. Perfusion with tobacco smoke-plasma increased the rate of LDL accumulation measured as fluorescence intensity (6.9 ± 1.8 mV/min (mean ± SEM)) when compared with control animals (1.6 ± 0.40 mV/min, $p < 0.01$). The maximal increase was observed after 40–60 min perfusion. LDL accumulation was primarily dependent on the interaction of tobacco smoke-plasma with LDL, which occurred before perfusion, rather than interaction with the artery wall. It was also noted that LDL accumulation resulted from its increased binding to artery wall rather than an increase in its permeability. Perfusion with tobacco smoke-plasma increased the lumen volume measured as fluorescence intensity (43.3 ± 5.1 mV versus 35.1 ± 4.4 mV; $p < 0.05$) in treated and untreated animals, respectively.

Rabbits receiving a 0.5% cholesterol diet and exposed for 6 h/day, 5 days/week for 10 weeks, to sidestream smoke (24 mg/m^3 TPM; 45 ppm CO) were compared with control animals. There was no difference in serum lipids between cholesterol fed and control animals. Exposure to sidestream smoke significantly increased the percentage of surface lipid lesions in the aorta (54 ± 5% versus 39 ± 4%; $p = 0.049$) and in the pulmonary artery (66 ± 4% versus 43 ± 3%; $p < 0.001$). Exposure to nicotine-free cigarettes (35 mg/m^3 TPM; 53 ppm CO) had the same effects as standard cigarettes. Vascular tension was measured in intact aortic rings. Endothelium-dependent and endothelium-independent relaxation were measured with acetylcholine and the calcium ionophore A23187, and nitroglycerin, respectively. There were no significant differences with any treatment between exposed and control animals (Sun *et al*., 2001).

Female ApoE-deficient mice, which are used as a mouse model of human atherosclerosis, were exposed to sidestream smoke (25 mg/m^3 TPM) 6 h/day, 5 days/week for 7, 10 and 14 weeks. There were no consistent differences in serum concentrations of cholesterol between control mice and those exposed to sidestream smoke. In exposed mice, atherosclerotic lesions in the aorta covered a larger part of the intimal area at all time points than in non-exposed mice. Also the total affected area increased at a higher rate than in controls. The increase was most evident in the thoracic region. Lesions appeared thicker, as reflected by increased amounts of esterified and unesterified cholesterol in the aortic tissues of mice exposed to sidestream smoke (Gairola *et al*., 2001).

(iii) *Immunological effects*

BALB/c mice, sensitized with aluminium hydroxide-precipitated ovalbumin (OVA/AL) antigen, were exposed for 6 h/day, 5 days/week to simulated environmental tobacco smoke (1 mg/m^3 TPM; 6.1 ppm CO; 269 µg/m^3 nicotine), from days 15 to 58 after sensitization. Sensitized mice, with or without smoke exposure, had elevated levels of IgE. Exposure to simulated environmental tobacco smoke enhanced and prolonged the IgE response in sensitized mice, and the levels were significantly increased at all time points at which measurements were made (day 19 to day 58); the concentrations of OVA-specific IgG1 were elevated in the smoke-exposed group from days 34 to 54. For both IgE and IgG1 the increase was strongest at 54 days. The numbers of eosinophils were increased in the blood and lungs of smoke-exposed, pre-sensitized mice. The total number of bronchoalveolar lavage cells was increased ($p = 0.016$); about 90% of the increase was due to alveolar macrophages. The concentrations of cytokines IL-4 and IL-10 were significantly higher in the smoke-exposed group than in the control animals. The demonstration of an exaggerated inflammatory response in sensitized mice may have relevance to the early events in carcinogenesis where an inflammatory response often precedes mild hyperplasia (Seymour *et al*., 1997).

(iv) *Effects on gastric ulceration*

A smoke chamber was designed to investigate the effects of exposure to secondhand smoke on gastric ulceration. Different concentrations of cigarette smoke (0%, 1%, 2% and 4%) were perfused during one hour into a chamber in which male Sprague-Dawley rats were placed. This exposure potentiated ethanol (70% v/v, oral administration)-induced gastric mucosal damage and increased serum nicotine concentrations, but did not affect the pH, pCO_2 or pO_2 and the concentration of HCO_3 in blood, or the systemic blood pressure and heart rate. Under these experimental conditions, exposure to cigarette smoke produced no significant changes in the blood acid/base balance or stress in the animals, but significantly potentiated ethanol-induced gastric mucosal damage. This experimental model is suitable for studying adverse interactions between passive smoking and alcohol drinking in gastric ulcer formation in rats (Chow *et al*., 1996).

(*b*) *Effects of perinatal exposure*

(i) *Effects on lung development and lung function*

Exposure of Sprague-Dawley rats to aged and diluted sidestream smoke from birth (1 mg/m^3 TPM; 6 h/day, 5 days/week) significantly reduced the labelling index of epithelial cells in distal airways at 7 and 14 days of age, but not at later times or in proximal bronchi (Ji *et al.*, 1994).

Gestating Sprague-Dawley rats were exposed to aged and diluted sidestream smoke (1 mg/m^3 TPM; 4.9 ppm CO) from gestational day 5 until gestational day 14, 18 or 21. Maternal exposure to sidestream smoke significantly increased fetal expression of Clara cell secretory protein and mRNA in the terminal bronchioles at gestational day 21, but not at gestational day 14 or 18 (Ji *et al*., 1998).

A series of studies was designed to determine the effects of perinatal exposure to sidestream smoke on airway reactivity in Sprague-Dawley rats. Female rats were exposed 6 h/day, 5 days/week from day 2 of life to week 8 or week 15 of age (1 mg/m^3 TPM; 6.5 ppm CO). Exposure to sidestream smoke did not change the ratio of lung weight/body weight or the baseline values for lung resistance, dynamic compliance or pulmonary artery pressure. Airway reactivity to methacholine was also unaffected at either time-point (all $p > 0.2$). In animals exposed from day 2 of life to week 11 of age, sidestream smoke reduced airway ($p = 0.004$), but not pulmonary artery ($p = 0.63$) reactivity to serotonin (Joad *et al*., 1993). In a further study, Joad *et al*. (1999) exposed rats to aged and diluted sidestream smoke (1 mg/m^3 TPM; 6.9 ppm CO) for 4–6 h/day from gestational day 3 until 21 days of age. The airway responsiveness of one female pup from each litter was assessed at 8 weeks of age. Perinatal exposure to sidestream smoke did not affect baseline lung function, but enhanced methacholine-induced changes in lung resistance (three-fold increase; $p = 0.02$), dynamic compliance ($p = 0.004$), and pulmonary pressure ($p = 0.007$). These changes occurred in the absence of any increase in pulmonary neuroendocrine cells, neuroepithelial bodies or mast cells. In another study, rats were exposed prenatally and/or postnatally to sidestream smoke (1 mg/m^3 TPM; 4.9 ppm CO; 344 µg/m^3 nicotine) for 4 h/day, 7 days/week from gestational day 3 until 7–10 weeks of age. Pulmonary pressure was not affected by any type of exposure. Prenatal or postnatal exposure alone did not affect baseline values or metacholine-induced changes in lung responsiveness. Prenatal followed by postnatal exposure to sidestream smoke reduced dynamic lung compliance at baseline ($p = 0.0006$) and increased lung responsiveness to methacholine ($p = 0.0001$). This reaction was accompanied by an increase in the number of neuroendocrine cells and neuroepithelial bodies (Joad *et al.*, 1995a).

Male guinea-pigs were exposed 6 h/day, 5 days/week from age 8 days to age 37–48 days (1 mg/m^3 TPM; 5.6 ppm CO; 586 µg/m^3 nicotine). Exposure to sidestream smoke did not change lung morphology, collagen or elastin deposition, lung volume, surface area or mean linear intercept length of alveolar airspace. Baseline dynamic lung compliance ($p = 0.05$), but not lung resistance ($p = 0.61$) was increased by exposure to sidestream smoke (see also Section 4.2.2(*b*)(iii)) (Joad *et al.*, 1995b).

(ii) *Cardiovascular effects*

Sprague-Dawley rats were exposed to filtered air or sidestream smoke (33 mg/m^3 TPM; 60 ppm CO) for 6 h/day, 5 days/week, for 3 weeks before birth and/or for 12 weeks in the neonatal to adolescent period. Exposure to sidestream smoke postnatally increased endothelin-1 levels in plasma ($p = 0.001$) independently of in-utero exposure. Infarct size (infarct mass/risk area × 100) was greater in all animals exposed postnatally than in unexposed controls ($p = 0.005$), and was greater in males than in females ($p < 0.001$) (Zhu *et al*., 1997).

In rats exposed under the same conditions, aortic rings were excised and isometric force responses to phenylephrine, acetylcholine, the calcium ionophore A23187 and nitroglycerin were studied in organ baths. In-utero exposure to sidestream smoke increased the

sensitivity of aortic rings to phenylephrine ($p < 0.0005$) and reduced the half-maximal contraction (EC_{50}; $p = 0.04$). It reduced the maximal endothelium-dependent relaxation response to acetylcholine ($p = 0.04$) and increased its half-maximal contraction value ($p = 0.05$). Finally, in-utero exposure decreased the sensitivity to the endothelium-independent vasodilator nitroglycerin ($p = 0.003$). The sensitivity of aortic rings to phenylephrine was reduced after neonatal exposure ($p = 0.01$) (Hutchison *et al*., 1998).

(iii) *Neurological effects*

Female Sprague-Dawley rats were exposed to filtered air or sidestream smoke for 4 h/day, 7 days/week from day 3 of gestation until birth and/or for 9 weeks postnatally (1 mg/m^3 TPM; 4.9 ppm CO; 344 μg/m^3 nicotine). Postnatal exposure to sidestream smoke increased the mortality of the pups during the first 18 days of life ($p < 0.001$) and significantly reduced body weights at 9 weeks of age ($p = 0.016$). In-utero exposure had no effect on DNA, protein, or cholesterol concentration or on the weight of forebrain or hindbrain. Postnatal exposure reduced DNA concentration in the hindbrain, an indicator of cellular density, by 4.4% ($p < 0.001$) and increased the hindbrain protein/DNA ratio, an index of cell size, by 8.4% ($p = 0.001$). The weight of the hindbrain was not affected by exposure to sidestream smoke (Gospe *et al*., 1996).

Rhesus monkeys were exposed to aged and diluted sidestream smoke (1 mg/m^3 TPM; 5.3 ppm CO; 190 μg/m^3 nicotine) from gestational day 100 until 70–80 days after birth. Expression of beta-adrenergic and m2-muscarinic cholinergic receptors in heart and lungs of the offspring were not changed by exposure to smoke. Whereas there were no changes in the heart, a strong induction of adenylyl cyclase was observed in the lungs (Slotkin *et al*., 2000).

To mimic fetal and childhood exposure to secondhand smoke, gestating Sprague-Dawley rats were exposed to mainstream smoke (29 mg/m^3 TPM; 94 ppm CO; 4600 μg/m^3 nicotine) for 6 h/day, 7 days/week from gestational days 5 to 20. One to two days after delivery, dams and pups were exposed to sidestream smoke (1 mg/m^3 TPM; 5.6 ppm CO; 117 μg/m^3 nicotine) until postnatal day 21. Animals were exposed either prenatally, postnatally, or both. Prenatal and/or postnatal exposure significantly increased total adenylyl cyclase activity in brain and heart when monitored with the direct enzymatic stimulant forskolin (see Section 4.1.2(*a*)(iii) for details). In the brain, the specific coupling of beta-adrenergic receptors to adenylyl cyclase was inhibited in all exposed animals, despite normal expression of beta-receptors. In the heart, a decrease in m2-receptor expression was observed after postnatal or continuous exposure, but no inhibition of beta-adrenergic receptors was seen. In both tissues, and for all parameters, the effects of combined prenatal and postnatal exposure were equivalent to those seen in response to postnatal exposure alone (Slotkin *et al*., 2001).

In a series of studies, guinea-pigs were exposed to sidestream smoke (1 mg/m^3 TPM; 6.2 ppm CO; 224 μg/m^3 nicotine) for 6 h/day, 5 days/week from age 1 to 6 weeks (age equivalent of human childhood). Sidestream smoke reduced capsaicin-induced changes in lung resistance ($p = 0.02$) and lung dynamic compliance ($p = 0.04$), indicating a down-

regulation of the lung C-fibre reflex response (Joad *et al.*, 1995b). Primary bronchopulmonary C-fibres were tested for their responsiveness to chemical and mechanical stimuli. Exposure to sidestream smoke had no effect on baseline activity of C-fibres but augmented the responsiveness to left atrial injection of capsaicin ($p = 0.047$) and to lung hyperinflation ($p = 0.03$) (Mutoh *et al.*, 1999). A study on the impulse activity of bronchopulmonary C-fibre-activated nucleus tractus solitarii neurons showed that exposure to sidestream smoke significantly augmented the peak ($p = 0.02$) and duration ($p = 0.01$) of the neuronal response to C-fibre activation, and prolonged the expiratory time (apnoea) ($p = 0.003$), at the higher dose of capsaicin (2.0 µg/kg). Exposure to sidestream smoke did not alter baseline values or capsaicin-induced changes in tracheal pressure, arterial blood pressure or heart rate (Mutoh *et al*., 2000). A recent study presented data to suggest that actions of the neuropeptide substance P in the nucleus tractus solitarius may contribute to these effects (Bonham *et al.*, 2001).

In summary, exposure of experimental animals to sidestream smoke can produce changes that are similar to those observed in response to exposure of humans to secondhand tobacco smoke, such as inflammatory changes in the airways and accelerated formation of arteriosclerotic plaques. The results obtained from studies of perinatal exposure may provide a potential mechanism to explain the association between exposure to secondhand smoke and sudden infant death syndrome.

4.3 Reproductive, developmental and hormonal effects

4.3.1 *Humans*

(*a*) *Reproductive effects*

There are inherent ambiguities in the interpretation of data on reproductive effects: if involuntary smoking in women is defined in terms of household exposure to secondhand smoke, reproductive effects could be due either to the exposure to secondhand smoke of the female or to a direct effect of active smoking on the fertility of the male partner. In most of the published studies, the effects of secondhand smoke have been estimated on the basis of paternal smoking. A possible direct effect of smoking on the father's sperm cannot be ruled out when the father has been the source of exposure to secondhand smoke (Lindbohm *et al.*, 2002).

(i) *Fertility and fecundability*

The available data regarding the effects of passive smoking by women on fertility and fecundity are conflicting (US DHHS, 2001): some studies have reported an increased risk of delayed conception (Hull *et al*., 2000), whereas others have found no association (US DHHS, 2001). The results of investigations of the association between passive smoking during the prenatal period or childhood and later fertility have also been inconsistent: in some studies such exposure has been associated with reduced fecundability (in the case of prenatal exposure) or an *increased* fecundability (in the case of childhood exposure),

whereas others have reported no association (Weinberg *et al.*, 1989; Wilcox *et al.*, 1989; Jensen *et al.*, 1998; US DHHS, 2001; Lindbohm *et al.*, 2002). These investigations are particularly hampered by potential exposure measurement error, confounding factors and other biases.

(ii) *Pregnancy outcomes*

The data regarding the association between maternal exposure to secondhand smoke and preterm birth are not entirely consistent, but in aggregate they suggest a modestly increased risk associated with high exposure (Lindbohm *et al*., 2002).

(iii) *Birth outcomes*

The adverse effect of cigarette smoking on birth weight is well-established; on average, women who smoke cigarettes deliver term infants that weigh about 150–250 g less than those of nonsmokers (Andres & Day, 2000; US DHHS, 2001). When expressed as relative risks, mothers who smoke have more than a doubled risk for having low-birth-weight babies (US DHHS, 2001). There is a similar association between maternal smoking and delivery of small-for-gestational-age infants (US DHHS, 2001). The association is characterized by a dose–response relationship that persists after adjustment for possible confounding factors, and seems to be more pronounced for older mothers (US DHHS, 2001).

Numerous studies have also investigated the association between fetal growth and maternal passive smoking (US DHHS, 2001). On average the birth weight of infants born to nonsmoking mothers exposed to secondhand smoke after adjustment for important potential confounders seems to be about 25–50 g lower than that of babies born to mothers who were not exposed (California EPA, 1997; Windham *et al.*, 1999a; US DHHS, 2001; Lindbohm *et al.*, 2002). However, some studies have not found such an adverse effect (Sadler *et al*., 1999; US DHHS, 2001).

There has been little investigation of the association between maternal exposure to secondhand smoke and spontaneous abortion or stillbirth. The available data are inconsistent, although some studies have shown effects as large as those seen in investigations of the effects of active smoking (Windham *et al*., 1999b; US DHHS, 2001; Lindbohm *et al*., 2002).

The association between maternal smoking during pregnancy and the risk of birth defects has been extensively investigated (US DHHS, 2001). When the focus is on major defects as a single end-point, generally no association has been found. When separate classes of malformations are considered individually, there are indications that maternal smoking during pregnancy is associated with oral clefts, limb reductions, and perhaps malformations of the urinary tract (US DHHS, 2001).

(*b*) *Body weight*

In contrast to the extensive and consistent literature describing the effects of active smoking on body weight, findings on the effects of passive smoking on weight are sparse.

The available data suggest that women exposed to secondhand smoke weigh more than women who are not exposed. However, this association may be confounded by a more sedentary and less healthy lifestyle being adopted by nonsmokers exposed to secondhand smoke (Cress *et al.*, 1994; Thornton *et al.*, 1994; Bernstein, 1996).

(*c*) *Hormones*

No data regarding involuntary exposure to tobacco smoke and levels of estrogens, androgens or vitamin D were available to the Working Group. In one study cord blood from mothers who smoke seemed to contain higher concentrations of insulin-like growth factor 1 (IGF-1) than specimens obtained from nonsmoking mothers (Beratis *et al.*, 1994). In other studies, a decreased concentration of IGF-1 in cord blood has been reported (Heinz-Erian *et al.*, 1998; Coutant *et al.*, 2001).

(*d*) *Menopause*

Three studies addressed the association between exposure to secondhand smoke and age at menopause. One study reported that passive smoking was associated with an advancement in the age at menopause similar to that reported for active smoking, but the study population was small (Everson *et al*., 1986). More recent investigations reported no association between exposure to secondhand smoke at home and age at menopause (Cramer *et al*., 1995; Cooper *et al*., 1999).

4.3.2 *Experimental systems*

A few studies have reported the effects of exposure of gestating female animals to sidestream smoke on embryo implantations, size of litters, mortality rate or body weight of pups in the first weeks of life.

Female hamsters were exposed to the smoke of 1, 2 or 3 cigarettes, twice a day, 7 days/week, from 14 days before mating until the third day of pregnancy. Transport of pre-implantation embryos through the hamster oviduct was retarded in exposed females at all three doses. In a study of exposure to a single dose of smoke, the rate of oviductal muscle contraction decreased significantly within 15 min of exposure and failed to return to baseline rates during a 25-min recovery period. Both pre-implantation embryo transport and muscle contraction were more sensitive to sidestream smoke than to mainstream smoke (see monograph on tobacco smoke, Section 4.3) (DiCarlantonio & Talbot, 1999).

Rats were exposed for 2 h/day, from days 1 to 20 of gestation, to the smoke of 10 king-size cigarettes/2 h [exposure concentrations not reported]. Exposure to smoke significantly reduced food consumption of gestating dams. The average fetal weight ($n = 8$) in the animals exposed to sidestream smoke was reduced to 91% of the pair-fed control values ($p < 0.05$). Litter size and proportion of resorptions were not significantly affected. Combination of smoke with alcohol had a synergistic effect that led to significantly smaller litter size and fetal weight than in pair-fed animals [no comparison was made with smoke exposure alone] (Leichter, 1989). In another study, gestating Sprague-Dawley rats

were exposed to aged and diluted sidestream smoke (1 mg/m^3 TPM; 5.5 ppm CO; 405 µg/m^3 nicotine) for 6 h/day on days 3, 6–10 and 13–17 of pregnancy and killed on day 20. Maternal body weight gain, average daily food consumption and the number of fetuses and of implantation sites per litter were comparable between smoke-exposed and pair-fed controls. However, there was a small, but significant reduction in mean pup weight ($p < 0.05$). This was not accompanied by any significant decrease in fetal ossification, an index of gestational age (Rajini *et al*., 1994). In a similar study, animals were exposed for 6 h/day to aged and diluted sidestream smoke (1 mg/m^3 TPM) from day 3 to day 11 of gestation. Average pup weight per litter was not affected by exposure to smoke, but the average number of implantations and of live pups per litter were significantly lower ($p < 0.05$) in the smoke-exposed animals (Witschi *et al.*, 1994).

Gestating rats were exposed for 3 weeks before delivery to sidestream smoke, 4 cigarettes/15 min, 6 h/day, 5 days/week. Mortality at birth was higher in the exposed animals than in controls (11.9% versus 2.8%; $p < 0.001$), and body weights at 3 and 4 weeks of age were lower than those of controls ($p < 0.001$) (Zhu *et al.*, 1997). In a later study under the same conditions, mortality at birth was also greater in rats exposed *in utero* than in those not exposed (12% versus 3%, $p < 0.001$), but in-utero exposure did not reduce body weight at 4 weeks (Hutchison *et al.*, 1998). Other studies found that exposure of rats to aged and diluted sidestream smoke (1 mg/m^3 TPM) *in utero* did not affect fetal body weight at any gestational age (Ji *et al.*, 1998) or at birth (Joad *et al.*, 1999).

4.4 Genetic and related effects

4.4.1 *Humans*

(*a*) *Mutagenicity, sister chromatid exchange and* HPRT *mutations*

(i) *Urinary mutagenicity*

Mutagenicity of urine from smokers has been detected by use of the *Salmonella* (Ames) mutagenicity test in a large number of studies ever since the first report by Yamasaki and Ames (1977). Urinary mutagenicity correlates significantly with the number of cigarettes smoked daily and with urinary nicotine and/or cotinine concentrations (e.g. Bartsch *et al*., 1990; Vermeulen *et al*., 2000).

Urine voided by nonsmokers exposed to secondhand tobacco smoke or to diluted sidestream smoke also shows bacterial mutagenicity (Bos *et al.*, 1983; Sorsa *et al*., 1985; IARC, 1986; Kado *et al*., 1987; Bartsch *et al*., 1990; Smith, C.J. *et al*., 2000; Vermeulen *et al*., 2000). This is in accordance with the mutagenicity of sidestream smoke and samples of airborne particulate matter or the vapour-phase of the air collected from environments contaminated with secondhand tobacco smoke (see Section 4.4.2). However, the increase in urinary mutagenicity was small in many of the studies (Sorsa *et al*., 1985; Husgafvel-Pursiainen *et al*., 1987; Kado *et al*., 1987; US Environmental Protection Agency, 1992; Smith C.J. *et al*., 2000), and no increase in mutagenicity was found in the urine of volunteers (nonsmokers) after 8 h of exposure to the gaseous phase of second-

hand tobacco smoke or to whole secondhand tobacco smoke under experimental conditions (Scherer *et al*., 1990). The small increases in urinary mutagenicity that have been detected are subject to confounding from dietary, occupational and environmental exposures. Such confounding factors affect the sensitivity and specificity of the assay for secondhand tobacco smoke exposure in the same manner as they do in smokers (Sasson *et al*., 1985; Malaveille *et al*., 1989; US Environmental Protection Agency, 1992; Scherer *et al*., 1996; Vermeulen *et al*., 2000).

Increased urinary mutagenicity was clearly associated with exposure to secondhand tobacco smoke in two studies that used urinary cotinine concentrations to indicate exposure to tobacco smoke in smokers and nonsmokers (Bartsch *et al*., 1990; Vermeulen *et al*., 2000). Bartsch *et al.* (1990) found urinary mutagenicity to be a specific indicator of exposure to secondhand tobacco smoke. In the study by Vermeulen *et al.* (2000), an increase in urinary mutagenicity was found to follow an increase in urinary cotinine in a manner similar to that seen in smokers. In fact, cotinine-adjusted urinary mutagenicity levels showed an almost identical increase for both nonsmokers exposed to secondhand smoke and smokers (Vermeulen *et al*., 2000).

(ii) *Sister chromatid exchange*

Significantly higher levels of sister chromatid exchange, chromosomal aberrations and micronuclei have been found in cultured peripheral lymphocytes of smokers than in nonsmokers (IARC, 1986). However, studies on nonsmokers exposed to secondhand tobacco smoke in experimental or field conditions, where cotinine measurements were used as indicators of exposure and uptake, have shown predominantly negative results for sister chromatid exchange in cultured lymphocytes of peripheral blood (Sorsa *et al*., 1985; Collman *et al*., 1986; Husgafvel-Pursiainen, 1987; Husgafvel-Pursiainen *et al*., 1987). A study of 106 adult nonsmokers who were divided into two groups according to whether they experienced high or low levels of exposure to secondhand tobacco smoke as determined from plasma cotinine levels, found no difference in sister chromatid exchange frequencies between the two groups (Gorgels *et al*., 1992). More recently, sister chromatid exchange was investigated in 109 preschool children, aged 1–6 years, whose mothers or other persons living in the same household smoked. Exposure to secondhand tobacco smoke at home, based on interview data and plasma cotinine measurements, was found to be associated with an almost significant increase in sister chromatid exchange ($p = 0.076$) when compared with the level measured in children living in nonsmoking households. The increase paralleled statistically significant increases ($p < 0.05$) in 4-ABP-haemoglobin and PAH-albumin adducts in the children exposed to secondhand smoke (Tang *et al*., 1999).

The frequencies of sister chromatid exchange in cord blood lymphocytes from mothers who smoked or who were exposed to secondhand tobacco smoke were not elevated when compared with those in non-exposed mothers (Sorsa & Husgafvel-Pursiainen, 1988). Chromosomal aberrations were not increased in nonsmoking waitresses and

waiters exposed to secondhand tobacco smoke who had increased cotinine levels (Sorsa *et al*., 1989).

In summary, studies on sister chromatid exchange have found marginal effects in nonsmokers exposed to secondhand tobacco smoke. However, the lack of sensitivity of the assay for exposure to low doses of this complex mixture needs to be taken into account.

(iii) HPRT *gene mutations*

Smokers have been found to have higher frequencies of *HPRT* mutant lymphocytes than nonsmokers in most of the populations studied (Ammenheuser *et al*., 1997; Curry *et al*., 1999; see monograph on tobacco smoke). A set of studies has been conducted on *HPRT* mutations in the newborns of mothers who were exposed or not exposed to secondhand tobacco smoke. After an initial study that found no difference between *HPRT* mutant frequencies in T lymphocytes from the cord blood of infants born to mothers exposed to secondhand tobacco smoke and to non-exposed mothers (Finette *et al*., 1997), the same authors carried out another study, in which the types of *HPRT* mutations were investigated (Finette *et al*., 1998). Maternal exposure was based on self-reported smoking status, interview data on exposure to secondhand tobacco smoke at home or at work and on measured concentrations of cotinine in cord blood plasma. Analysis of 30 *HPRT* mutants from 12 infants whose mothers were classified as not exposed and 37 mutant isolates from 12 infants born to mothers who were exposed found a significant difference between the mutation spectra in these groups. The difference was attributed to *HPRT* exon 2–3 deletions, which are mutational events presumably mediated by illegitimate combinatorial rearrangement of multiple V (variable), D (diversity) and J (junctional) coding gene segments (V(D)J) recombinase activity (Finette *et al*., 1998).

In another study, cord blood T lymphocytes from 60 newborns were investigated and were found not to show an independent effect of (self-reported) maternal exposure to secondhand tobacco smoke on *HPRT* mutant frequencies. However, the exon 2–3 deletions comprised 26.3 and 28.6% of all mutants in cord blood of infants of mothers who were not exposed or were passively exposed to secondhand smoke, respectively. In infants born to mothers who smoked, this percentage was 85.7% (Bigbee *et al*., 1999).

(iv) *Other*

A study of lift workers conducted in China examined DNA damage in lymphocytes with the single-cell gel electrophoresis (comet) assay. It was found that in 255 never-smokers, the tail moment in the assay was significantly increased by any reported exposure to secondhand tobacco smoke at home or at work. Analysis of covariance showed a significant, independent effect of domestic, but not of occupational, exposure to secondhand tobacco smoke, measured by the number of smokers nearby, on the comet tail moment (Lam *et al*., 2002).

(*b*) *Mutations in* TP53*,* KRAS *and related genes*

(i) TP53 *gene mutations*

The frequency of mutations of the *TP53* gene is higher in lung tumours from smokers than in those from nonsmokers (as reviewed in Hussain & Harris, 1998; Hernandez-Boussard *et al*., 1999; see monograph on tobacco smoke) and this correlates with lifetime cigarette consumption or duration of smoking (Takeshima *et al*., 1993; Wang *et al*., 1995; Kondo *et al*., 1996; Husgafvel-Pursiainen *et al*., 1999). In addition, a significant difference has been observed between mutation spectra in smokers and nonsmokers (see monograph on tobacco smoke).

Frequencies of *TP53* mutations found in lung cancer tissues from lifetime nonsmokers vary between 10 and 35% (Huang *et al*., 1998; Marchetti *et al*., 1998; Takagi *et al*., 1998; Gealy *et al*., 1999; Husgafvel-Pursiainen *et al*., 2000; Vähäkangas *et al*., 2001). A few studies have investigated lung tumours from patients who, as determined from interview data, were lifetime nonsmokers who had experienced long-term exposure to secondhand tobacco smoke at home and compared the mutation frequencies with those recorded in lifetime nonsmokers without exposure to secondhand smoke (Husgafvel-Pursiainen *et al*., 2000; Vähäkangas *et al*., 2001). Life-long nonsmokers studied as a single group (i.e. irrespective of exposure to secondhand tobacco smoke) were found to have a significantly lower prevalence of *TP53* mutations than smokers (odds ratio, 2.9; 95% CI, 1.2–7.2; n = 91 for never-smokers) (Husgafvel-Pursiainen *et al*., 2000) or ex-smokers (odds ratio, 9.1; 95% CI, 2.1–40.0; n = 117 for never-smokers) (Vähäkangas *et al*., 2001). When the prevalence of mutations in the lifetime nonsmokers who reported exposure to secondhand tobacco smoke from spousal smoking was compared with that in cases who reported no exposure to secondhand tobacco smoke at home, mutations were more common in exposed cases who reported exposure from spousal smoking (odds ratio, 2.0; 95% CI, 0.5–8.7; based on six exposed cases with mutation and 42 exposed cases without mutation) (Husgafvel-Pursiainen *et al*., 2000). In addition, the predominant type of mutation detected in nonsmokers was GC→AT transition, but the number of mutations was too small to allow comparisons to be made between the exposure groups (Husgafvel-Pursiainen *et al*., 2000; Vähäkangas *et al*., 2001).

(ii) KRAS *mutations*

Mutations of the *KRAS* gene (codons 12, 13 or 61) occur in approximately 30% of lung adenocarcinomas obtained from smokers (Rodenhuis *et al*., 1988; Slebos *et al*., 1991; Husgafvel-Pursiainen *et al*., 1993; Westra *et al*., 1993; Gealy *et al*., 1999). Studies that have looked for *KRAS* mutations in lung tumours from nonsmokers (typically codon 12) have found low frequencies of mutation: 0% (0/35) (Marchetti *et al*., 1998), 5% (2/40) (Rodenhuis & Slebos, 1992), 7% (2/27) (Westra *et al*., 1993), 9% (2/23) (Gealy *et al*., 1999) and 11% (13/117) (Vähäkangas *et al*., 2001). Only Vähäkangas *et al.* (2001) studied *KRAS* mutations in lifetime nonsmokers exposed to secondhand tobacco smoke: of the 13 nonsmokers with a *KRAS* mutation in codon 12, seven had been exposed to secondhand smoke and six had not.

(*c*) *Polymorphisms in xenobiotic metabolizing genes*

Many studies have investigated smokers for associations between polymorphisms of genes involved in xenobiotic metabolism, proposed as markers of susceptibility, and various end-points of genotoxicity and related effects (Vineis & Malats, 1999). However, many of the data from such studies are contradictory and were frequently based on small numbers. Few studies have addressed the influence of genetic polymorphisms on nonsmokers exposed to secondhand tobacco smoke, and no firm conclusion can be drawn regarding the influence of polymorphisms on smoking-associated biomarkers.

4.4.2 *Experimental systems*

(*a*) *In-vitro studies on genotoxicity*

The genotoxicity of whole sidestream smoke or fractions of sidestream smoke or secondhand tobacco smoke has been investigated in many studies. Sidestream smoke or secondhand tobacco smoke collected from indoor environments has been shown to be mutagenic in the *Salmonella* (Ames) mutagenicity assay (Husgafvel-Pursiainen *et al*., 1986; Löfroth & Lazaridis, 1986; Ling *et al*., 1987; Claxton *et al*., 1989; Doolittle *et al*., 1990) as reviewed by Sorsa and Löfroth (1989). Condensates of mainstream smoke and cigarette smoke were mutagenic in the presence of S9 activation systems (IARC, 1986; see monograph on tobacco smoke), and some studies found that sidestream smoke or secondhand tobacco smoke also induced bacterial mutagenicity in the absence of S9 (Ling *et al*., 1987; Claxton *et al*., 1989). One study that found that secondhand tobacco smoke condensate induced mutations in the *Salmonella* assay also observed a genotoxic response in the SOS chromotest with *Escherichia coli* (Chen & Lee, 1996). Another study investigated the particulate matter of secondhand tobacco smoke collected near the breathing zone of nonsmoking individuals and detected mutagenicity that correlated with the concentrations of nicotine in air (Kado *et al*., 1991).

Several studies have shown sidestream smoke, secondhand tobacco smoke and their fractions to be potent inducers of sister chromatid exchange in Chinese hamster ovary cells in the presence and absence of metabolic activation (Husgafvel-Pursiainen *et al*., 1986; Salomaa *et al*., 1988; Doolittle *et al*., 1990). Other studies have reported smaller effects (e.g. Chen & Lee, 1996). Sidestream smoke has also been found to induce chromosomal aberrations, but not *Hprt* gene mutations, in Chinese hamster ovary cells (Doolittle *et al*., 1990).

(*b*) *In-vivo studies on genotoxicity*

Studies in rodents have indicated in-vivo genotoxicity of sidestream smoke, or of the combination of sidestream smoke and mainstream smoke, as reviewed by IARC (1986). Various studies have been conducted on the clastogenic effects of sidestream cigarette smoke in mice or rats under whole-body or nose-only exposure conditions. In mice exposed to sidestream smoke in an exposure chamber (whole-body exposure), a signifi-

cant increase in the frequency of micronucleated polychromatic erythrocytes in the bone marrow was observed (Mohtashamipur *et al*., 1987). Similarly, sidestream smoke and mainstream smoke condensates injected either separately or in a mixture increased the formation of micronuclei in polychromatic erythrocytes in treated mice in a dose-dependent manner (Mohtashamipur *et al*., 1988). In agreement with chemical analyses showing that the concentrations of several genotoxic and carcinogenic substances are higher in sidestream smoke than in mainstream smoke, sidestream smoke condensate induced significantly more micronuclei than mainstream smoke condensate. This difference was more pronounced in animals pretreated with the enzyme inducer Arochlor 1254 (Mohtashamipur *et al*., 1988).

Aged and diluted sidestream smoke was not found to induce chromosomal aberrations in alveolar macrophages in rats after nose-only exposure for 7 days (Lee *et al*., 1992), or after 28 days or 90 days (Lee *et al*., 1993). More recently, whole-body exposure of rats to a mixture of mainstream (11%) and sidestream (89%) cigarette smoke for 28 consecutive days was found to induce DNA adducts and cytogenetic damage in all tissues examined. The frequencies of micronucleated and polynucleated pulmonary alveolar macrophages as well as those of micronucleated polychromatic erythrocytes in bone marrow were significantly increased in animals exposed to sidestream smoke when compared with sham-exposed animals (Izzotti *et al*., 2001).

4.5 Mechanistic considerations

Biological measurements have demonstrated uptake and metabolism of tobacco smoke constituents in nonsmokers who reported regular exposure to secondhand tobacco smoke. In particular, cotinine concentrations measured in the body fluids of nonsmokers have provided both qualitative and quantitative evidence of exposure to secondhand tobacco smoke. In addition, the presence of tobacco-specific nitrosamines and their metabolites in the urine of nonsmokers exposed to secondhand tobacco smoke, with a correlation between the metabolites and cotinine concentration in the urine, provides clear evidence of the exposure of nonsmokers to carcinogenic constituents of tobacco smoke. The results of current studies on individual variation due to environmental or genetic factors are insufficient to permit conclusions regarding the influence of these factors on the response of people to exposure to secondhand tobacco smoke.

Evidence is provided in this monograph for the genotoxicity of secondhand tobacco smoke in humans. Exposure of nonsmokers to secondhand tobacco smoke has often been demonstrated by measurements of both cotinine and protein adducts. Studies analysing somatic mutations in the *TP53* and *KRAS* genes in lung tumours from life-long nonsmokers have suggested that the mutation burden in nonsmokers who are exposed to secondhand tobacco smoke may be higher than that in nonsmokers who have not been exposed. These observations in humans are supported by the findings from animal studies and other experimental systems that have demonstrated the genotoxicity of sidestream smoke (a major component of secondhand tobacco smoke), of a mixture of mainstream

and sidestream smoke, and of secondhand tobacco smoke collected in indoor environments.

The evidence from studies of nonsmokers exposed to secondhand tobacco smoke, supported by other data from experimental systems, is compatible with the current concept of tobacco-related carcinogenesis. According to this concept, tobacco smoke carcinogens, regardless of the type of smoke in which they occur, are associated with genetic effects that disrupt crucial biological processes of normal cellular growth and differentiation in smokers as well as in nonsmokers (see monograph on tobacco smoke).

5. Summary of Data Reported and Evaluation

5.1 Exposure data

Involuntary (or passive) smoking is exposure to secondhand tobacco smoke, which is a mixture of exhaled mainstream smoke and sidestream smoke released from the smouldering cigarette or other smoking device (cigars, pipes, bidis, etc.) and diluted with ambient air. Involuntary smoking involves inhaling carcinogens, as well as other toxic components, that are present in secondhand tobacco smoke. Secondhand tobacco smoke is sometimes referred to as 'environmental' tobacco smoke. Carcinogens that occur in secondhand tobacco smoke include benzene, 1,3-butadiene, benzo[*a*]pyrene, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone and many others.

Secondhand tobacco smoke consists of a gas phase and a particulate phase; it changes during its dilution and distribution in the environment and upon ageing. The concentrations of respirable particles may be elevated substantially in enclosed spaces containing secondhand tobacco smoke. The composition of tobacco smoke inhaled involuntarily is variable quantitatively and depends on the smoking patterns of the smokers who are producing the smoke as well as the composition and design of the cigarettes or other smoking devices. The secondhand tobacco smoke produced by smoking cigarettes has been most intensively studied.

Secondhand tobacco smoke contains nicotine as well as carcinogens and toxins. Nicotine concentrations in the air in homes of smokers and in workplaces where smoking is permitted typically range on average from 2 to 10 μg/m^3.

5.2 Human carcinogenicity data

Lung cancer

Involuntary smoking involves exposure to the same numerous carcinogens and toxic substances that are present in tobacco smoke produced by active smoking, which is the principal cause of lung cancer. As noted in the previous *IARC Monograph* on tobacco smoking, this implies that there will be some risk of lung cancer from exposure to secondhand tobacco smoke.

More than 50 studies of involuntary smoking and lung cancer risk in never-smokers, especially spouses of smokers, have been published during the last 25 years. These studies

have been carried out in many countries. Most showed an increased risk, especially for persons with higher exposures. To evaluate the information collectively, in particular from those studies with a limited number of cases, meta-analyses have been conducted in which the relative risk estimates from the individual studies are pooled together. These meta-analyses show that there is a statistically significant and consistent association between lung cancer risk in spouses of smokers and exposure to secondhand tobacco smoke from the spouse who smokes. The excess risk is of the order of 20% for women and 30% for men and remains after controlling for some potential sources of bias and confounding. The excess risk increases with increasing exposure. Furthermore, other published meta-analyses of lung cancer in never-smokers exposed to secondhand tobacco smoke at the workplace have found a statistically significant increase in risk of 12–19%. This evidence is sufficient to conclude that involuntary smoking is a cause of lung cancer in never-smokers. The magnitudes of the observed risks are reasonably consistent with predictions based on studies of active smoking in many populations.

Breast cancer

The collective evidence on breast cancer risk associated with involuntary exposure of never-smokers to tobacco smoke is inconsistent. Although four of the 10 case–control studies found statistically significant increases in risks, prospective cohort studies as a whole and, particularly, the two large cohort studies in the USA of nurses and of volunteers in the Cancer Prevention Study II provided no support for a causal relation between involuntary exposure to tobacco smoke and breast cancer in never-smokers. The lack of a positive dose–response also argues against a causal interpretation of these findings. Finally, the lack of an association of breast cancer with active smoking weighs heavily against the possibility that involuntary smoking increases the risk for breast cancer, as no data are available to establish that different mechanisms of carcinogenic action operate at the different dose levels of active and of involuntary smoking.

Childhood cancer

Overall, the findings from studies of childhood cancer and exposure to parental smoking are inconsistent and are likely to be affected by bias. There is a suggestion of a modest association between exposure to maternal tobacco smoke during pregnancy and childhood cancer for all cancer sites combined; however, this is in contrast with the null findings for individual sites. Studies on paternal tobacco smoking suggest a small increased risk for lymphomas, but bias and confounding cannot be ruled out.

Other cancer sites

Data are conflicting and sparse for associations between involuntary smoking and cancers of the nasopharynx, nasal cavity, paranasal sinuses, cervix, gastrointestinal tract and cancers at all sites combined. It is unlikely that any effects are produced in passive

smokers that are not produced to a greater extent in active smokers or that types of effects that are not seen in active smokers will be seen in passive smokers.

5.3 Animal carcinogenicity data

Secondhand tobacco smoke for carcinogenicity studies in animals is produced by machines that simulate human active smoking patterns and combine mainstream and sidestream smoke in various proportions. Such mixtures have been tested for carcinogenicity by inhalation studies in rodents. The experimental model systems for exposure to secondhand tobacco smoke do not fully simulate human exposures, and the tumours that develop in animals are not completely representative of human cancer. Nevertheless, the animal data provide valuable insights regarding the carcinogenic potential of secondhand tobacco smoke.

A mixture of 89% sidestream smoke and 11% mainstream smoke has been tested for carcinogenic activity in mouse strains that are highly susceptible to lung tumours (strains A/J and Swiss). In strain A/J mice, this mixture consistently produces a significant, modest increase in lung tumour incidence and lung tumour multiplicity when the mice are exposed for 5 months followed by a 4-month recovery period. These lung tumours are predominantly adenomas. Continuous exposure of strain A/J mice to the above mixture of mainstream and sidestream tobacco smoke for 9 months with no recovery period did not increase the incidence of lung tumours. In Swiss strain mice, the same mixture induced lung tumours by both protocols, i.e. when the animals were exposed for 5 months followed by a 4-month recovery period and when they were exposed continuously for 9 months with no recovery period. In addition, exposure of Swiss mice to the tobacco smoke mixture for a shorter period was sufficient to induce lung tumours.

Condensates of sidestream and of mainstream cigarette smoke have been tested for carcinogenicity. Both kinds of condensates produced a spectrum of benign and malignant skin tumours in mice following topical application, and the sidestream condensate exhibited higher carcinogenic activity. Sidestream smoke condensate was shown to produce a dose–dependent increase in lung tumours in rats following implantation into the lungs.

Increased relative risks for lung and sinonasal cancer have been reported in companion animals (dogs) exposed to secondhand tobacco smoke in homes.

5.4 Other relevant data

Involuntary smoking has been associated with a number of non-neoplastic diseases and adverse effects in never-smokers, including both children and adults. Epidemiological studies have demonstrated that exposure to secondhand tobacco smoke is causally associated with coronary heart disease. From the available meta-analyses, it has been estimated that involuntary smoking increases the risk of an acute coronary heart disease event by 25–35%. Adverse effects of involuntary smoking on the respiratory system have also been detected. In adults, the strongest evidence for a causal relation exists for chronic

respiratory symptoms. Some effects on lung function have been detected, but their medical relevance is uncertain.

Data on the hormonal and metabolic effects of involuntary smoking are sparse. However, female involuntary smokers do not appear to weigh less than women who are not exposed to secondhand tobacco smoke, a pattern that contrasts with the findings for active smoking. No consistent association of maternal exposure to secondhand smoke with fertility or fecundity has been identified. There is no clear association of passive smoking with age at menopause.

Maternal cigarette smoking has repeatedly been associated with adverse effects on fetal growth; full-term infants born to women who smoke weigh about 200 g less than those born to nonsmokers. A smaller adverse effect has been attributed to maternal passive smoking.

Cotinine, and its parent compound nicotine, are highly specific for exposure to secondhand smoke. Because of its favourable biological half-life and the sensitivity of techniques for quantifying it, cotinine is currently the most suitable biomarker for assessing recent exposure to secondhand tobacco smoke uptake and metabolism in adults, children and newborns.

Several studies in humans have shown that concentrations of adducts of carcinogens to biological macromolecules, including haemoglobin adducts of aromatic amines and albumin adducts of polycyclic aromatic hydrocarbons, are higher in adult involuntary smokers and in the children of smoking mothers than in individuals not exposed to secondhand tobacco smoke. Protein adduct concentrations in fetal cord blood correlate with those in maternal blood but are lower. Fewer studies have investigated DNA adduct levels in white blood cells of exposed and unexposed nonsmokers, and most studies have not shown clear differences.

In studies of urinary biomarkers, metabolites of the tobacco-specific carcinogen, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, have been found to be consistently elevated in involuntary smokers. Levels of these metabolites are 1–5% as great as those found in smokers. The data demonstrating uptake of 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, a lung carcinogen in rodents, by nonsmokers are supportive of a causal link between exposure to secondhand tobacco smoke and development of lung cancer.

The exposure of experimental animals, primarily rodents, to secondhand tobacco smoke has several biological effects that include (i) increases or decreases in the activity of phase I enzymes involved in carcinogen metabolism; (ii) increased expression of nitric oxide synthase, xanthine oxidase and various protein kinases; (iii) the formation of smoke-related DNA adducts in several tissues; and (iv) the presence of urinary biomarkers of exposure to tobacco smoke.

In adult experimental animals, sidestream tobacco smoke has been found to produce changes that are similar to those observed with exposure of humans to secondhand tobacco smoke. These include inflammatory changes in the airways and accelerated formation of arteriosclerotic plaques. Although the changes are often comparatively minor and require exposure to rather elevated concentrations of sidestream smoke, they support

the results of human epidemiological studies. During pre- and postnatal exposure, sidestream smoke produces intrauterine growth retardation, changes the pattern of metabolic enzymes in the developing lung, and gives rise to hyperplasia of the pulmonary neuroendocrine cell population. In addition, it adversely affects pulmonary compliance and airway responsiveness to pharmacological challenges.

In humans, involuntary smoking is associated with increased concentrations of mutagens in urine. Some studies have shown a correlation of urinary mutagenicity with concentrations of urinary cotinine. Increased levels of sister chromatid exchange have not been observed in involuntary smokers; however, there is some indication of elevated levels in exposed children. Lung tumours from nonsmokers exposed to tobacco smoke contain *TP53* and *KRAS* mutations that are similar to those found in tumours from smokers. The genotoxicity of sidestream smoke, 'environmental' tobacco smoke, sidestream smoke condensate or a mixture of sidestream and mainstream smoke condensates has been demonstrated in experimental systems *in vitro* and *in vivo*.

5.5 Evaluation

There is *sufficient evidence* that involuntary smoking (exposure to secondhand or 'environmental' tobacco smoke) causes lung cancer in humans.

There is *limited evidence* in experimental animals for the carcinogenicity of mixtures of mainstream and sidestream tobacco smoke.

There is *sufficient evidence* in experimental animals for the carcinogenicity of sidestream smoke condensates.

In addition, the Working Group noted that there are published reports on possible carcinogenic effects of secondhand tobacco smoke in household pet dogs.

Overall evaluation

Involuntary smoking (exposure to secondhand or 'environmental' tobacco smoke) is *carcinogenic to humans (Group 1)*.

LIST OF ABBREVIATIONS USED IN THIS VOLUME

3-ABP: 3-aminobiphenyl
4-ABP: 4-aminobiphenyl
AC: adenylyl cyclase
AH: acetylhydrolase
AHH: aryl hydrocarbon hydroxylase
ALDH: aldehyde dehydrogenase
AMI: acute myocardial infarction
ApoE: apolipoprotein E
B*a*P: benzo[*a*]pyrene
BPDE: benzo[*a*]pyrene diolepoxide
CDK: cyclin-dependent kinase
CEVal: *N*-(2-cyanoethyl)valine
ChAT: choline acetyltransferase
CHD: coronary heart disease
CO: carbon monoxide
COHb: carboxyhaemoglobin
COPD: chronic obstructive pulmonary disease
COTAC: cotinine acid 4-(methylamino)-4-(3-pyridyl)butyric acid
COX: cyclooxygenase
CSC: cigarette smoke condensate
DDD: dichlorodiphenyldichloroethane
DDE: 1,1-dichloro-2,2-bis(p-chlorophenyl)ethylene
DDT: 1,1,1-trichloro-2,2-di-(4-chlorophenyl)ethane
DHEAS: dihydroepiandrosterone sulfate
DMBA: 7,12-dimethylbenz[*a*]anthracene
DRZ: diagonal radioactive zone
EH: epoxide hydrolase
ELISA: enzyme-linked immunosorbent assay
ERK: extracellular signal-regulated protein kinase
FAL: fractional allelic loss
FCTC: Framework Convention on Tobacco Control
FEF: forced expiratory flow

FEV_1: forced expiratory volume in 1 second
FGF-2: fibroblast growth factor-2
***FHIT* gene**: a gene coding for a dinucleoside 5′,5‴-P^1,P^3-triphosphate hydrolase, a putative tumour suppressor protein
FID: flame ionizing detection
FISH: fluorescence in-situ hybridization
FPM: fluorescent particular matter
FTC: Federal Trade Commission
FVC: forced vital capacity
GC–MS: gas chromatography–mass spectrometry
gluc: glucuronide
GSH: glutathione
GST: glutathione-*S*-transferase
HCAs: heterocyclic amines
HC-3: [^{3}H]hemicholinium-3
HOEtVal: *N*-(2-hydroxyethyl)valine
1-HOP: 1-hydroxypyrene
HPB: 4-hydroxy-1-(3-pyridyl)-1-butanone
HPLC: high-performance liquid chromatography
ICCSS: International Committee for Cigar Smoke Study
IgE: immunoglobulin E
IGF1: insulin-like growth factor 1
IgG: immunoglobulin G
IHD: ischaemic heart disease
IL: interleukin
iNOS: inducible nitric oxide synthase
ISO: International Standardization Organization
***iso*-NNAC**: 4-(*N*-nitrosomethylamino)-4-(3-pyridyl)butyric acid
KRAS oncogene: Kirsten-*ras* oncogene
LALN: lung-associated lymph nodes
LDL: low-density lipoproteins
LOH: loss of heterozygosity
MAPK: mitogen-activated protein kinase
7-MedG: 7-methyldeoxyriboguanosine
MEF: maximal expiratory flow
MEH: mitochondriol epoxyde hydrolase
MEK1: mitogen-activated extracellular kinase 1
MeP: methylpurine
MF: mutant frequency
MT: myocardial infarction
NAC: *N*-acetyl-L-cysteine
nAChRs: nicotinic acetylcholine receptors

NADPH: nicotinamide-adenine dinucleotide phosphate
NAT: *N*-acetyltransferase
NBOPA: *N*-nitrosobis(2-oxopropyl)amine
NDEA: *N*-nitrosodiethylamine
NDELA: *N*-nitrosodiethanolamine
NDMA: *N*-nitrosodimethylamine
NEMA: *N*-nitroethylmethylamine
NF: nuclear factor
nic: nicotine
NMBA: 4-(*N*-nitroso-*N*-methylamino)butyric acid
NMPA: 3-(*N*-nitroso-*N*-methylamino)propionic acid
NMTCA: *N*-nitroso-2-methylthiazolidine 4-carboxylic acid
iso-NNAC: see under *iso*
NNAL: 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanol
NNAL-*O*-gluc: [4-(methylnitrosamino)-1-(3-pyridyl)but-1-yl]-β-*O*-D-glucosiduronic acid
NNK: 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone
NNN: *N*′-nitrosonornicotine
NO: nitric oxide
NO_2: nitrogen dioxide, also called nitrous oxide
NOx: nitrogen oxides
NOS: NO synthase
NPIC: *N*-nitrosopipecolic acid
NPIP: *N*-nitropiperidine
NPRO: *N*-nitrosoproline
NPYR: *N*-nitrosopyrrolidine
NSAR: *N*-nitrososarcosine
NTCA: *N*-nitrosothiazolidine 4-carboxylic acid
***O*^{6}-MedG**: O^6-methyldeoxyriboguanosine
25-OH vitamin D: 25-hydroxyvitamin D
8-OHdG: 8-hydroxy-2′-deoxyguanosine
OVA/AL: aluminium hydroxide-precipitated ovalbumin
8-oxodG: 8-oxo-7,8-dihydro-2′-deoxyguanosine
P450: cytochrome P450
PAF: platelet-activating factor
PAH: polycyclic aromatic hydrocarbons
PCDD: polychlorodibenzodioxins
PCDF: polychlorodibenzofurans
PEF: peak expiratory flow
PhIP: 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine
PKC: protein kinase C
RB gene: retinoblastoma gene

ROS: reactive oxygen species
RSP: respirable suspended particles
RYO: roll-your-own
SCN: serum thiocyanate
SFS: synchronous fluorescence spectroscopy
SH: spontaneously hypertensive
S-PMA: *S*-phenylmercapturic acid
S9: supernatant of 9000 g centrifugation
tar: particulate phase
TCDD: 2,3,7,8-tetrachloro-*para*-dibenzodioxin
TPM: total particulate matter
TSNA: tobacco-specific nitrosamines
***tt*-MA**: *trans*,*trans*-muconic acid
UDP: uridine-5′-diphosphate
UGT: uridine-5′-diphosphate glucuronosyltransferase
UVPM: ultraviolet particulate matter
V(D)J recombination: combinatorial rearrangement of multiple V (variable), D (diversity) and J (junctional) coding gene segments
VOC: volatile organic compounds
WBC: white blood cell

Uracil mustard	*9*, 235 (1975); *Suppl. 7*, 370 (1987)
Uranium, depleted (*see* Implants, surgical)	
Urethane	*7*, 111 (1974); *Suppl. 7*, 73 (1987)

V

Vat Yellow 4 *48*, 161 (1990)
Vinblastine sulfate *26*, 349 (1981) (*corr. 42*, 261); *Suppl. 7*, 371 (1987)
Vincristine sulfate *26*, 365 (1981); *Suppl. 7*, 372 (1987)
Vinyl acetate *19*, 341 (1979); *39*, 113 (1986); *Suppl. 7*, 73 (1987); *63*, 443 (1995)
Vinyl bromide *19*, 367 (1979); *39*, 133 (1986); *Suppl. 7*, 73 (1987); *71*, 923 (1999)
Vinyl chloride *7*, 291 (1974); *19*, 377 (1979) (*corr. 42*, 258*); Suppl. 7*, 373 (1987)
Vinyl chloride-vinyl acetate copolymers *7*, 311 (1976); *19*, 412 (1979) (*corr. 42*, 258); *Suppl. 7*, 73 (1987)
4-Vinylcyclohexene *11*, 277 (1976); *39*, 181 (1986) *Suppl. 7*, 73 (1987); *60*, 347 (1994)
4-Vinylcyclohexene diepoxide *11*, 141 (1976); *Suppl. 7*, 63 (1987); *60*, 361 (1994)
Vinyl fluoride *39*, 147 (1986); *Suppl. 7*, 73 (1987); *63*, 467 (1995)
Vinylidene chloride *19*, 439 (1979); *39*, 195 (1986); *Suppl. 7*, 376 (1987); *71*, 1163 (1999)
Vinylidene chloride-vinyl chloride copolymers *19*, 448 (1979) (*corr. 42*, 258); *Suppl. 7*, 73 (1987)
Vinylidene fluoride *39*, 227 (1986); *Suppl. 7*, 73 (1987); *71*, 1551 (1999)
N-Vinyl-2-pyrrolidone *19*, 461 (1979); *Suppl. 7*, 73 (1987); *71*, 1181 (1999)
Vinyl toluene *60*, 373 (1994)
Vitamin K substances *76*, 417 (2000)

W

Welding *49*, 447 (1990) (*corr. 52*, 513)
Wollastonite *42*, 145 (1987); *Suppl. 7*, 377 (1987); *68*, 283 (1997)
Wood dust *62*, 35 (1995)
Wood industries *25* (1981); *Suppl. 7*, 378 (1987)

X

X-radiation *75*, 121 (2000)
Xylenes *47*, 125 (1989); *71*, 1189 (1999)
2,4-Xylidine *16*, 367 (1978); *Suppl. 7*, 74 (1987)
2,5-Xylidine *16*, 377 (1978); *Suppl. 7*, 74 (1987)
2,6-Xylidine (*see* 2,6-Dimethylaniline)

Y

Yellow AB	*8*, 279 (1975); *Suppl. 7*, 74 (1987)
Yellow OB	*8*, 287 (1975); *Suppl. 7*, 74 (1987)

Z

Zalcitabine	*76*, 129 (2000)
Zearalenone (*see* Toxins derived from *Fusarium graminearum*, *F. culmorum* and *F. crookwellense*)	
Zectran	*12*, 237 (1976); *Suppl. 7*, 74 (1987)
Zeolites other than erionite	*68*, 307 (1997)
Zidovudine	*76*, 73 (2000)
Zinc beryllium silicate (*see* Beryllium and beryllium compounds)	
Zinc chromate (*see* Chromium and chromium compounds)	
Zinc chromate hydroxide (*see* Chromium and chromium compounds)	
Zinc potassium chromate (*see* Chromium and chromium compounds)	
Zinc yellow (*see* Chromium and chromium compounds)	
Zineb	*12*, 245 (1976); *Suppl. 7*, 74 (1987)
Ziram	*12*, 259 (1976); *Suppl. 7*, 74 (1987); *53, 423* (1991)

List of IARC Monographs on the Evaluation of Carcinogenic Risks to Humans*

Volume 1
Some Inorganic Substances, Chlorinated Hydrocarbons, Aromatic Amines, *N*-Nitroso Compounds, and Natural Products
1972; 184 pages (out-of-print)

Volume 2
Some Inorganic and Organometallic Compounds
1973; 181 pages (out-of-print)

Volume 3
Certain Polycyclic Aromatic Hydrocarbons and Heterocyclic Compounds
1973; 271 pages (out-of-print)

Volume 4
Some Aromatic Amines, Hydrazine and Related Substances, *N*-Nitroso Compounds and Miscellaneous Alkylating Agents
1974; 286 pages (out-of-print)

Volume 5
Some Organochlorine Pesticides
1974; 241 pages (out-of-print)

Volume 6
Sex Hormones
1974; 243 pages (out-of-print)

Volume 7
Some Anti-Thyroid and Related Substances, Nitrofurans and Industrial Chemicals
1974; 326 pages (out-of-print)

Volume 8
Some Aromatic Azo Compounds
1975; 357 pages

Volume 9
Some Aziridines, *N*-, *S*- and *O*-Mustards and Selenium
1975; 268 pages

Volume 10
Some Naturally Occurring Substances
1976; 353 pages (out-of-print)

Volume 11
Cadmium, Nickel, Some Epoxides, Miscellaneous Industrial Chemicals and General Considerations on Volatile Anaesthetics
1976; 306 pages (out-of-print)

Volume 12
Some Carbamates, Thiocarbamates and Carbazides
1976; 282 pages (out-of-print)

Volume 13
Some Miscellaneous Pharmaceutical Substances
1977; 255 pages

Volume 14
Asbestos
1977; 106 pages (out-of-print)

Volume 15
Some Fumigants, the Herbicides 2,4-D and 2,4,5-T, Chlorinated Dibenzodioxins and Miscellaneous Industrial Chemicals
1977; 354 pages (out-of-print)

Volume 16
Some Aromatic Amines and Related Nitro Compounds—Hair Dyes, Colouring Agents and Miscellaneous Industrial Chemicals
1978; 400 pages

Volume 17
Some *N*-Nitroso Compounds
1978; 365 pages

Volume 18
Polychlorinated Biphenyls and Polybrominated Biphenyls
1978; 140 pages (out-of-print)

Volume 19
Some Monomers, Plastics and Synthetic Elastomers, and Acrolein
1979; 513 pages (out-of-print)

Volume 20
Some Halogenated Hydrocarbons
1979; 609 pages (out-of-print)

Volume 21
Sex Hormones (II)
1979; 583 pages

Volume 22
Some Non-Nutritive Sweetening Agents
1980; 208 pages

Volume 23
Some Metals and Metallic Compounds
1980; 438 pages (out-of-print)

Volume 24
Some Pharmaceutical Drugs
1980; 337 pages

Volume 25
Wood, Leather and Some Associated Industries
1981; 412 pages

Volume 26
Some Antineoplastic and Immunosuppressive Agents
1981; 411 pages

Volume 27
Some Aromatic Amines, Anthraquinones and Nitroso Compounds, and Inorganic Fluorides Used in Drinking-water and Dental Preparations
1982; 341 pages

Volume 28
The Rubber Industry
1982; 486 pages

Volume 29
Some Industrial Chemicals and Dyestuffs
1982; 416 pages

Volume 30
Miscellaneous Pesticides
1983; 424 pages

---

*Certain older volumes, marked out-of-print, are still available directly from IARCPress. Further, high-quality photocopies of all out-of-print volumes may be purchased from University Microfilms International, 300 North Zeeb Road, Ann Arbor, MI 48106-1346, USA (Tel.: 313-761-4700, 800-521-0600).

Volume 31
Some Food Additives, Feed Additives and Naturally Occurring Substances
1983; 314 pages (out-of-print)

Volume 32
Polynuclear Aromatic Compounds, Part 1: Chemical, Environmental and Experimental Data
1983; 477 pages (out-of-print)

Volume 33
Polynuclear Aromatic Compounds, Part 2: Carbon Blacks, Mineral Oils and Some Nitroarenes
1984; 245 pages (out-of-print)

Volume 34
Polynuclear Aromatic Compounds, Part 3: Industrial Exposures in Aluminium Production, Coal Gasification, Coke Production, and Iron and Steel Founding
1984; 219 pages

Volume 35
Polynuclear Aromatic Compounds, Part 4: Bitumens, Coal-tars and Derived Products, Shale-oils and Soots
1985; 271 pages

Volume 36
Allyl Compounds, Aldehydes, Epoxides and Peroxides
1985; 369 pages

Volume 37
Tobacco Habits Other than Smoking; Betel-Quid and Areca-Nut Chewing; and Some Related Nitrosamines
1985; 291 pages

Volume 38
Tobacco Smoking
1986; 421 pages

Volume 39
Some Chemicals Used in Plastics and Elastomers
1986; 403 pages

Volume 40
Some Naturally Occurring and Synthetic Food Components, Furocoumarins and Ultraviolet Radiation
1986; 444 pages

Volume 41
Some Halogenated Hydrocarbons and Pesticide Exposures
1986; 434 pages

Volume 42
Silica and Some Silicates
1987; 289 pages

Volume 43
Man-Made Mineral Fibres and Radon
1988; 300 pages

Volume 44
Alcohol Drinking
1988; 416 pages

Volume 45
Occupational Exposures in Petroleum Refining; Crude Oil and Major Petroleum Fuels
1989; 322 pages

Volume 46
Diesel and Gasoline Engine Exhausts and Some Nitroarenes
1989; 458 pages

Volume 47
Some Organic Solvents, Resin Monomers and Related Compounds, Pigments and Occupational Exposures in Paint Manufacture and Painting
1989; 535 pages

Volume 48
Some Flame Retardants and Textile Chemicals, and Exposures in the Textile Manufacturing Industry
1990; 345 pages

Volume 49
Chromium, Nickel and Welding
1990; 677 pages

Volume 50
Pharmaceutical Drugs
1990; 415 pages

Volume 51
Coffee, Tea, Mate, Methyl-xanthines and Methylglyoxal
1991; 513 pages

Volume 52
Chlorinated Drinking-water; Chlorination By-products; Some Other Halogenated Compounds; Cobalt and Cobalt Compounds
1991; 544 pages

Volume 53
Occupational Exposures in Insecticide Application, and Some Pesticides
1991; 612 pages

Volume 54
Occupational Exposures to Mists and Vapours from Strong Inorganic Acids; and Other Industrial Chemicals
1992; 336 pages

Volume 55
Solar and Ultraviolet Radiation
1992; 316 pages

Volume 56
Some Naturally Occurring Substances: Food Items and Constituents, Heterocyclic Aromatic Amines and Mycotoxins
1993; 599 pages

Volume 57
Occupational Exposures of Hairdressers and Barbers and Personal Use of Hair Colourants; Some Hair Dyes, Cosmetic Colourants, Industrial Dyestuffs and Aromatic Amines
1993; 428 pages

Volume 58
Beryllium, Cadmium, Mercury, and Exposures in the Glass Manufacturing Industry
1993; 444 pages

Volume 59
Hepatitis Viruses
1994; 286 pages

Volume 60
Some Industrial Chemicals
1994; 560 pages

Volume 61
Schistosomes, Liver Flukes and *Helicobacter pylori*
1994; 270 pages

Volume 62
Wood Dust and Formaldehyde
1995; 405 pages

Volume 63
Dry Cleaning, Some Chlorinated Solvents and Other Industrial Chemicals
1995; 551 pages

Volume 64
Human Papillomaviruses
1995; 409 pages

Volume 65
Printing Processes and Printing Inks, Carbon Black and Some Nitro Compounds
1996; 578 pages

Volume 66
Some Pharmaceutical Drugs
1996; 514 pages

Volume 67
Human Immunodeficiency Viruses and Human T-Cell Lymphotropic Viruses
1996; 424 pages

Volume 68
Silica, Some Silicates, Coal Dust and *para*-Aramid Fibrils
1997; 506 pages

Volume 69
Polychlorinated Dibenzo-*para*-Dioxins and Polychlorinated Dibenzofurans
1997; 666 pages

Volume 70
Epstein-Barr Virus and Kaposi's Sarcoma Herpesvirus/Human Herpesvirus 8
1997; 524 pages

Volume 71
Re-evaluation of Some Organic Chemicals, Hydrazine and Hydrogen Peroxide
1999; 1586 pages

Volume 72
Hormonal Contraception and Post-menopausal Hormonal Therapy
1999; 660 pages

Volume 73
Some Chemicals that Cause Tumours of the Kidney or Urinary Bladder in Rodents and Some Other Substances
1999; 674 pages

Volume 74
Surgical Implants and Other Foreign Bodies
1999; 409 pages

Volume 75
Ionizing Radiation, Part 1, X-Radiation and γ-Radiation, and Neutrons
2000; 492 pages

Volume 76
Some Antiviral and Anti-neoplastic Drugs, and Other Pharmaceutical Agents
2000; 522 pages

Volume 77
Some Industrial Chemicals
2000; 563 pages

Volume 78
Ionizing Radiation, Part 2, Some Internally Deposited Radionuclides
2001; 595 pages

Volume 79
Some Thyrotropic Agents
2001; 763 pages

Volume 80
Non-Ionizing Radiation, Part 1: Static and Extremely Low-Frequency (ELF) Electric and Magnetic Fields
2002; 429 pages

Volume 81
Man-made Vitreous Fibres
2002; 418 pages

Volume 82
Some Traditional Herbal Medicines, Some Mycotoxins, Naphthalene and Styrene
2002; 590 pages

Volume 83
Tobacco Smoke and Involuntary Smoking
2004; 1452 pages

Supplement No. 1
Chemicals and Industrial Processes Associated with Cancer in Humans (*IARC Monographs*, Volumes 1 to 20)
1979; 71 pages (out-of-print)

Supplement No. 2
Long-term and Short-term Screening Assays for Carcinogens: A Critical Appraisal
1980; 426 pages (out-of-print)
(updated as IARC Scientific Publications No. 83, 1986)

Supplement No. 3
Cross Index of Synonyms and Trade Names in Volumes 1 to 26 of the *IARC Monographs*
1982; 199 pages (out-of-print)

Supplement No. 4
Chemicals, Industrial Processes and Industries Associated with Cancer in Humans (*IARC Monographs*, Volumes 1 to 29)
1982; 292 pages (out-of-print)

Supplement No. 5
Cross Index of Synonyms and Trade Names in Volumes 1 to 36 of the *IARC Monographs*
1985; 259 pages (out-of-print)

Supplement No. 6
Genetic and Related Effects: An Updating of Selected *IARC Monographs* from Volumes 1 to 42
1987; 729 pages

Supplement No. 7
Overall Evaluations of Carcinogenicity: An Updating of *IARC Monographs* Volumes 1–42
1987; 440 pages

Supplement No. 8
Cross Index of Synonyms and Trade Names in Volumes 1 to 46 of the *IARC Monographs*
1990; 346 pages (out-of-print)

All IARC publications are available directly from
IARCPress, 150 Cours Albert Thomas, 69372 Lyon cedex 08, France
(Fax: +33 4 72 73 83 02; E-mail: press@iarc.fr).

IARC Monographs and Technical Reports are also available from the
World Health Organization Marketing and Dissemination, 1211 Geneva 27, Switzerland
(Fax: +41 22 791 4857; E-mail: publications@who.int)
and from WHO Sales Agents worldwide.

IARC Scientific Publications, IARC Handbooks and IARC CancerBases are also available from
Oxford University Press, Walton Street, Oxford, UK OX2 6DP (Fax: +44 1865 267782).

IARC Monographs are also available in an electronic edition,
both on-line by internet and on CD-ROM, from GMA Industries, Inc.,
20 Ridgely Avenue, Suite 301, Annapolis, Maryland, USA
(Fax: +01 410 267 6602; internet: https//www.gmai.com/Order_Form.htm)
