Overview information for

Nicotine free dry aerosol collected mass (NFDACM)

TOBACCO SMOKING

Tobacco smoking was considered by previous IARC Working Groups in 1986, 1987 and 2002 (IARC, 1986, 1987, 2004a). Since that time, new data have become available, these have been incorporated into the *Monograph*, and taken into consideration in the present evaluation.

1. Exposure Data

1.1 Smoked tobacco products

Smoked forms of tobacco include various kinds of cigarettes (manufactured, hand-rolled, filtered, un-filtered and flavoured), cigars and pipes. While cigarette smoking, particularly manufactured cigarettes, is by far the main form of tobacco smoked globally, in some countries other forms of smoked tobacco are dominant (IARC, 2004a). In India, for example, bidis (made of coarse and uncured tobacco) account for about 60% of smoked tobacco products whereas cigarettes account for 20% (Ray & Gupta, 2009; IIPS, 2010). Water pipes, another form of smoked tobacco known by other various names such as gaza, hookah, narghile, shisha, hubble-bubble, are commonly smoked in the Eastern Mediterranean region, in some parts of Asia including India, and in North Africa (Asma *et al.*, 2009).

1.2 Chemical composition of tobacco smoke

1.2.1 Smoke from cigarettes

One cubic cm of fresh, un-aged cigarette mainstream smoke [the smoke emerging from the mouth end of a cigarette during smoking] has about 4×10^9 particles with a mean diameter of about 0.2 μm (Borgerding & Klus, 2005). The size of the particles increases as the smoke ages. Temperatures in the burning cone of the cigarette are about 800 °C during the smoulder period between puffs and increase to 910–920 °C at the periphery of the cone during puffing (Borgerding & Klus, 2005). Hydrogen is generated in the glowing cone, resulting in an oxygen deficient reducing atmosphere (Borgerding & Klus, 2005). The approximate composition of mainstream smoke of a plain cigarette is summarized in Table 1.1 (Borgerding & Klus, 2005). The total particulate matter, after subtraction of the amounts of nicotine and water, is referred to as 'tar'.

Over 5300 compounds have been identified in tobacco smoke (Rodgman & Perfetti, 2009). Classes of compounds include but are not limited to neutral gases, carbon and nitrogen oxides, amides, imides, lactams, carboxylic acids, lactones, esters, aldehydes, ketones,

Table 1.1 Approximate chemical composition of mainstream smoke generated by a plain cigarette

From Borgerding & Klus (2005)

alcohols, phenols, amines, *N*-nitrosamines, *N*-heterocyclics, aliphatic hydrocarbons, monocyclic and polycyclic aromatic hydrocarbons (PAHs), nitriles, anhydrides, carbohydrates, ethers, nitro compounds and metals (Rodgman & Perfetti, 2009).

The addictive properties of tobacco smoke are attributed to nicotine, the principal tobacco alkaloid in smoke (Hukkanen *et al.*, 2005). Minor tobacco alkaloids include nornicotine, anatabine and anabasine (Hukkanen *et al.*, 2005). The tobacco alkaloids are not generally considered carcinogenic, but are accompanied by carcinogens in each puff of smoke.

There are over 70 carcinogens in tobacco smoke that have been evaluated by the *IARC Monographs* programme as having sufficient evidence for carcinogenicity in either laboratory animals or humans (IARC, 2004a). The different chemical classes of carcinogens and representatives of each are presented in Table 1.2 (IARC, 2004a). Sixteen of these – benzo[*a*]pyrene (BaP), 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) and *N*′-nitrosonornicotine (NNN), 2-naphthylamine, 4-aminobiphenyl, formaldehyde, 1,3-butadiene, benzene, vinyl chloride, ethylene oxide, arsenic, beryllium, nickel compounds, chromium VI, cadmium, and polonium-210 – are classified as carcinogenic to humans (Group 1). Structures of some representative carcinogens in cigarette smoke are shown in Fig. 1.1. There are other likely carcinogens in cigarette smoke that have not been evaluated by the *IARC Monographs* programme. These include, for example, PAHs with incompletely characterized occurrence levels and carcinogenic activities; over 500 PAHs have been identified (Rodgman & Perfetti, 2006).

PAHs, tobacco-specific *N*-nitrosamines, aromatic amines, aldehydes and certain volatile organics likely contribute significantly to the carcinogenic activity of tobacco smoke (Hecht, 2003).

In the early part of the 20th century, PAHs were identified as carcinogenic constituents of coal tar (Phillips, 1983). They are products of incomplete combustion of all organic matter and occur, always as complex mixtures, in tars, soots, broiled foods, vehicle engine exhaust and tobacco smoke. PAHs are generally locally acting carcinogens, and some, such as the prototypic compound BaP, have strong carcinogenic activity on mouse skin and in rodent lung. Heterocyclic analogues of PAHs also occur in cigarette smoke. Concentrations of individual PAHs in mainstream cigarette smoke are generally in the range of 1–50 ng per cigarette (IARC, 2004a).

Among the carcinogenic *N*-nitrosamines in tobacco smoke are tobacco-specific *N*-nitrosamines, which are derived from, and structurally related to, the tobacco alkaloids. Two of the most important of these are NNK and NNN (Hecht & Hoffmann, 1988). Levels of NNK and NNN in cigarette smoke vary depending on tobacco type and other factors, but are frequently in the range of 50–200 ng per cigarette (IARC, 2004a).

Aromatic amines were first identified as human carcinogens from industrial exposures in the dye industry in the early part of the 20th century. They include the well known human bladder carcinogens 2-naphthylamine and 4-aminobiphenyl which, along with other

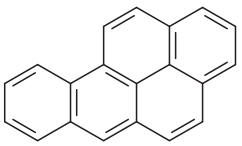
Table 1.2 Tobacco smoke carcinogens evaluated in the *IARC Monographs*

Chemical Class	Number of Carcinogens	Representative Carcinogens
Polycyclic aromatic hydrocarbons (PAHs) and their heterocyclic analogues	15	Benzo[*a*]pyrene (BaP) Dibenz[*a*,*h*]anthracene
N-Nitrosamines	8	4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) *N*′-Nitrosonornicotine (NNN)
Aromatic amines	12	4-Aminobiphenyl 2-Naphthylamine
Aldehydes	2	Formaldehyde Acetaldehyde
Phenols	2	Catechol Caffeic acid
Volatile hydrocarbons	3	Benzene 1,3-Butadiene Isoprene
Other organics	12	Ethylene oxide Acrylonitrile
Inorganic compounds	8	Cadmium Polonium-210

There are many other carcinogens in cigarette smoke that have not been evaluated in an *IARC Monograph*.
From IARC (2004a)

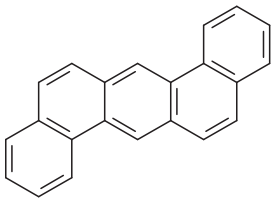
isomers, are found in cigarette smoke, but their levels are generally quite low (1–20 ng per cigarette) (IARC, 2004a).

Aldehydes such as formaldehyde and acetaldehyde occur widely in the human environment and are also found in human blood. Concentrations of acetaldehyde and formaldehyde in cigarette smoke are far higher than those of PAHs, *N*-nitrosamines or aromatic amines but their carcinogenic activities are weak (Hecht, 2003). Cigarette mainstream smoke typically contains 10–30 µg formaldehyde/cigarette and 800–900 µg acetaldehyde/cigarette (IARC, 2004a).



Volatile hydrocarbons in cigarette smoke include 1,3-butadiene, a powerful multi-organ carcinogen in the mouse, and benzene, a known human leukaemogen. 1,3-Butadiene (20–40 µg/cigarette) and benzene (12–50 µg/cigarette) are two of the most prevalent strong carcinogens in cigarette smoke (IARC, 2004a).

In summary, cigarette smoke is an exceedingly complex mixture which contains over 5300 compounds including multiple toxicants and carcinogens.



1.2.2 Smoke from other tobacco products

Some constituents have been measured in roll-your-own cigarettes, and their levels are comparable to or higher than those in commercial brands. Carcinogen and toxicant levels expressed per unit are higher in cigars than in cigarettes because of their larger size, and in some instances are also higher per litre of smoke. Levels of nicotine and tobacco-specific nitrosamines were comparable in bidis and commercial Indian cigarettes; bidis also contain high levels of eugenol, as do kreteks. Levels of NNK and NNN in chuttas were considerably higher than in standard cigarettes (IARC, 2004a).

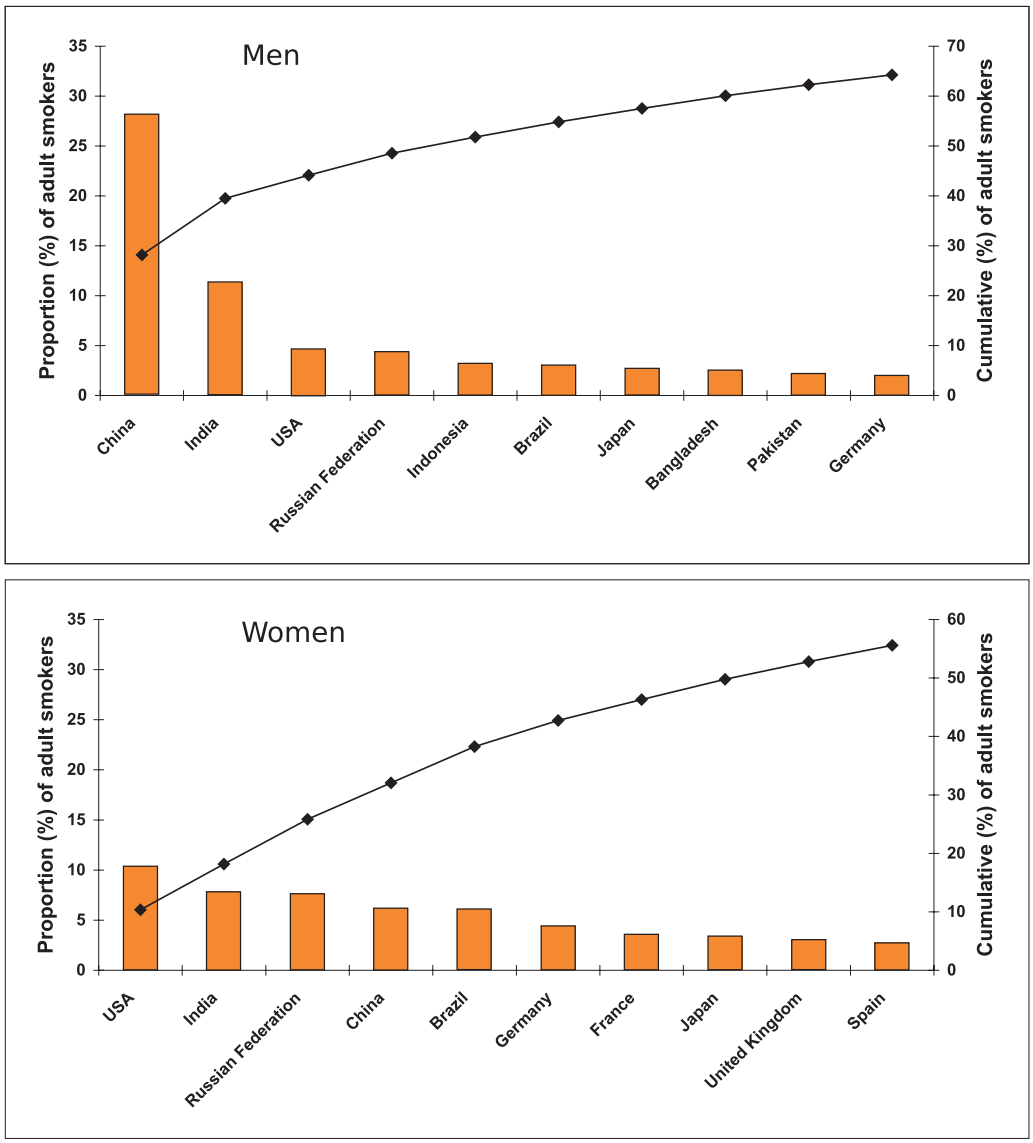
From WHO (2011)

1.3 Prevalence of tobacco smoking

1.3.1 Data collection and methods



Data on smoking tobacco are available from WHO's Global Infobase (www.who.int/infobase) and the WHO Global Health Observatory (www.who.int/gho/en) – repositories of information on tobacco use and other risk factors in young people (13–15 years old) and adults (aged 15 years and over). The data span several years and are acquired from government reports, journals and unpublished sources. WHO has in the recent past used and modelled these data to produce estimates of tobacco smoking prevalence, published in the WHO Reports on the Global Tobacco Epidemic. For a complete explanation of methods used, the reader is referred to the Technical Note on Prevalence in the 3rd WHO Report on the Global Tobacco Epidemic (WHO, 2011). The six WHO regions are: EMRO, Eastern Mediterranean Region; EURO, European Region; AFRO, African Region; WPRO, Western Pacific Region; SEARO, South East Asian Region; AMRO, Region of the Americas. A listing of the countries in each region can be viewed at http://www.who.int/about/structure/en/index.html.

1.3.2 Distribution of smokers by WHO region and country

WHO estimates that in 2009, there was about 1.1 billion adult smokers worldwide, representing nearly a quarter (22%) of the global adult population (WHO, 2011). A disaggregation by the six WHO regions (Fig. 1.2) shows that over a third of smokers worldwide live in WPRO (highly influenced by the People's Republic of China), followed by SEARO, which has around a fifth of the world's smokers (influenced by India and Indonesia).

The number of smokers in any country is a function of both the prevalence of smoking and the size of the population. A further

Fig. 1.3 Proportion and cumulative percentage of smokers in high-burden countries, in men (A) and women (B) in 2009

From WHO (2011)

disaggregation of the regions by country shows that a few countries account for a large proportion of tobacco smokers. Ranked in descending order of the number of smokers, the five countries of China, India, United States of America (USA), Russian Federation and Indonesia account for about 52% of adult smokers in the world, with China and India alone accounting for 40% (Fig. 1.3). Furthermore, nearly two-thirds of the world's smokers live in only ten countries of the world.

1.3.3 Distribution of smokers by sex

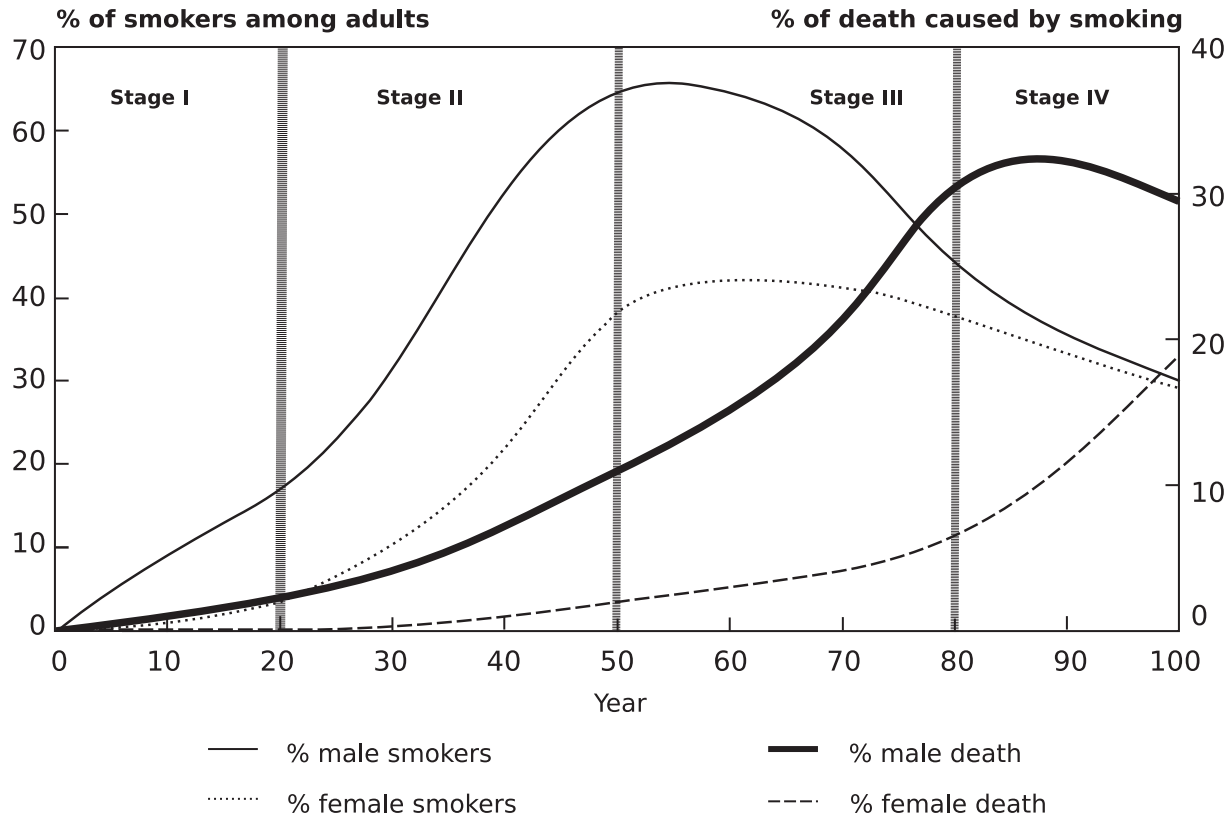
With a global average smoking prevalence of 36%, men account for just over 80% of all smokers. The male adult prevalence is 4–5 times that for women, at 8%. This difference varies across WHO

regions. Smoking among men, concentrated in the five countries of China, India, Indonesia, Russian Federation and USA (Fig. 1.3), accounts for about 56% of global smoking among men. Women smokers are mostly concentrated in EURO and AMRO. These two regions account for 40% and 26% of all women smokers globally, respectively. The prevalences for women in these two regions are about half of those in men, whereas the difference is substantially greater in the other regions. Just as men smoke more than women everywhere, so too among young people, boys generally smoke more than girls. There is an increasing concern, however, that the gap may diminish, not because of a reduction in boys prevalence but because of an increase in the proportion of girls who are taking up smoking (Warren *et al.*, 2006).

1.3.4 The four stage smoking model

(a) The four stages of tobacco use

Lopez *et al.* (1994) used trend data on smoking prevalence and tobacco attributable mortality to show the evolution of tobacco use in a country. Four stages of smoking and attributable mortality have been identified to represent the growth and eventual decline of smoking among men and women (Fig. 1.4).



Stage 1 is characterized by low smoking prevalence in men (less than 15%) and very low in women (less than 10%). Death and disease from smoking are not apparent in this phase, as nearly all health effects from smoking are related to past smoking habits and their cumulative effects rather than current smoking. In Stage 2, smoking prevalence in men rapidly increases while it increases more slowly in women. Towards the end of this stage, smoking prevalence in men typically peaks to lie at 50–60%, with 10% of deaths in men attributable to smoking; deaths in women are comparatively fewer. After a protracted period of high smoking prevalence, Stage 3 shows a decline in smoking prevalence in men to around 40%. Smoking prevalence in women peaks and then begins to decline; towards the end of this stage the gap between men's and women's prevalence starts to narrow. However, smoking attributable deaths in men increase from around 10% to 25–30% within a span of three decades; in women the deaths are increasing but are still quite low. In the final Stage 4, smoking prevalences in both men and women continue to decline albeit relatively slowly in comparison with Stage 3, with the gap substantially narrowing to lie at around five percentage points, and as little as one percentage point in some countries. In Stage 4, smoking mortality in men peaks to between 30–35% and then declines to below 30% at the end of this period. In women, the health effects from past smoking persist, with increasing mortality, but remain lower than in men, and recently have begun to decline in some countries.

(b) Smoking prevalence worldwide

Using prevalence data for men and women collected in 2006 for 140 countries, WHO determined at which stage of the tobacco epidemic countries are in the model of Lopez *et al.* (1994). In Fig. 1.5, countries have been ranked by smoking prevalence in men in ascending order for Stages 1 and 2, and then in descending order for Stages 3 and 4. (Smoking prevalence in men is almost always higher than in women, with a few exceptions observed in the fourth stage.) While most countries fit the classification, there are a few exceptions, most of which in the last stage. Prevalence between Stage 3 and Stage 4 is discontinuous in both sexes. This is due to the classification followed, which puts countries with a relatively narrow difference in prevalence between men and women in Stage 4 even though their prevalence is largely comparable with those in Stage 3.

Most African countries fall in the first stage of the smoking model, characterized by low smoking prevalence in men and very low prevalence in women. Three of the five high burden

Fig. 1.4 The four stages of the tobacco epidemic

From Lopez *et al.* (1994)

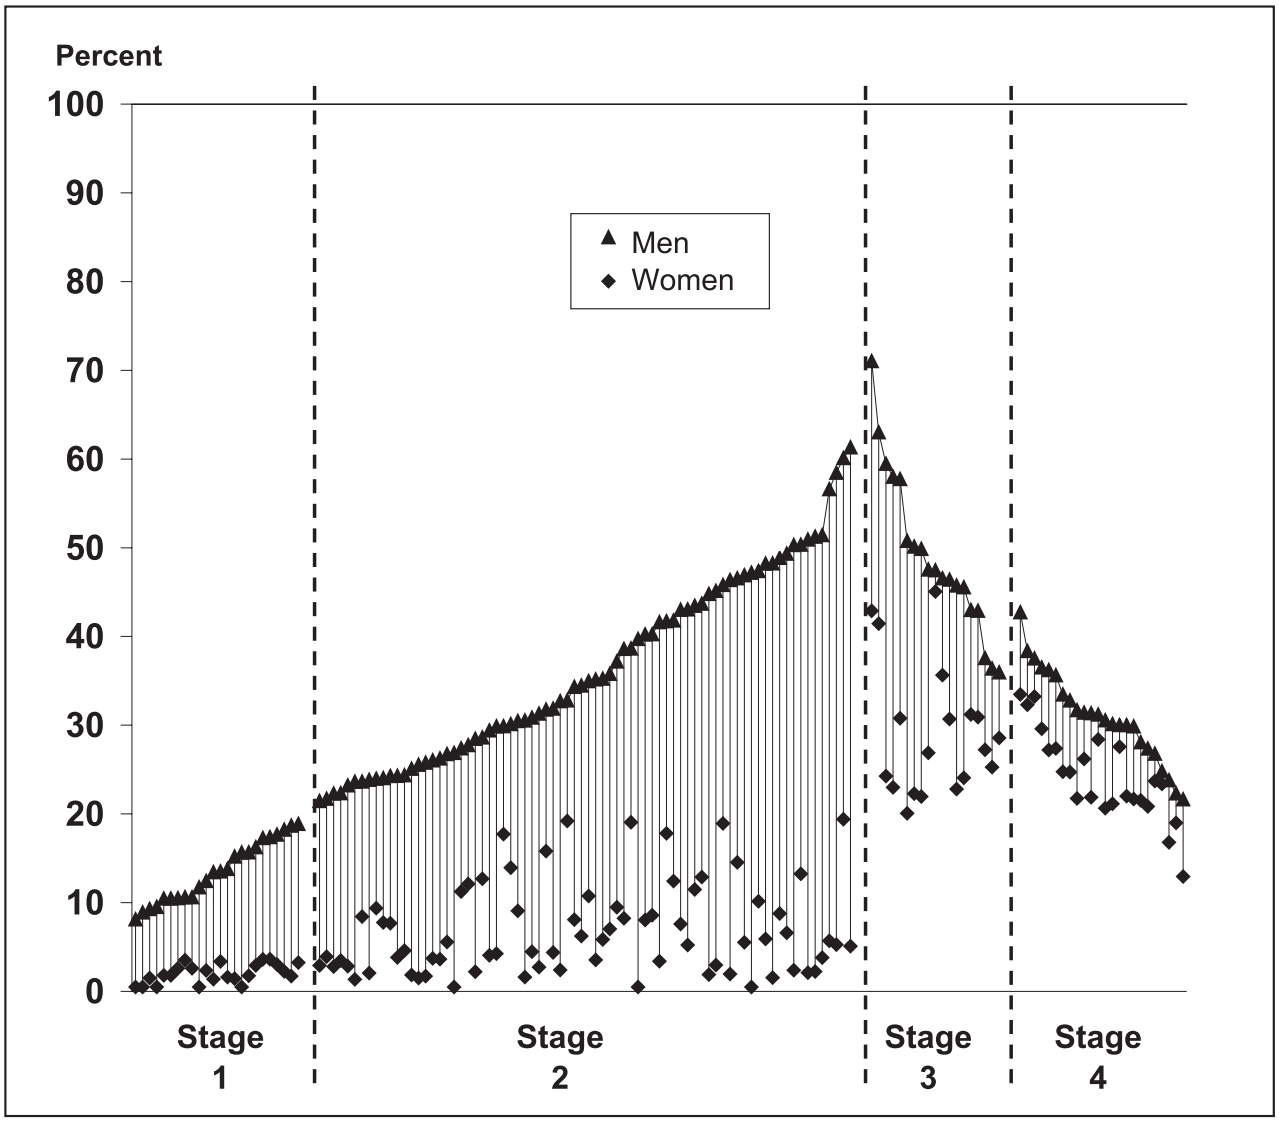
countries fall in stage 2 (India, Indonesia and China), with the rest comprising a combination of countries from Africa, South East Asia, eastern Europe and the Middle East. At this stage smoking prevalences in women continue to remain very low, most countries having a prevalence in adult women of less than 10%.

Stage 3 includes the fourth high burden country (Russian Federation), along with countries in eastern Europe, South America and western Europe, which fall at the end of Stage 3. Stage 4 is populated entirely by the developed countries of western Europe, North America and Oceania. The USA, the fifth high burden country, fall in the last stage as a result of the relatively small difference in the smoking prevalence between men and women compared to the other intermediate stages. As mentioned before, Stage 4 includes countries where the smoking prevalence is higher in women than in men, with a small (< 8%) difference.

(c) Age-specific prevalence

Age-specific prevalence for men and women aged 15 years or older is presented for six representative countries for current smoking (Fig. 1.6). There are wide variations in age-specific prevalence between these countries. In men, prevalence varies from less than 10% to 75% in the 15–19 years age range to lie between 10% and 55% in the oldest age range. Prevalence among women varies from less than 1% to as high as 45% in young adults (15–19 years). Unlike men, prevalence in women tends to converge after age

Fig. 1.5 Prevalence of smoking in 140 countries in 2009, staged according to the model by Lopez



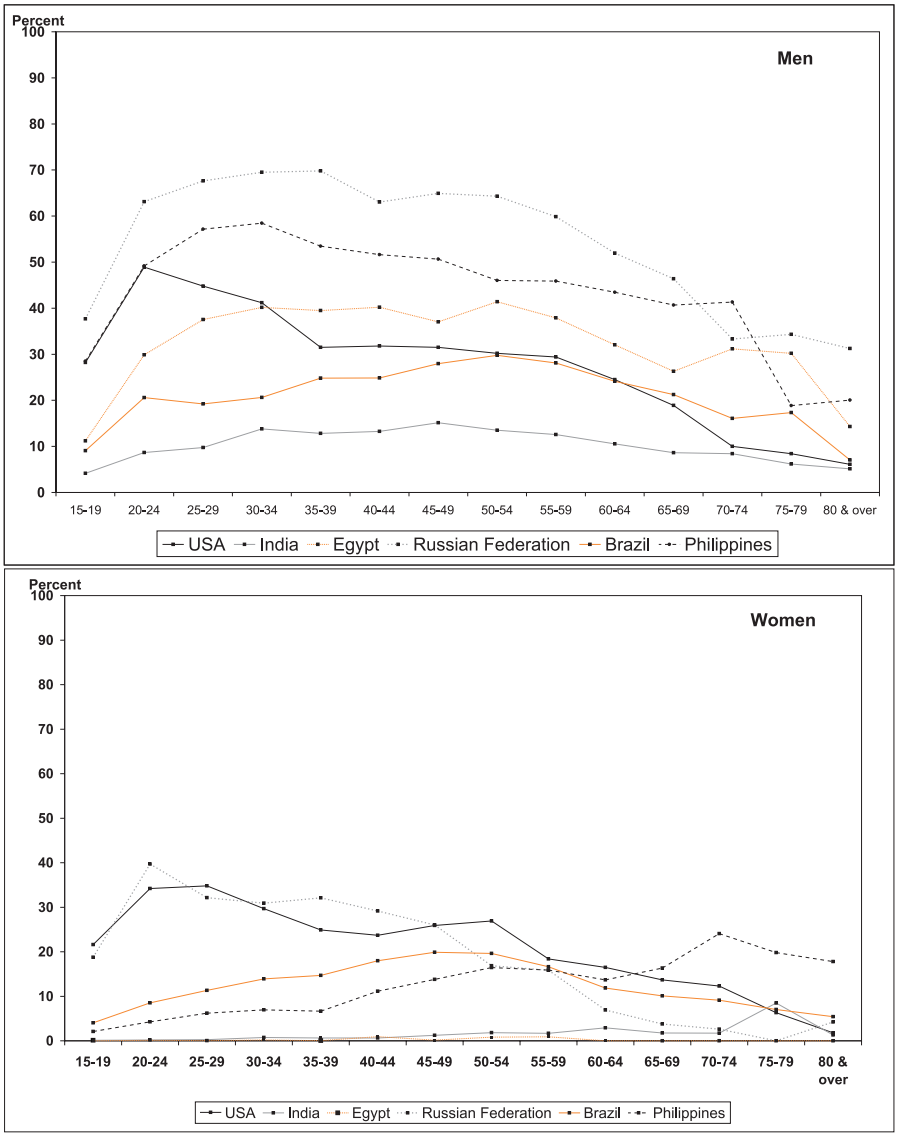


Fig. 1.6 Age-specific rates of smoking prevalence, in men and women in 2009

50, lying within 15 percentage points. Prevalence in women is almost always lower than in men in all age groups.

Initiation of smoking is shifting, and is taking place at earlier ages in both developed and developing countries. In developed countries, quitting smoking is also shifting to occur at a younger age, whereas in developing countries there is no such evidence.

(d) Smoking in youth

Information on smoking habits in youth are collected from a variety of youth surveys that include the Global Youth Tobacco Survey (GYTS), Global school-based Student Health Survey (GSHS) and Health Behaviour in School Aged Children (HBSC). Some countries have their own youth surveys, or have them as part of a general health or household survey, such as the Student Survey in Argentina, the Youth Smoking Survey in Canada, and New Zealand's Tobacco Survey.

The GYTS is a school-based survey designed to monitor tobacco use among youths aged 13 to 15 years. The GYTS uses a standard set of questions and sampling methods in over 160 countries. The survey has core questions that span seven thematic areas pertinent to tobacco. In addition to these, countries can include country-specific questions that allow assessment of tobacco use unique to the country. To assess prevalence of smoking, students are asked to report their smoking habits for both cigarettes and other tobacco products that they may have consumed over the past 30 days. Since its inception in 1999, the GYTS has covered over 2 million students. Although most GYTS are national surveys, in some countries they are limited to subnational locations. Further, countries conduct the GYTS in different years, rendering comparison for the same year difficult.

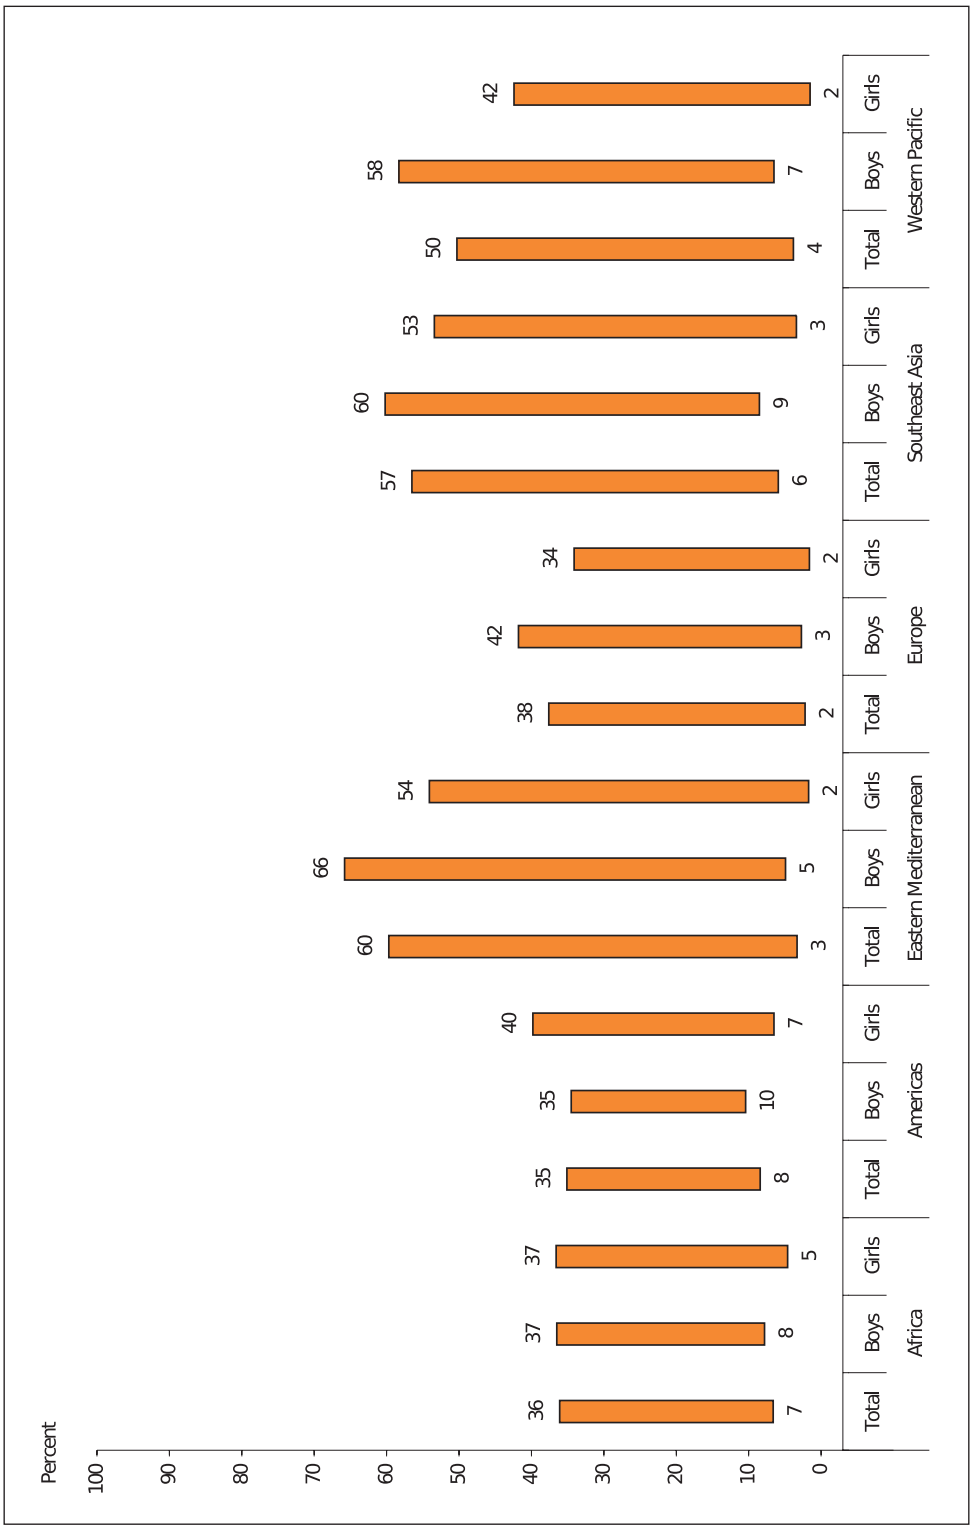
Prevalence of current tobacco use [including smokeless tobacco] in youth in 2004–09 for fourteen high burden low and middle income countries is shown in Fig. 1.7. The Russian Federation has the highest prevalence of current tobacco use among the high burden countries for which national data are available. Further, in the Americas and Europe the difference in prevalence between boys and girls is smaller than in other regions. In contrast, in Egypt, India and Thailand, prevalences in boys are significantly higher than in girls.

Fig. 1.8 shows the range of current tobacco use by WHO region for boys and for girls and for both sexes combined. There are wide variations in current tobacco use within each region. The largest variations are observed in EMRO and SEARO irrespective of sex, reflecting potentially disparate initiation rates in countries within the region. In AFRO, the range of current tobacco use between boys and girls is virtually the same. In some countries (e.g. Argentina, Peru, Sierra Leone, Bulgaria, Croatia, Cook Islands, New Zealand), tobacco use in girls exceeds that in boys; but overall boys and girls show remarkably similar propensity to take up tobacco use.

Warren *et al.* (2006) present global estimates and regional averages for current tobacco smoking in youth using GYTS data spanning 1999–2005. Their estimates show that one in five boys and one in seven girls currently smoke tobacco. Prevalence of current smoking for both boys and girls combined was highest in AMRO (22.2%) and lowest in WPRO (11.4%). AMRO have the highest average for current tobacco smoking for boys (24%) and for girls (20.4%) whereas the lowest prevalence was in WPRO among boys (15%) and in SEARO among girls (7.1%).

1.4 Regulations and policies: the WHO Framework Convention on Tobacco Control

The WHO Framework Convention on Tobacco Control (WHO FCTC) – the first multilateral evidence-based treaty on tobacco control



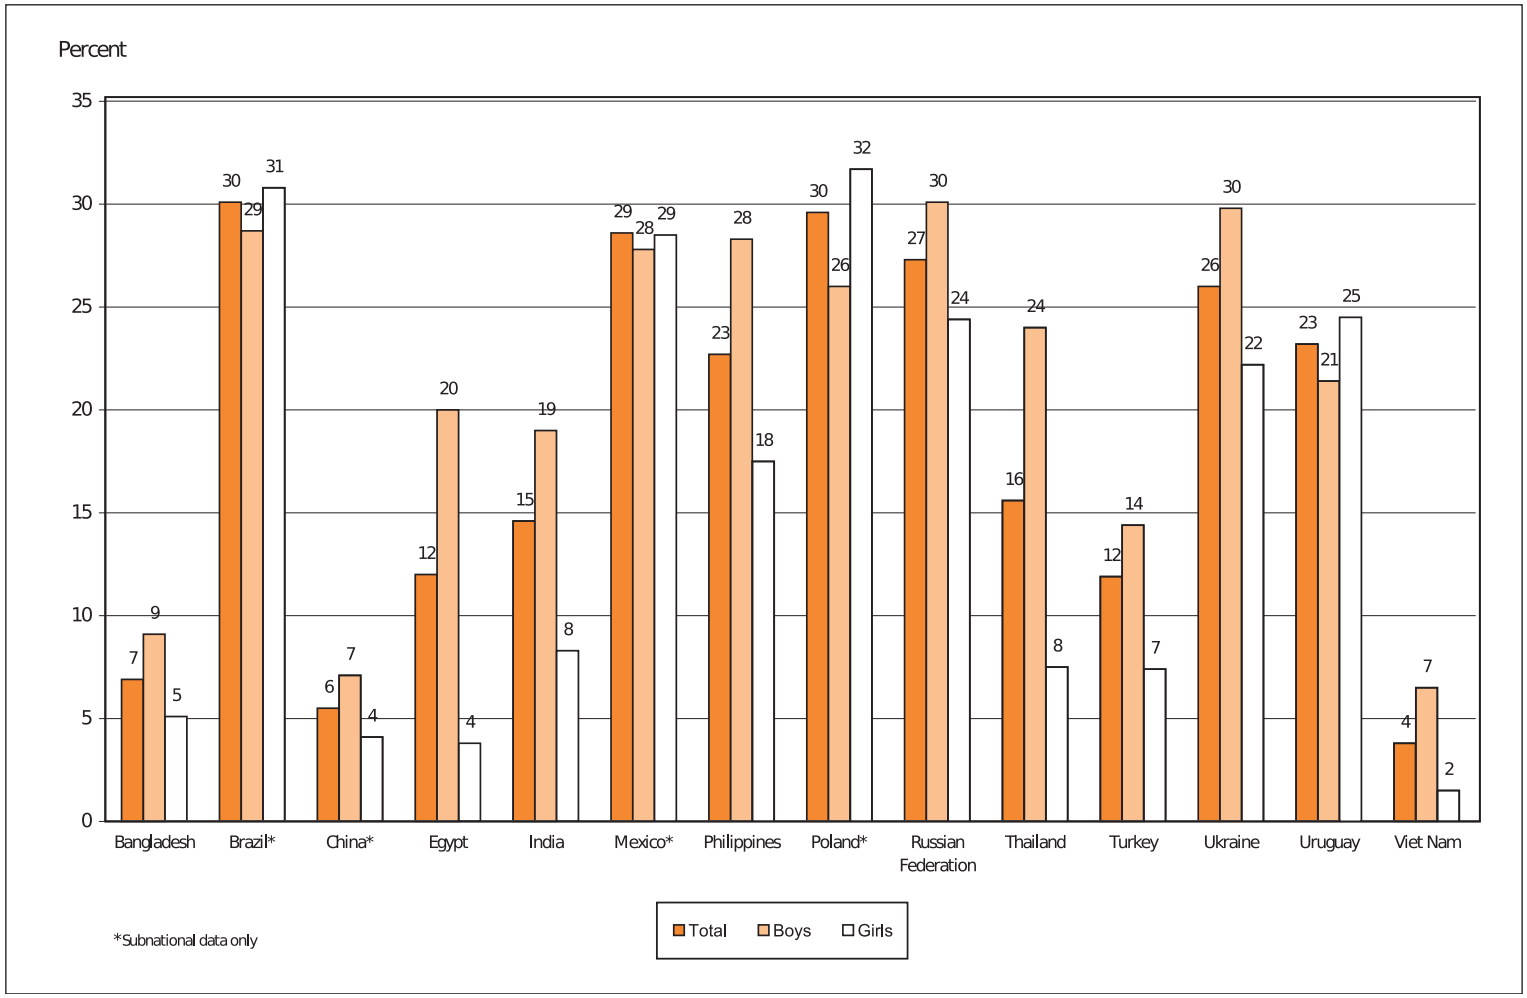


Fig. 1.7 Prevalence of current tobacco use in youth for selected countries, 2005–2009

Fig. 1.8 Range of prevalence of current tobacco use in youth, 2005–2009, by WHO region

Figures have been rounded off and show prevalences in countries with national and subnational jurisdiction.

– articulates tobacco control measures available to countries to counter the growing tobacco epidemic. This treaty, which entered into force in 2005, represents one of the most universal treaties in the United Nations history. In 2008, the WHO launched MPOWER, a technical assistance package comprised of six strategies that reflects one or more of the WHO FCTC measures and helps countries meet their commitments to the WHO FCTC.

2. Cancer in Humans

2.1 Introduction

The available knowledge on the relationship between tobacco smoking and a variety of human cancers is based primarily on epidemiological evidence. An immense amount of such evidence has been obtained, and only a small proportion can be referred to here. The cancers considered to be causally related to tobacco smoking in the previous *IARC Monograph* on tobacco smoking (IARC, 2004a) included lung, oral cavity, nasal cavity and paranasal sinuses, nasopharynx, oropharynx, hypopharynx, larynx, oesophagus (adenocarcinoma and squamous cell carcinoma), upper aerodigestive tract combined, stomach, pancreas, liver, kidney (body and pelvis), ureter, urinary bladder, cervix and myeloid leukaemia. In addition, it was concluded that there was evidence suggesting lack of carcinogenicity for cancers of the breast and of the endometrium.

Since 2002, there have been additional cohort and case–control studies on the relationship of tobacco smoking in different forms to these and other cancers in many countries. A large body of evidence has been obtained from cohort studies with respect to different cancer sites and types of tobacco product. These cohort studies are described briefly in Table 2.1 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.1.pdf), listed by country. Case–control studies are described in the sections pertaining to cancer sites. More studies are now available from countries and populations that are still at an early stage of the tobacco epidemic. These studies are prone to underestimate the true strengths of the association between tobacco smoking and any specific cancer as the full effect of duration of smoking cannot be evaluated.

2.2 Cancer of the lung

2.2.1 Overview of studies

The main cause of lung cancer in humans is tobacco smoking and most information establishing this fact comes from epidemiological studies in which the assessment of exposure was based on self-reported information on personal smoking habits via self-administered questionnaire or in-person interviews. Since the previous *IARC Monograph* (IARC, 2004a), numerous studies have been published on the issues of tobacco smoking and sex and racial/ethnic susceptibility, 'tar' yields as measured by machine smoking, the relationship between histological changes and the design of cigarettes, dose–response association, genetic susceptibilities and interactions.

2.2.2 Factors affecting risk

Recent epidemiological studies incorporating measures of smoking metabolites in serum or urine are helping to refine our understanding of exposure-response relationships with tobacco smoke. Dose–response evidence has been obtained from three cohort studies (Flanders *et al.*, 2003; Boffetta *et al.*, 2006; Yuan *et al.*, 2009; Table 2.2 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.2.pdf) and four pooled analyses (Lubin & Caporaso, 2006; Lubin *et al.*, 2007a, b, 2008; Table 2.3 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.3.pdf)

since the previous *IARC Monograph* (IARC, 2004a).

The US American Cancer Society Cancer Prevention Study-II (CPS-II) is the largest cohort study on smoking and lung cancer risk using questionnaire assessment of exposure (Flanders *et al.*, 2003). In this study cigarette smoking duration is a much stronger predictor of lung cancer mortality than is cigarette smoking intensity, regardless of age in both men and women. These results are qualitatively similar to those reported by Doll & Peto (1978) and are consistent with IARC (2004a).

In a questionnaire-based assessment of the association of tobacco smoking with lung cancer risk, smokers at higher smoking intensities seem to experience a "reduced potency" per pack such that for equal total exposure, the excess odds ratio per pack–year decreases with intensity (Lubin *et al.* 2008). Below 15–20 cigarettes/day, the excess odds ratio/pack–year increases with intensity (Lubin & Caporaso, 2006; Lubin *et al.*, 2007a) while above 20 cigarettes/day, there is an 'inverse-exposure-rate' effect (Lubin *et al.*, 2007a) suggesting a greater risk for total exposure delivered at lower intensity (or a longer duration) than the equivalent exposure delivered at a higher intensity. The intensity effects were also statistically homogeneous across diverse cancer types, indicating that after accounting for risk from total pack–years, intensity patterns were comparable for cancer of the lung, bladder, oral cavity, pancreas and oesophagus. These analyses suggest that the risk of lung cancer increases with increasing tobacco exposure at all dose levels, but there is some levelling-off effect at the highest intensity of tobacco smoking.

However, when serum cotinine was used as a measure of exposure to tobacco smoking, rather than questionnaire-based data, the odds ratio of lung cancer increased linearly over the full range of exposure from ≤ 5 ng/mL through ≥ 378 ng/mL, with an odds ratio of 55.1 (95% confidence interval (CI): 35.7–85.0) in the highest exposure group. These results suggest that the decreased rate of lung cancer risk at high intensity of tobacco smoke previously described is a statistical artefact. Such an effect may be due to an inaccurate assessment of total tobacco smoke exposure from questionnaire-based studies at high exposure levels (Boffetta *et al.*, 2006). Somewhat similar results were obtained when both 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) and total cotinine in urine were measured in subjects of two large cohort studies from Shanghai men and Singapore men and women (Yuan *et al.*, 2009). Among smokers with comparable smoking histories (as noted in questionnaire data) there is a 9-fold variation in subsequent risk of lung cancer between those with high and those with low levels of total urinary NNAL and cotinine. Thus measurements of urinary cotinine and total NNAL at a single point in time in a smoker could substantially improve the predictive power of a lung cancer assessment model based solely on self-reported smoking history (number of cigarettes/day, number of years of regular smoking). A positive NNAL-lung cancer association of comparable magnitude was observed in both Shanghai and Singapore subjects despite differences in the NNK content of tobacco smoked. The independent association between total urinary cotinine and lung cancer risk, after adjustment for total urinary NNAL and smoking history, suggests that tobacco smoke compounds other than NNK play a role in lung cancer development in smokers. Further, a single measurement of urinary NNAL may closely predict the average level of NNAL measured over a much longer period of time.

2.2.3 Types of tobacco or of cigarette

(a) Tar levels

In a previous *IARC Monograph* (IARC, 1986), it was concluded on the basis of the case–control, cohort studies and ecological evaluations

available at the time that prolonged use of 'high-tar' and unfiltered cigarettes is associated with greater risks than prolonged use of filter-tipped and 'low-tar' cigarettes. More recently (IARC, 2004a), it has been recognized that the actual quantitative impact of reduced 'tar' and filter-tipped cigarettes is difficult to assess because of, respectively, the concomitant increase in tobacco-specific nitrosamines that accompanies the greater use of blend tobacco and the compensatory changes in smoking behaviour by smokers attempting to maintain their accustomed level of nicotine intake. Nevertheless, it was concluded that changes in cigarette types since the 1950s have probably tended to reduce the risk for lung cancer associated with tobacco smoking.

Additional refinement in assessing the health effects associated with smoking cigarettes of various tar content has been possible since the publication of the earlier reports. Compared with smokers of medium tar (15–21 mg) filtered cigarettes risk was higher among men and women who smoked high tar (≥ 22 mg) non-filtered brands but there was no difference in risk among men and women who smoked 'very low tar' or 'low tar' brands compared with those who smoked 'medium tar' brands (Harris *et al.*, 2004). Regardless of tar content of their cigarettes, all current smokers had a far greater risk for lung cancer than people who had stopped smoking or had never smoked (Harris *et al.*, 2004).

(b) Mentholated cigarettes

In the previous *IARC Monograph* (IARC, 2004a) the conclusion was drawn that there is no additional risk associated with smoking mentholated cigarettes when total consumption (pack–years) was controlled versus non-mentholated ones. Recent evidence supports that conclusion.

Mentholated cigarettes first appeared in the 1920s, but were not widely used until the mid-1950s (Bogen, 1929; Federal Trade Commission, 2001). Since the early 1970s, menthol varieties have accounted for 25–60% of all cigarettes sold in the USA (Federal Trade Commission, 2001). There are strong ethnic differences in the use of menthol cigarettes; more than 60% of Black smokers of both sexes use menthol brands compared to fewer than 25% of White smokers (Royce *et al.*, 1993; Hymowitz *et al.*, 1995). Studies have generally not demonstrated an increased risk of lung cancer for mentholated cigarettes versus non-mentholated cigarettes (Kabat & Hebert, 1994; Carpenter *et al.*, 1999; Brooks *et al.*, 2003; Stellman *et al.*, 2003). Recent evidence also suggests that users of mentholated cigarettes smoke fewer pack–years than those of non-mentholated cigarettes.

The higher incidence of lung cancer among Blacks is an important public health concern but the causes remain unclear. Mentholated cigarette use does not appear to explain the racial disparity observed in lung cancer risk among those having the same total tobacco consumption.

2.2.4 Histology

Compiled databases from IARC and other sources indicated that squamous cell carcinoma rates [per 100000 person-years] among men declined by 30% or more in North America and some European countries between 1980–82 and 1995–97, while changing less dramatically in other areas; small cell carcinoma rates decreased less rapidly. In contrast, the proportion of adenocarcinoma cases rose among men and women in virtually all areas, with the increases among men exceeding 50% in many areas of Europe (Devesa *et al.*, 2005).

Based on a comparison of two large cohort studies initiated by the American Cancer Society (ACS) (CPS-I and CPS-II) in 1960 and 1980, respectively, a stronger association between smoking and adenocarcinoma was observed in recent compared to earlier follow-up periods (Thun & Heath, 1997). Additionally, an association between cigarette smoking and bronchioloalveolar carcinoma was also found in several

studies (Falk *et al.*, 1992; Morabia & Wynder, 1992).

A meta-analysis of 8 cohort and 14 case–control studies conducted in Japan among active smokers indicated significant excess lung cancer risks among men for both squamous cell carcinoma (relative risk (RR), 11.7) and adenocarcinoma (RR, 2.30). Among women the risks were 11.3 for squamous cell carcinoma and 1.37 for adenocarcinoma (Wakai *et al.*, 2006).

2.2.5 Population characteristics

(a) Sex

Meta-analyses on sex-specific susceptibility to lung cancer associated with tobacco smoking are presented in Table 2.4 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.4.pdf) and cohort studies in Table 2.5 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.5.pdf).

In the 1990s, two case–control studies indicated that relative risks for lung cancer associated with specific amounts and duration of cigarette smoking may be higher among women than among men (Risch *et al.*, 1993; Zang & Wynder, 1996).

In the large NIH-AARP [National Institutes of Health-American Association of Retired People] cohort (Freedman *et al.*, 2008), smoking was associated with lung cancer risk in both men and women. Age-standardized incidence rates for lung cancer tended to be higher in men than in women with comparable smoking histories (for current smokers and for quitters of less than 10 years), and in cases with squamous cell tumours. However, lung cancer risk was generally similar between men and women.

In a joint analysis, results from the Nurses' Health Study of women and the Health Professionals Follow-up Study in men (Bain *et al.*, 2004) suggest little difference in lung cancer susceptibility between men and women given equal smoking exposure. The hazard ratio in women ever smokers compared with men was 1.11 (95%CI: 0.95–1.31).

Serum cotinine levels were analysed in lung cancer cases and controls (Boffetta *et al.*, 2006). The lung cancer odds ratios (ORs) estimated for men and women were very similar for those with comparable serum cotinine levels. Other studies that have carefully quantified tobacco exposure via self-administered questionnaire or interview provide additional evidence of a comparable increase in lung cancer risk in the two sexes (Kreuzer *et al.*, 2000; Flanders *et al.*, 2003; Bain *et al.*, 2004).

In a meta-analysis of observational studies on cigarette smoking and cancer from 1961–2003 (conducted on 177 case–control studies, 75 cohort studies and two nested case–control studies), dose–response estimates were available in 44 studies: 19 with estimates for men only, 11 with estimates for women only and 14 with separate estimates for men and women (Gandini *et al.*, 2008). Overall, the risk of lung cancer for men and women increased by 7% for each additional cigarette smoked per day (RR, 1.07; 95%CI: 1.06–1.08). The increased risk appears to be slightly higher in women (RR, 1.08; 95%CI: 1.07–1.10) than in men (RR, 1.07; 95%CI: 1.05–1.08) ($P < 0.001$; adjusting for study type).

(b) Ethnicity

It has been postulated that susceptibility to lung cancer from tobacco smoking may differ by race and ethnicity (Schwartz & Swanson, 1997; Peto *et al.*, 1999; Stellman *et al.*, 2001; Kiyohara *et al.*, 2004, 2005, 2006; Pinsky, 2006; Wakai *et al.*, 2006; Vineis *et al.*, 2007; Takahashi *et al.*, 2008; Table 2.6 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.6.pdf). Lung cancer incidence rates vary considerable across racial/ethnic groups in the USA and elsewhere. Black men have higher rates than white men, while Hispanics, Asians and American Indians of both sexes have lower rates than whites (Stellman *et al.*, 2003; SEER, 2004).

Nutritional habits, smoking patterns, type of tobacco smoked and genetic factors may play a role in such differences between racial and ethnic groups.

The association of tobacco smoking and lung cancer does not appear to be as strong among Japanese as among populations of North America or Europe (Wakai *et al.*, 2006). In a meta-analysis of 8 cohort studies and 14 case–control studies conducted in Japan, the excess lung cancer risks observed for both men (RR, 4.39; 95%CI: 3.92–4.92) and women (RR, 2.79; 95%CI: 2.44–3.20) in both case–control and cohort studies were lower than would have been expected from studies in North America and Europe. The lower lifetime consumption of cigarettes in Japanese, due in part to a later initiation of smoking and a lower consumption per day has been suggested to explain this. Other differences that may have etiological significance include tobacco ingredients, different filters on cigarettes, lifestyle factors including diet, and possibly differences in genetic susceptibility. [The Working Group noted that North American or European populations were not directly included in any of these studies.]

Data from the Asian Pacific Cohort Studies Collaboration, 31 studies involving 480125 persons, evaluated the risk of death from lung cancer associated with smoking habits in Australia, New Zealand and Asia (Huxley *et al.*, 2007b). Among Asian men the hazard ratio was 2.48 versus 9.87 in men in Australia and New Zealand. Among women, the corresponding estimates were 2.35 and 19.33, respectively. [In these studies, Asian populations smoked fewer cigarettes for a shorter period of time compared to those in Australia and New Zealand.]

Based on data from the National Cancer Institute's Surveillance, Epidemiology, and End Results program (SEER), Chinese women residing in the USA have a fourfold increased risk of lung cancer, and Filipino women a twofold increased risk, compared to that expected based on rates in non-Hispanic whites in the USA with a similar amount of cigarettes smoked (Epplein *et al.*, 2005). Among Chinese women, the increased risk was largely restricted to adenocarcinoma and large cell undifferentiated carcinoma. Chinese females residents of the western US mainland have a much higher risk of lung cancer than would be expected from their tobacco use patterns, just as they do in Asia (Peto *et al.*, 1999; Epplein *et al.*, 2005), the reason for these difference have not been identified. [Controlling for potential confounding factors was limited using aggregate data from SEER.]

Age, sex and race-specific risks of lung cancer mortality among lifetime non-smokers were compared in the two large ACS Cancer Prevention Study cohorts (CPS-I; CPS-II). The mortality rate was higher among African American women than among white women in CPS-II (hazard ratio (HR), 1.43; 95%CI: 1.11–1.36) (Thun *et al.*, 2006). This suggests an inherent susceptibility difference between white and black women but it could also be explained by access to care, diet, or exposure to environmental carcinogens.

The risk for lung cancer associated with cigarette smoking in 183813 African-American, Japanese-American, Latino, native Hawaiian and white men and women was examined in the Multiethnic Cohort Study in the USA (Haiman *et al.*, 2006). Information on demographic factors, smoking status, cigarettes/day smoked, years of smoking, years since quitting, diet, occupations, educational level and racial and ethnic group were collected for all subjects through a self-administered questionnaire at enrolment. Information about age of smoking initiation and cessation rates were collected on a subgroup of 5090 study subjects. Incident lung cancer cases were identified by linkage to the SEER cancer registries covering California and Hawaii. Among those who smoked no more than 10 cigarettes/day and those who smoked 11–20 cigarettes/day, relative risks ranged from 0.21 to 0.39 ($P < 0.001$) among Japanese Americans and Latinos and from 0.45

to 0.57 ($P < 0.001$) among whites as compared with African Americans. However, at levels exceeding 30 cigarettes/day, differences between racial/ethnic groups were no longer significant. The differences in lung cancer risk by racial group associated with smoking were observed for both men and women and for all histological types of lung cancer. These findings could not be explained by differences between populations in other known or suspected risk factors, including diet, occupation, and education level or by age at starting smoking or cessation of smoking.

Polymorphisms in glutathione-*S*-transferase (GST), GSTM1, GSTT1 and GSTP1 genes in humans are associated with reduction of enzymatic activity towards several substrates, including those found in tobacco smoke. In a population based case–control study involving early-onset lung cancer, African Americans carrying at least one G allele at the GSTP1 locus were more likely to have lung cancer compared with African Americans without a G allele after adjustment for age, sex, pack–years of smoking and a history of lung cancer in a first degree relative (OR, 2.9; 95%CI: 1.29–6.20). African Americans with either one or two risk genotypes at the GSTM1 (i.e. null genotype) and GSTP1 loci were at increased risk of having lung cancer compared with those having fully functional GSTM1 and GSTP1 genes (one risk genotype: OR, 2.8; 95%CI: 1.1–7.2 and two risk genotypes: OR, 4.0; 95%CI: 1.3–12.2). No significant single gene associations between GSTM1, GSTT1 and GSTP1 and early-onset lung cancer were observed in Caucasians, after adjusting for age, sex, pack–years and a family history of lung cancer (Cote *et al.*, 2005).

The cytochrome P450 (CYP) superfamily of enzymes catalyses one of the first steps in the metabolism of carcinogens such as polycylic aromatic hydrocarbons, nitroaromatics and arylamines. A population-based case–control study of lung cancer in the metropolitan Detroit area found that neither CYP1A1 MspI nor CYP1A1 Ile^{462}Val was associated with lung cancer susceptibility among Caucasians or African Americans. Among Caucasians, however, CYP1B1 Leu^{432} Val was significantly associated with lung cancer susceptibility (OR for at least one Val allele, 2.87; 95%CI: 1.63–5.07). Individuals with both this polymorphism and exposure to second-hand tobacco smoke were at particularly high risk for lung cancer. Combinations of particular CYP1B1 polymorphisms appeared to increase risk, although no combination differed significantly from the risk associated with CYP1B1 Leu^{432} Val alone (Cote *et al.*, 2005; Wenzlaff *et al.*, 2005).

The hypothesis that polymorphisms in TP53 may modulate the risk for lung cancer associated with tobacco smoke was evaluated in a case–control study of lung cancer in Baltimore, Maryland. African-Americans with Pro-T-A-G-G haplotype (combining the polymorphisms TP53_01 (rs1042522), TP53_65 (rs9895829), TP53_66 (re2909430), TP53_16 (rs1625895), and TP_11 (rs12951053)) had both an increased risk for lung cancer (HR, 2.32; 95%CI: 1.38–4.10) and a worsened lung cancer prognosis (HR, 2.38; 95%CI: 0.38–4.10) compared with those having the Arg-T-A-G-T haplotype. No association of TP53 polymorphisms with lung cancer was observed in Caucasians (Mechanic *et al.*, 2007). Common genetic variation in TP53 could modulate lung cancer pathways in African Americans. Differences in lung cancer susceptibility may exist based on race, tobacco exposure and selected genetic polymorphisms (Mechanic *et al.*, 2007).

2.2.6 Interactions

(a) Diet and exercise

Antioxidant vitamins, carotenoids, isothiocyanates, total dietary vegetables and fruit, and physical exercise have been associated with a decreased risk for cancer in some studies but the overall protective effect of diet and exercise account for only a small fraction of the total risk associated with tobacco smoking.

The association of fruit and vegetable with lung cancer incidence among both smokers and non-smokers was evaluated in the European Prospective Investigation into Cancer and Nutrition (EPIC). In current smokers lung cancer risk was significantly decreased with higher vegetable consumption, the hazard ratio being 0.78 (95%CI: 0.62–0.98) per 100 g increase in daily vegetable consumption, and 0.90 (95%CI: 0.81–0.99) per 100 g fruit (Linseisen *et al.*, 2007). While overall consumption of fruits and vegetables was not found to be protective of lung cancer in the NIH-AARP Diet and Health Study, higher consumption of several botanical subgroups (i.e. rosaceae, convolvulaceae, and umbelliferae) was significantly inversely associated with risk, but only in men (Wright *et al.*, 2008).

Cruciferous vegetables (i.e. broccoli, cabbage, cauliflower, Brussels sprouts, kale) are rich in isothiocyanates and have been hypothesized to have anticancer properties that may contribute to reduced risk for lung cancer. Isothiocyanates may inhibit the bioactivation of procarcinogens found in tobacco smoke such as polycyclic aromatic hydrocarbons and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (Hecht, 2000). Isothiocyanates may also enhance excretion of carcinogenic metabolites before they can damage DNA (Gasper *et al.*, 2005). Furthermore, sulforaphane, a major isothiocyanate found in broccoli, can induce cell cycle arrest and apoptosis (Seow *et al.*, 2005). GSTM1 and GSTT1 encode isoenzymes that play an important role in xenobiotic metabolism (Hecht, 2000). Individuals with homozygous deletion of GSTM1 and GSTT1, or both may metabolize isothiocyanates less efficiently and may be more intensely exposed to isothiocyanates after consumption of cruciferous vegetables. Epidemiological evidence from 30 studies on the association between lung cancer and either total cruciferous vegetable consumption (6 cohort and 12 case–control studies) or specific cruciferous vegetables (1 cohort and 11 case–control studies) was recently evaluated (Lam *et al.*, 2009). The risk for lung cancer among those in the highest category of total cruciferous vegetable intake was 22% lower in case–control studies (pooled OR, 0.78; 95%CI: 0.70–0.88) and 17% lower in cohort studies (pooled RR, 0.83; 95%CI: 0.62–1.08). The strongest inverse association of total cruciferous vegetable intake with lung cancer was seen among individuals with GSTM1 and GSTT1 double null genotypes (OR, 0.41; 95%CI: 0.26–0.65; p for interaction = 0.01). The inverse association was observed in both smokers and non-smokers.

The potential role of vitamin A in the development of lung cancer attracted early research interest (Bjelke, 1975). Carotenoids were thought to have anti-cancer properties and early evidence from case–control studies tended to support an inverse association of lung cancer incidence with β-carotene intake and with serum concentrations of β-carotene. However, the case–control design is not ideal for assessing the effect of serum carotenoids as a risk factor for lung cancer risk since the disease is likely to effect serum levels. In a meta-analysis of six randomized clinical trials and 25 prospective observational studies, Gallicchio *et al.* (2008) computed a pooled relative risk for studies comparing β-carotene supplements with placebo of 1.10 (95%CI: 0.89–1.36). Among observational studies, the pooled relative risk for total carotenoid dietary intake from six studies was 0.86 (95%CI: 0.75–0.99) among current smokers. For dietary intake of β-cryptoxanthin, data from six studies gave a pooled relative risk among smokers of 0.75 (95%CI: 0.58–0.96). No other carotenoids significantly reduced the risk in current, former or never smokers.

Based on a review of the literature, antioxidant vitamins show no clear protective effect on lung cancer risk in smokers or non-smokers, although there was some, albeit inconsistent, evidence pointing to a protective role for vitamin C and E. No clear protective role was observed for vitamin A (Ruano-Ravina *et al.*, 2006).

Increased physical activity has been associated with a reduction in the incidence and mortality from all-site cancer and some site-specific cancers in studies of non-smokers, but less is known about whether physical activity is associated with similar risk reduction in smokers. Several early studies suggested that physical activity is associated with decreased risk of lung cancer in men and women after adjusting for smoking, with risk reductions estimated from 18% (Peterson *et al.*, 2001) to 62% (Kubík *et al.*, 2001). The effect of physical activity on lung cancer risk was assessed in a sample drawn from participants in the Beta-Carotene and Retinol Efficacy Trial. The results suggested that physical activity may play a small role in reducing cancer risk and mortality among those with significant tobacco exposure. The incidence of lung cancer and of all cancer sites combined seemed to be more attenuated by exercise in men than in women, while the attenuation in lung cancer mortality was greater in women than in men. These effects may be more pronounced for younger people and may differ inconsistently by pack–years of smoking (Alfano *et al.*, 2004).

(b) Radon

In a pooled analysis of data from 13 case–control studies of residential radon and lung cancer from nine European countries (7148 cases of lung cancer and 14208 controls), the dose–response relation seemed to be linear with no threshold and remained significant in analyses limited to individuals from homes with measured radon < 200 Bq/m^3. The absolute risks of lung cancer by age 75 years at radon concentrations of 0, 100, and 400 Bq/m^3 would be about 0.4%, 0.5% and 0.7%, respectively, for lifelong non-smokers, and about 25 times greater (10%, 12% and 16%) for cigarette smokers. These studies show appreciable hazards from residential radon, particularly for smokers and recent ex-smokers (Darby *et al.*, 2005). Similar risks were identified in a pooling project of North American case–control studies (Krewski *et al.*, 2005).

(c) Asbestos

Exposure to asbestos and tobacco smoking are both known causes of lung cancer in humans (Doll & Peto, 1978; de Klerk *et al.*, 1996). Some studies suggest a multiplicative effect [where the effect of asbestos exposure is a multiple of the effect of smoking] (Hammond *et al.*, 1979; Doll & Peto, 1985), and meta-analyses have suggested that the additive model [where asbestos exposure and smoking are independent of each other] is unsound (Lee, 2001; Liddell, 2001). In a recent study of 2935 asbestos miners, persons exposed to asbestos and tobacco who subsequently quit smoking remained at a 90% increased risk of lung cancer up to 20 years after smoking cessation, compared to never-smoker asbestos workers (Reid *et al.*, 2006a).

(d) Genetic polymorphisms

Lung cancer is plausibly caused by the interplay between environmental factors and several low-risk alleles. Attempts in identifying specific single nucleotide polymorphisms (SNPs) responsible for modulating lung cancer risk have yielded few conclusive results. Recent studies have focused on mechanistically plausible polymorphisms in genes coding for enzymes involved in the activation, detoxification and repair of chemical damage caused by tobacco smoke. Genetic association studies indicate that several inherited genetic polymorphisms may be associated with lung cancer risk, but the data from individual studies with low statistical power are conflicting. Evidence from pooled or meta-analyses, along with some individual studies, is briefly summarized below.

(i) Metabolic genes

Most of the 70 carcinogens in tobacco smoke are procarcinogens that must be activated by phase I enzymes and may then be deactivated by

phase II enzymes. Polymorphisms that alter the function of the genes involved in the activation or detoxification of tobacco smoke carcinogens can potentially influence an individual's risk of developing a tobacco-related cancer.

Meta and pooled analyses of 34 case–control, genotype-based studies were conducted to assess the effect of GSTT1 genotypes and smoking on lung cancer risk. No significant interaction was observed (Raimondi *et al.*, 2006). A pooled analysis of 21 case–control studies from the International Collaborative study of Genetic Susceptibility to Environmental Carcinogens showed no evidence of increased risk for lung cancer among carriers of the GSTM1 null genotype and there was no evidence of interaction between GSTM1 genotype and either smoking status or cumulative tobacco consumption (Benhamou *et al.*, 2002). Similarly, in another pooled analysis the summary OR indicated the slow acetylator genotype of N-acetyltransferase 2 (NAT2) detoxification enzyme was not associated with lung cancer risk among Caucasians (Borlak & Reamon-Buettner, 2006). In a pooled analysis to test the hypothesis of interaction among genetic variants in increasing the individual risk for cancer, the cumulative effect of variants in three metabolic genes, CYP1A1, GSTM1 and GSTT1 was assessed. The risk for lung cancer was increased with the combination of CYP1A1*2B or CYP1A1*4 alleles and the double deletion of both GSTM1 and GSTT1 up to an OR of 8.25 (95%CI: 2.29–29.77). The combination including CY1A1*4 among never smokers was associated with an OR of 16.19 (95%CI: 1.90–137). These estimates did not change after adjustment by the number of cigarettes smoked and duration of smoking. The results were consistent across ethnicities and were approximately the same for adenocarcinoma and squamous cell carcinoma (Vineis *et al.*, 2007).

Microsomal epoxide hydrolase 1 (EPHX1) plays an important role in both the activation and detoxification of tobacco-derived carcinogens. Polymorphisms at exons 3 and 4 of the EPHX1 gene have been reported to be associated with variations in EPHX1 activity. In a meta-analysis of 13 case–control studies the low-activity (variant) genotype of EPHX1 polymorphism at exon 3 was associated with decreased risk for lung cancer (OR, 0.65; 95%CI: 0.44–0.96) among whites. In white-populations, the high activity (variant) genotype of EPHX1 polymorphism at exon 4 was associated with a modest increased risk of lung cancer (OR, 1.22; 95%CI: 0.79–1.90) and the predicted low activity was associated with a modest decrease in risk (OR, 0.72; 95%CI: 0.43–1.22) (Kiyohara *et al.*, 2006).

(ii) DNA repair and cell cycle pathways

Data from 14 studies of lung cancer were used in a pooled analysis focusing on 18 sequence variants in 12 DNA repair genes, including APEX1, OGG1, XRCC1, XRCC2, XRCC3, ERCC1, XPD, XPF, XPG, XPA, MGMT and TP53 (Hung *et al.*, 2008a). None of the variants appeared to have a large effect on lung cancer risk. In a recent meta-analysis the X-ray repair cross-complementing protein group 3 (XRCC3) and the xeroderma pigmentosum group D (XPD)/excision repair cross-complementing group 2 (ERCC2) genes were evaluated (Manuguerra *et al.*, 2006). The authors found no association between these genes and the cancer sites investigated (skin, breast and lung). A significant association was identified for XPD/ERCC2 single nucleotide polymorphisms (codons 312 and 751) and lung cancer.

(iii) Nicotine acetylcholine receptor genes

A series of large genome-wide association studies for lung cancer have identified susceptibility loci for lung cancer in chromosome arms 5p, 6p and 15q (Landi *et al.*, 2009). In particular, the susceptibility locus at chromosome region 15q25 includes several genes, including three that encode nicotinic acetylcholine receptor subunits (CHRNA5, CHRNA3 and CHRNB4). Nicotinic acetylcholine receptor subunit genes

code for proteins that form receptors present in neuronal and other tissue, in particular alveolar epithelial cells, pulmonary neuroendocrine cells, and lung cancer cell lines (Wang *et al.*, 2001; Minna, 2003) and bind to nicotine and nicotine derivatives including NNN. An association of CHRNA3 and CHRNA5 variants with nicotine dependence has been reported (Saccone *et al.*, 2007; Berrettini *et al.*, 2008). These genes may act, at least partially, upon cigarette smoking. Current smokers with one or two copies of the susceptibility variant are likely to smoke between one and two cigarettes more a day (Spitz *et al.*, 2008). Evidence for an effect of the 15q25 locus among never smokers is conflicting, with an association found in one study in Europe (Hung *et al.*, 2008b) and one in Asia (Wu *et al.*, 2009a), but not in others. Whether genes in the 15q25 locus have an effect on lung cancer beyond their propensity to increase numbers of cigarettes smoked is unclear.

Three genome-wide association studies identified genetic factors that modified disease risk. The first was a genome-wide association analysis to identify genetic polymorphisms associated with lung cancer risk in 1154 lung cancer patients of European ancestry who were current or former smokers and 1137 control subjects who were frequency matched to the lung cancer patients by age, sex, race and smoking status. Two SNPs, rs105173 and rs803419, which mapped to a region of strong linkage disequilibrium within 15q25.1, were strongly associated with risk of lung cancer, with an odds ratio for rs105173 of 1.31 ($P = 9.84 \times 10^{-6}$). This finding was replicated with an additional 711 case subjects and 632 control subjects from Texas ($P = 0.00042$) and in 2013 case subjects and 3062 control subjects in the United Kingdom ($P = 2.33 \times 10^{-10}$). The region of interest encompasses the nicotinic acetylcholine receptor subunit genes CHRNA3 and CHRNA5 (as well as CHRNB4) (Spitz *et al.*, 2008). A second genome-wide association study conducted among 1989 lung cancer cases and 2625 controls from six central European countries confirm these results (Hung *et al.*, 2008a). In a third genome-wide association study of 665 Icelandic, 269 Spanish and 90 Dutch lung cancer cases and 32244 controls a common variant in the nicotinic acetylcholine receptor gene cluster [chromosome region 15q24] was significantly associated with lung cancer risk (OR, 1.31; 95%CI: 0.1.19–1.44). The variant was observed to have a significant effect on the number of cigarettes smoked per day (Thorgeirsson *et al.*, 2008). These studies have all shown a link between this variant and lung cancer risk either through a mechanism involving nicotine dependence or a direct role in downstream signalling pathways that promote carcinogens. Together these results provide compelling evidence of a locus at 15q25 and 15q24 predisposing to lung cancer.

(iv) Alpha(1)-antitrypsin

Alpha(1)-antitrypsin deficiency (α(1)ATD) is one of the most common genetic disorders, especially among European descendents. Recent results suggest that α(1)ATD carriers are at a 70–100% increased risk of lung cancer, accounting for 11% to 12% of patients with lung cancer (Yang *et al.*, 2008). [The specific effect by smoking status was not evaluated.]

(v) Other genes

Mutations in the checkpoint CHEK2 gene have been associated with increased risk of breast, prostate and colon cancer and a decreased risk of lung cancer among those with the I157T missense variant of the CHEK2 gene. In a large Polish case–control study CHEK2 mutations were protective against lung cancer (OR, 0.3; 95%CI: 0.2–0.5) (Cybulski *et al.*, 2008).

The Swedish Family-Cancer Database was used to compare the rate of lung cancers among persons without family history of lung cancer to those with a family history (Li & Hemminki, 2004). A high risk by family history in adenocarcinoma (standardized incidence ratio (SIR),

2.03) and large cell carcinoma (SIR, 2.14) was found, a slightly lower risk among patients with squamous cell carcinoma (SIR, 1.63) and small cell carcinoma (SIR, 1.55). Among siblings, an increased risk was shown for concordant adenocarcinoma and small cell carcinoma at all ages and for all histological types when cancer was diagnosed before age 50. At young age, risks between siblings were higher than those between offspring and parents. These data suggest that a large proportion of lung cancers before age 50 are heritable and due to a high-penetrant recessive gene or genes that predispose to tobacco carcinogen susceptibility.

(e) Viral infection

Data are limited regarding lung cancer risk in human immunodeficiency virus (HIV)-infected persons with modest immune suppression, before the onset of acquired immunodeficiency syndrome (AIDS). Among 57350 HIV-infected persons registered in the USA during 1991–2002 (median CD4 counts 491 cells/mm^3), 871 cancers occurred. Risk was elevated for several non-AIDS defining malignancies, including cancer of the lung (SIR, 2.6 [n = 109]) (Engels *et al.*, 2008). [Specific evaluation with smoking status was not performed.]

2.3 Cancers of the upper aerodigestive tract

Evidence relating to cancers of the upper aerodigestive tract obtained from relevant cohort and case–control studies on specific sites is described in Sections 2.3.1 to 2.3.6; studies that looked at several subsites combined are described in Section 2.3.7. The major potential confounders for the relationship between smoking and cancers of the upper aerodigestive tract are alcohol consumption and use of any form of smokeless tobacco, and for some sites infection with human papillomavirus (HPV) (especially HPV16). In general, the studies examined by the Working Group had adjusted for these two confounders when appropriate. Some studies also adjusted for dietary intake, especially of fruits and vegetables, although few reported stratified relative risks.

2.3.1 Cancer of the oral cavity

Tobacco smoking was found to be causally related to oral cancer (IARC, 1986, 2004a). New studies on the relationship between oral cancer and cigarette smoking published since the most recent *IARC Monograph* (IARC, 2004a) include four cohort studies (Table 2.7 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.7.pdf), and eight case–control studies (Tables 2.8–2.11 online; see below).

(a) Intensity and duration of smoking

Intensity of smoking was measured in almost all cohort (Table 2.7 online) and case–control studies (IARC 2004a; Table 2.8 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.8.pdf and Table 2.9 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.9.pdf). In addition to the number of cigarettes or amount of tobacco smoked daily, cumulative exposure to cigarette smoke was also measured in terms of pack–years, tobacco-years or lifetime tobacco consumption. The link between duration of cigarette consumption and oral cancer was examined in 15 case–control studies. Seven case–control studies also considered age at starting smoking.

One cohort study (McLaughlin *et al.*, 1995) and 14 case–control studies reported a dose-dependent increase in risk with increasing number of cigarettes smoked daily or increasing daily tobacco consumption (Franceschi *et al.*, 1990, 1992, 1999; Nandakumar *et al.*, 1990; Zheng *et al.*, 1990; Choi & Kahyo, 1991; Oreggia *et al.*, 1991; Bundgaard *et al.*, 1995; Zheng *et al.*, 1997; De Stefani *et al.*, 1998; Hayes *et al.*, 1999; De Stefani

et al., 2007; Subapriya et al., 2007; Muwonge et al. 2008). Whenever analysed, the trend was always statistically significant (Franceschi et al., 1990, 1992; Oreggia et al., 1991; Bundgaard et al., 1995; McLaughlin et al. 1995; Hayes et al., 1999; Subapriya et al., 2007), except in the study of Muwonge et al. (2008) which also included bidi smokers.

Bundgaard et al. (1995) used lifetime tobacco consumption divided into four categories and reported a positive, significant trend after adjustment for life-time consumption of alcohol and other risk factors. A positive trend was also found in all studies that have analysed consumption in pack–years or tobacco-years (Zheng et al., 1990; Maier et al., 1992a; Macfarlane et al., 1995; Hung et al., 1997; Zheng et al., 1997; De Stefani et al., 1998, 2007; Applebaum et al., 2007; Muwonge et al., 2008), except Muwonge et al. (2008).

Ten studies (Franceschi et al., 1990, 1992; Nandakumar et al., 1990; Zheng et al., 1990; Choi & Kahyo, 1991; Oreggia et al., 1991; Zheng et al., 1997; De Stefani et al., 1998, 2007; Znaor et al., 2003; Subapriya et al., 2007; Muwonge et al., 2008) classified the duration of smoking in up to four categories, and all but one (Nandakumar et al., 1990) reported increased relative risks and a positive trend.

Of six studies that considered age at start of smoking (Franceschi et al., 1990, 1992; Choi & Kahyo, 1991; Oreggia et al., 1991; Zheng et al., 1997; Balaram et al., 2002) two reported a statistically significant trend of increasing risk with decreasing age at starting (Franceschi et al., 1990, 1992).

(b) Cessation of smoking

Three cohort studies (McLaughlin et al., 1995; Freedman et al., 2007a; Friborg et al. 2007) and nine case–control studies (Zheng et al., 1990; Choi & Kahyo, 1991; Oreggia et al., 1991; Franceschi et al., 1992; Ko et al., 1995; Zheng et al., 1997; De Stefani et al., 1998, 2007; Schildt et al., 1998; Balaram et al., 2002; Pacella-Norman et al., 2002; Muwonge et al. 2008) estimated risks for former smokers which were always lower than those for current smokers and in five studies almost reached unity (Zheng et al., 1990; Choi & Kahyo, 1991; Zheng et al., 1997; Schildt et al., 1998; Muwonge et al., 2008). Twelve case–control studies examined the risk by years since quitting and all reported a negative trend, with relative risks compared with those in non-smokers decreasing to near unity after 10 or more years (Franceschi et al., 1990, 1992; De Stefani et al., 1998, 2007; Schlecht et al., 1999a; Table 2.7 online; Table 2.10 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.10.pdf).

(c) Type of cigarette

The effect of the type of cigarette smoked was examined in several case–control studies (Table 2.11 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.11.pdf). The characteristics of the cigarettes included the presence of a filter, the type of tobacco, the tar content and whether the product was manufactured or hand-rolled. Two studies reported a statistically significantly higher risk for black than for blond tobacco (Oreggia et al., 1991; De Stefani et al., 1998, 2007). Similarly, a much higher risk was found for hand-rolled cigarettes than for manufactured cigarettes, and plain cigarettes had a much higher risk than filter-tipped cigarettes (De Stefani et al., 1998, 2007). In one study the differences between black and blond tobacco and between hand-rolled and manufactured cigarettes persisted after stratification by duration of smoking (De Stefani et al., 1998). Smoking cigarettes with a high-tar content led to higher risks than smoking cigarettes with a low-tar content (Franceschi et al., 1992) and the same trend was observed for cigarettes without filter compared to cigarettes with filter (De Stefani et al., 2007).

(d) Sex

Sex-specific effects were examined in two case–control studies (Zheng *et al.*, 1990; Hayes *et al.*, 1999). In both studies, the relative risks for all categories of intensity, duration of smoking and pack–years were higher for women than for men. [The Working Group noted that the background risk of oral cancer is considerably lower in women than men. Thus, the higher relative risk estimates in women than men indicate a higher proportionate contribution from smoking in women than men, rather than higher absolute risk.]

2.3.2 Cancer of the pharynx

Tobacco smoking was considered to be an important cause of oropharyngeal and hypopharyngeal cancers in the previous *IARC Monographs* on tobacco smoking (IARC, 1986, 2004a). Since then, results available from three cohort (Table 2.12 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.12.pdf) and seven case–control studies (Table 2.13 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.13.pdf and Table 2.14 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.14.pdf) provide further support for the association. Many studies, however, combine cancers of the oral cavity and pharynx (see Section 2.3.7). This section summarizes the evidence from all eight cohort and 21 case–control studies that reported results specifically on oropharyngeal and hypopharyngeal cancer, or on pharyngeal cancer in general; the latter may include data on nasopharyngeal cancer.

The risk for pharyngeal cancer was significantly increased in smokers in four cohort studies (Doll *et al.*, 2005; McLaughlin *et al.*,1995; Freedman *et al.*, 2007a; Friborg *et al.*, 2007) and all but one of the case–control studies (Rao *et al.*, 1999). The trend of increasing risk associated with increasing daily or cumulative consumption of cigarettes was evident from all these studies, particularly those from Europe (Brugere *et al.*, 1986; Tuyns *et al.*, 1988; Franceschi *et al.*, 1990, 1999; Maier *et al.*, 1994; Escribano Uzcudun *et al.*, 2002; Vlajinac *et al.*, 2006), India (Znaor *et al.*, 2003; Sapkota *et al.*, 2007), Uruguay (De Stefani *et al.*, 1998, 2007) and the USA (McLaughlin *et al.*, 1995; Applebaum *et al.*, 2007), and less strongly so in studies from Canada (Elwood *et al.*, 1984) and the Republic of Korea (Choi & Kahyo, 1991). The multicentre study in Europe, North and South America of Hashibe *et al.* (2007c) showed increased risks according to frequency (cigarettes/day) and duration (years) in never drinkers. Applebaum *et al.* (2007) found a relationship between increasing risk of pharyngeal cancer and increased pack–years of smoking in subjects with negative HPV16 serology but not in those with positive HPV16 serology (p value for interaction = 0.007).

In two case–control studies the risk increased with decreasing age at starting smoking (Franceschi *et al.*, 1990; Choi & Kahyo, 1991,), but adjustment was not made for duration and intensity of smoking. In a case–control study from Spain (Escribano Uzcudun *et al.*, 2002) the risk increased with the age of starting smoking.

Former smokers had consistently lower relative risks than did current smokers in both cohort (McLaughlin *et al.*, 1995; Freedman *et al.*, 2007a) and case–control studies (Choi & Kahyo, 1991; De Stefani *et al.*, 1998; Vlajinac *et al.*, 2006). In comparison with non-smokers, the relative risks for former smokers who had quit smoking for more than 10 years were between 2 and 4 (Franceschi *et al.*, 1990; De Stefani *et al.*, 1998; La Vecchia *et al.*, 1999), whereas the relative risks for current smokers in these studies were 10–14. In one study in Brazil (Schlecht *et al.*, 1999a), relative risks for former smokers who had stopped smoking for more than 10 years approached 1, whereas that for current smokers was just below 6. Consumption of black tobacco, hand-rolled cigarettes or plain cigarettes resulted in a higher

risk for pharyngeal cancer than consumption of blond tobacco, manufactured cigarettes or filter-tipped cigarettes (De Stefani *et al.*, 1998; 2007).

2.3.3 Cancer of the nasal cavity and accessory sinuses

In the Life Span Study in Japan (Akiba, 1994) the association of tobacco use with sinonasal cancer was examined. A total of 26 cases of sinonasal cancer were identified among 61505 adults during follow-up. Relative risk estimates, adjusted for sex, location, population group, atomic bomb exposure, year of birth and attained age, were 2.9 (95%CI: 0.5–) and 4.0 (95%CI: 1.2–) for former and current smokers, respectively, when compared with non-smokers [upper confidence limits were not reported]. The cohort of 34439 British doctors followed up to 50 years (Doll *et al.*, 2005) showed increased risk for current smokers and smokers of more than 25 cigarettes per day, but only six deaths from nasal cavity and sinuses cancers were observed (Table 2.15 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.15.pdf).

A total of nine case–control studies of nasal cavity and sinus cancers have been conducted. When histological types were combined, all studies found an increased risk associated with cigarette smoking, but only one was statistically significant (Caplan *et al.*, 2000). In seven studies, dose–response in terms of intensity of smoking (cigarettes/day), duration of smoking or pack–years was considered. A positive significant trend was found in five studies (Brinton *et al.*, 1984; Hayes *et al.*, 1987; Fukuda & Shibata, 1990; Zheng *et al.*, 1993; Caplan *et al.*, 2000) and suggested in the other two (Strader *et al.*, 1988; Zheng *et al.*, 1992c).

One study (Zheng *et al.*, 1993a) found a significant decrease in risk for sinonasal cancer associated with increasing number of years since cessation of smoking. In a previous study, the same authors had found a negative, non-significant association (Zheng *et al.*, 1992c).

Five studies analysed squamous-cell carcinomas and adenocarcinomas separately (Brinton *et al.*, 1984; Hayes *et al.*, 1987; Strader *et al.*, 1988; Zheng *et al.*, 1992c; 't Mannetje *et al.*, 1999). In all studies, there was a significantly increased risk for squamous-cell carcinomas, whereas the risk was generally not increased for adenocarcinomas.

2.3.4 Cancer of the nasopharynx

(a) Cohort studies

The risk for nasopharyngeal carcinoma has been examined in relation to tobacco use in six cohort studies, three of them reported since the last evaluation (IARC 2004a; Table 2.16 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.16.pdf). In one study, conducted in a low-risk area (Chow *et al.*, 1993a), a significant increase in risk among smokers and suggestive positive dose–response relationships by duration of smoking and age at starting smoking were found. In another study, conducted in Province of Taiwan, China, an area in which nasopharyngeal cancer area is endemic, a similarly increased risk was found, but it was not statistically significant (Liaw & Chen, 1998). Doll *et al.* (2005) identified a risk only for smokers of more than 25 cigarettes per day, however, this result was based on only four deaths. Friborg *et al.* (2007) in Singapore found statistically significant increased risk of nasopharyngeal cancer only for those smoking for 40 years or more. Hsu *et al.* (2009) in Taiwan, China observed increased statistically significant risks only for those smoking for 30 years or more and those with cumulative exposure of 30 pack–years or more.

(b) Case–control studies

The study designs and the results of the case–control studies on the association of nasopharyngeal carcinoma with cigarette smoking

reported since the previous *IARC Monograph* (IARC, 2004a) are given in Table 2.17 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.17.pdf) and Table 2.18 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.18.pdf), one being a nested case–control analysis within a cohort study (Marsh *et al.*, 2007).

In total, 14 informative case–control studies were available. In almost all of these, the risk for nasopharyngeal carcinoma was higher in smokers than in non-smokers. In Taiwan, China (Cheng *et al.*, 1999) high risks were statistically significant only for duration of smoking of 20 years or more. In the five studies conducted in the USA (Mabuchi *et al.*, 1985; Nam *et al.*, 1992; Zhu *et al.*, 1995; Vaughan *et al.*, 1996; Marsh *et al.*, 2007), where the incidence of nasopharyngeal carcinoma is low, the relative risks for current smokers ranged between 2 and 4, but were not statistically significant in the two studies (Mabuchi *et al.*, 1985; Marsh *et al.*, 2007). In a study conducted in Shanghai, an area of China in which nasopharyngeal carcinoma is not endemic (Yuan *et al.*, 2000), the relative risk was just below 2. In one study from the Philippines there was a sevenfold increase in risk after more than 30 years of smoking (West *et al.*, 1993). The four studies (Lin *et al.*, 1973; Yu *et al.*, 1990; Ye *et al.*, 1995; Cao *et al.*, 2000) conducted in areas of China in which nasopharyngeal carcinoma is endemic (Taiwan, China, Guangzhou, and Sihui) found relative risks for ever smoking ranging between 2 and 5. In the study from the North of Africa (Feng *et al.*, 2009) the only statistically significant increased risk was found for differentiated nasopharyngeal cancer in those that had smoked more than 22 cigarettes/day. [The result, based only on three cases, is very unstable (RR, 313; 95%CI: 1.94–50336).]

A statistically significant dose–response relationship was detected in seven studies that evaluated the effects of daily or cumulative exposure to tobacco smoke (Yu *et al.*, 1990; Nam *et al.*, 1992; Zhu *et al.*, 1995; Vaughan *et al.*, 1996; Cao *et al.*, 2000; Yuan *et al.*, 2000; Feng *et al.*, 2009) and was suggestive in two others (Lin *et al.*, 1973; West *et al.*, 1993). In two studies the risk of nasopharyngeal carcinoma decreased with increasing time since quitting smoking (Nam *et al.*, 1992; Vaughan *et al.*, 1996).

In the remaining studies, six from areas in which nasopharyngeal carcinoma is endemic (Ng, 1986; Yu *et al.*, 1986; Sriamporn *et al.*, 1992; Zheng *et al.*, 1994; Cheng *et al.*, 1999; Feng *et al.*, 2009; Guo *et al.*, 2009) and seven from areas in which it was not endemic (Henderson *et al.*, 1976; Lanier *et al.*, 1980; Mabuchi *et al.*, 1985; Ning *et al.*, 1990; Armstrong *et al.*, 2000, Marsh *et al.*, 2007), the relative risks for nasopharyngeal carcinoma for ever smoking were not significantly increased (Lanier *et al.*, 1980; Mabuchi *et al.*, 1985; Cheng *et al.*, 1999) or were close to 1.0 (Henderson *et al.*, 1976; Ng, 1986; Yu *et al.*, 1986; Ning *et al.*, 1990; Sriamporn *et al.*, 1992; Zheng *et al.*, 1994; Guo *et al.*, 2009).

In the two studies that distinguished between different histological types, relative risks were higher for keratinized (squamous-cell) carcinoma than for unkeratinized carcinoma (Zhu *et al.*, 1995; Vaughan *et al.*, 1996).

In the three studies in which men and women were analysed separately (Lin *et al.*, 1973; Nam *et al.*, 1992; Yuan *et al.*, 2000), the relative risks were found to increase similarly in both sexes in two studies (Nam *et al.*, 1992; Yuan *et al.*, 2000) and were higher among women in the study of Lin *et al.* (1973).

2.3.5 Cancer of the oesophagus

In the previous *IARC Monograph* (IARC, 2004a), both histological subtypes of oesophageal cancer (squamous-cell carcinoma and adenocarcinoma) were considered to be causally related to cigarette smoking. Many more epidemiological studies have since been conducted, and results of these studies further support this conclusion.

(a) *Squamous cell carcinoma and unspecified cancer of the oesophagus*

Since the previous *IARC Monograph* (IARC, 2004a), there have been reports on 9 cohort studies (Table 2.19 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.19.pdf) and 22 case–control studies (Tables 2.20–2.23; see below), making 30 cohort and 55 case–control studies in all. All showed that the risk of oesophageal squamous cell carcinoma was associated with cigarette smoking. In one study (Li *et al.*, 1989), the elevated risk was observed only in an area with a relatively low incidence of oesophageal cancer. However, two later studies in the same area, Lin County, China, found a twofold increase in risk for oesophageal cancer among smokers (Gao *et al.*, 1994; Lu *et al.*, 2000).

In most cohort studies and in most case–control studies with relatively large sample sizes (IARC, 2004a; Table 2.19 online; Table 2.20 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.20.pdf; Table 2.21 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.21.pdf), the risk for oesophageal cancer was shown to increase with increasing duration of smoking (11 cohort and 32 case–control studies) or number of cigarettes smoked daily (18 cohort and 31 case–control studies), and to decrease with increasing age at starting smoking (12 case–control studies). In comparison with pharyngeal and laryngeal cancers, relative risks for oesophageal cancer estimated by duration and by intensity of smoking were somewhat lower (see Sections 2.3.2 and 2.3.6, respectively).

Ten cohort and 20 case–control studies (IARC, 2004a; Table 2.19 online; Table 2.22 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.22.pdf) investigated the effect of smoking cessation on risk of oesophageal cancer. Although not all studies analysed the trend, all found a decreasing relative risk with increasing number of years since quitting. In some studies, the risk first started to decrease after 10 years of cessation (Brown *et al.*, 1988; Rolón *et al.*, 1995; Gammon *et al.*, 1997; Castellsagué *et al.*, 1999; Freedman *et al.*, 2007b; Bosetti *et al.*, 2008) or after 30 years of cessation (Pandeya *et al.*, 2008).

When comparing the types of tobacco smoked (Table 2.23 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.23.pdf), consumption of black tobacco resulted in a higher risk for oesophageal cancer than did consumption of blond tobacco (De Stefani *et al.*, 1990; Rolón *et al.*, 1995; Castellsagué *et al.*, 1999; Launoy *et al.*, 2000; Vioque *et al.*, 2008). Similarly, smoking untipped cigarettes generally resulted in a higher risk than smoking filter-tipped cigarettes (Vaughan *et al.*, 1995; Gammon *et al.*, 1997; Castellsagué *et al.*, 1999).

Two studies from the USA reported risks separately for blacks and whites. After adjustment for alcohol consumption, age and income, risks were very similar for former and current smokers and for the number of cigarettes smoked per day and duration of smoking (Brown *et al.*, 1994a; Brown *et al.*, 2001).

(b) *Adenocarcinoma of the oesophagus*

Two decades ago it was noted that incidence rates for adenocarcinoma of the oesophagus and gastric cardia had increased steadily in the USA, whereas the incidence rate for squamous-cell carcinoma of the oesophagus had remained relatively stable (Blot *et al.*, 1991). An increase in the incidence of adenocarcinoma of the distal oesophagus and cardia was also noted in the United Kingdom (Powell & McConkey, 1990), and in several other countries. Since 1990, several studies have focused on the risk factors for adenocarcinoma of the oesophagus. Since the last evaluation (IARC, 2004a) one cohort study (Freedman *et al.*, 2007b) and three case–control studies (Table 2.24 available at http://monographs.iarc.fr/ENG/Monographs/

vol100E/100E-01-Table2.24.pdf; Table 2.25 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.25.pdf) have been reported, totaling 13 case–control studies on the association of cigarette smoking and adenocarcinoma of the oesophagus.

(i) Intensity and duration of smoking

Ten studies, three that included only cases of adenocarcinoma of the oesophagus (Menke-Pluymers *et al.*, 1993; Gammon *et al.*, 1997; Wu *et al.*, 2001), three that included cases of adenocarcinoma of the oesophagus, gastro-oesophageal junction and gastric cardia combined (Kabat *et al.*, 1993; Brown *et al.*, 1994b; Vaughan *et al.*, 1995), and four that stratified by histology (Lindblad *et al.*, 2005; Freedman *et al.*, 2007b; Hashibe *et al.*, 2007a; Pandeya *et al.*, 2008), showed a significant positive association of adenocarcinoma of the oesophagus with cigarette smoking. The relative risks were somewhat lower than those for squamous cell carcinoma of the oesophagus. Three studies, one in China (Gao *et al.*, 1994), one in Sweden (Lagergren *et al.*, 2000), and one in the USA (Zhang *et al.*, 1996), reported similarly elevated relative risks, but some of these risks were not statistically significant, probably because of relatively small numbers of cases.

Of those studies that reported risks adjusted for alcohol consumption, a positive, significant dose–response relationship was found with intensity of smoking (Kabat *et al.*, 1993; Brown *et al.*, 1994b; Gammon *et al.*, 1997; Hashibe *et al.*, 2007a), duration of smoking (Gammon *et al.*, 1997; Pandeya *et al.*, 2008) and/or pack–years (Vaughan *et al.*, 1995; Zhang *et al.*, 1996; Gammon *et al.*, 1997; Pandeya *et al.*, 2008).

(ii) Cessation of smoking

Ten studies provided point estimates for former smokers. In eight, relative risks were lower in former smokers than in current smokers, although they remained elevated (Kabat *et al.*, 1993; Gao *et al.*, 1994; Vaughan *et al.*, 1995; Gammon *et al.*, 1997; Wu *et al.*, 2001; Lindblad *et al.*, 2005; Freedman *et al.*, 2007b; Pandeya *et al.*, 2008), and were increased in the other studies (Lagergren *et al.*, 2000; Hashibe *et al.*, 2007a). The decrease in relative risk associated with years since cessation was weak, but a significant trend was found in two out of six studies (Gammon *et al.*, 1997; Wu *et al.*, 2001).

(iii) Confounding

With the exception of two studies (Levi *et al.*, 1990; Wu *et al.*, 2001), all studies adjusted for alcohol intake as a potential confounder. Three more recent studies also adjusted for fruit and vegetables intake (Freedman *et al.*, 2007b; Hashibe *et al.*, 2007a; Pandeya *et al.*, 2008). Ten of these studies were conducted in the USA (Kabat *et al.*, 1993; Brown *et al.*, 1994b; Vaughan *et al.*, 1995; Zhang *et al.*, 1996; Gammon *et al.*, 1997; Freedman *et al.*, 2007b) the Netherlands (Menke-Pluymers *et al.*, 1993), the United Kingdom (Lindblad *et al.*, 2005), central and eastern Europe (Hashibe *et al.*, 2007a) and Australia (Pandeya *et al.*, 2008), where chewing of betel quid with tobacco or use of other forms of smokeless tobacco are not likely confounders. One study conducted in Sweden was adjusted for snuff use (Lagergren *et al.*, 2000).

(iv) Sex

Kabat *et al.* (1993) examined risks for men and women separately and observed similar patterns in both sexes, although risks among current smokers and heavy smokers were somewhat higher for women than for men. Lindblad *et al.* (2005) also found higher risks in women than in men, but they were not statistically significant.

2.3.6 Cancer of the larynx

Laryngeal cancer is one of the cancers most strongly associated with cigarette smoking (IARC, 1986, 2004a). Since the previous *IARC*

Monograph, more epidemiological evidence has become available to strengthen this conclusion.

(a) Potential confounders

Other causes of laryngeal cancer include alcohol consumption, some occupational exposures (e.g. sulphuric acid; IARC, 2012a) and possibly some dietary habits. In investigating associations between smoking and laryngeal cancer, potential confounding by alcohol consumption has been considered in most of the studies.

(b) Intensity and duration of smoking

Cohort and case–control studies have been carried out in Asia, Europe, North and South America, and South Africa. In all, the risk for laryngeal cancer was consistently higher in smokers, and a positive significant trend was observed with increasing duration and intensity of smoking (IARC, 2004a; Table 2.26 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.26.pdf; Table 2.27 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.27.pdf; Table 2.28 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.28.pdf).

In most case–control studies, the relative risks for laryngeal cancer were near to or greater than 10 for smokers who had smoked for longer than 40 years (Falk *et al.*, 1989; Zheng *et al.*, 1992b) or had smoked more than 20 cigarettes per day (Tuyns *et al.*, 1988; Falk *et al.*, 1989; Choi & Kahyo, 1991; Zatonski *et al.*, 1991; Muscat & Wynder, 1992; Zheng *et al.*, 1992b; Hedberg *et al.*, 1994; Sokić *et al.*, 1994; Talamini *et al.*, 2002). Cancer of the larynx in non-smokers is so rare that several studies used as the reference category light smokers (Herity *et al.*, 1982; Olsen *et al.*, 1985a; De Stefani *et al.*, 1987; Zatonski *et al.*, 1991; López-Abente *et al.*, 1992; Maier & Tisch, 1997), or former smokers (Hashibe *et al.*, 2007b). Consequently, relative risks were lower in these studies, although the increases were still statistically significant.

Three case–control studies reported odds ratios for cancer of the larynx that increased with decreasing age of starting smoking (Franceschi *et al.*, 1990; Zatonski *et al.*, 1991; Talamini *et al.*, 2002).

(c) Cessation of smoking

The risk for cancer of the larynx declines rather rapidly after cessation of smoking (IARC, 2004a; Table 2.29 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.29.pdf). No detectable higher risk compared with never-smokers was seen among subjects who had quit smoking for at least 10 years (Franceschi *et al.*, 1990; Ahrens *et al.*, 1991; Schlecht *et al.*, 1999a, b; Bosetti *et al.*, 2006; Hashibe *et al.*, 2007b).

(d) Types of tobacco or of cigarette

Some investigators considered the role of type of tobacco (IARC, 2004a; Table 2.30 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.30.pdf). An average 2.5-fold higher risk was observed in smokers of black tobacco compared to smokers of blond tobacco (De Stefani *et al.*, 1987; Tuyns *et al.*, 1988; López-Abente *et al.*, 1992). Smoking untipped cigarettes also led to a higher risk than smoking filter-tipped cigarettes (Wynder & Stellman, 1979; Tuyns *et al.*, 1988; Falk *et al.*, 1989). Those that smoke cigarettes only had higher risks of larynx cancer than those that smoke cigars only (Hashibe *et al.*, 2007b).

(e) Subsites

Six studies investigated the risk for glottic and supraglottic cancer separately (Olsen *et al.*, 1985a; Tuyns *et al.*, 1988; López-Abente *et al.*, 1992; Maier *et al.*, 1992b; Muscat & Wynder, 1992; Sapkota *et al.*, 2007). The cancer risk increased with increasing amount smoked per

day and with cumulative exposure for both subsites (IARC, 2004a; Table 2.28 online). In addition, the observed relative risks were higher for supraglottic cancer than for glottic cancer (Maier *et al.*, 1992b; Sapkota *et al.*, 2007).

(f) Sex

Few studies investigated sex-specific effects. In one cohort study (Raitiola & Pukander, 1997) similar risks were found for men and women, whereas in two case–control studies (Zheng *et al.*, 1992b; Tavani *et al.*, 1994), the relative risks for women were up to 10-fold higher than for the corresponding categories in men, though a small number of cases were involved. However, Freedman *et al.* (2007a) observed higher relative risks in men than women (Table 2.26 online). One study looked at women only and found higher risks of laryngeal cancer in former and current smokers relative to non-smokers, and also according to the number of cigarettes per day with a clear dose–response effect ($P < 0.001$) (Gallus *et al.*, 2003b).

2.3.7 Cancer of the upper aerodigestive tract combined

In epidemiological studies, especially in cohort studies in which there are few cases at some sites, investigators often combine cancers of the oral cavity, pharynx, larynx and oesophagus and term these 'cancer of the upper aerodigestive tract'. This section summarizes the data from 19 cohort studies (IARC, 2004a; Table 2.31 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.31.pdf), and 40 case–control studies (IARC, 2004a; Tables 2.32–2.35; see below).

(a) Intensity and duration of smoking

In all but two cohort studies from Japan (Kono *et al.*, 1987; Akiba, 1994), the risk for cancer of the upper aerodigestive tract was strongly associated with cigarette smoking. Relative risks increased with increasing daily cigarette consumption (Hammond & Horn, 1958; Doll *et al.*, 1980, 1994; Akiba & Hirayama, 1990; Kuller *et al.*, 1991; Chyou *et al.*, 1995; Engeland *et al.*, 1996; Murata *et al.*, 1996; Yuan *et al.*, 1996; Kjaerheim *et al.*, 1998; Liaw & Chen, 1998; Yun *et al.*, 2005; Freedman *et al.*, 2007a), duration of smoking (Chyou *et al.*, 1995; Yun *et al.* 2005; Friborg *et al.*, 2007) or pack–years (Liaw & Chen, 1998; Freedman *et al.*, 2007a).

The main characteristics and results of the case–control studies are presented in IARC (2004a), and in Table 2.32 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.32.pdf) and Table 2.33 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.33.pdf), respectively. Intensity of smoking was measured in most of these studies. The link between duration of smoking and cancer of the upper aerodigestive tract was examined in 20 case–control studies (Blot *et al.*, 1988; Merletti *et al.*, 1989; Barra *et al.*, 1991; De Stefani *et al.*, 1992, 2007; Franceschi *et al.*, 1992; Day *et al.*, 1993; Mashberg *et al.*, 1993; Kabat *et al.*, 1994; Lewin *et al.*, 1998; Bosetti *et al.*, 2000a; Garrote *et al.*, 2001; Gallus *et al.*, 2003a; Lissowska *et al.*, 2003; Znaor *et al.*, 2003; Castellsagué *et al.*, 2004; Menvielle *et al.*, 2004a, b; Rodriguez *et al.*, 2004; Hashibe *et al.*, 2007c; Sapkota *et al.*, 2007). Nine also considered age at starting smoking (Blot *et al.*, 1988; Merletti *et al.*, 1989; Barra *et al.*, 1991; Franceschi *et al.*, 1992; Day *et al.*, 1993; Lewin *et al.*, 1998; Garrote *et al.* 2001; Lissowska *et al.* 2003; Menvielle *et al.* 2004a).

In all but one study (Rao *et al.*, 1999) there was an increased risk for cancer of the upper aerodigestive tract associated with cigarette smoking. A clear dose–response relationship was seen with increasing daily tobacco consumption and duration of smoking as well as with decreasing age at starting smoking in most of the studies examined.

(b) Cessation of smoking

Twelve cohort studies (Doll *et al.*, 1980, 1994; Tomita *et al.*, 1991; Akiba, 1994; Chyou *et al.*, 1995; Engeland *et al.*, 1996; Nordlund *et al.*, 1997; Kjaerheim *et al.*, 1998; Yun *et al.*, 2005; Freedman *et al.*, 2007a; Friborg *et al.*, 2007; Ide *et al.*, 2008) provided point estimates for former smokers (IARC 2004a; Table 2.31 online). The relative risks for former smokers were always lower than those for current smokers.

In 16 case–control studies the relative risk by years since quitting was examined and generally a statistically significant negative trend was found (Table 2.34 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.34.pdf).

(c) Types of cigarette

The characteristics studied in several case–control studies included the use of a filter, the type of tobacco, the tar content and whether the product was manufactured or hand-rolled (IARC, 2004a; Table 2.35 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.35.pdf). Consumption of black tobacco, cigars, untipped cigarettes, hand-rolled cigarettes, or cigarettes with a high-tar yield generally resulted in a higher risk than consumption of blond tobacco (Merletti *et al.*, 1989; Castellsagué *et al.*, 2004; De Stefani *et al.*, 2007), filter-tipped cigarettes (Merletti *et al.*, 1989; Mashberg *et al.*, 1993; Kabat *et al.*, 1994; Lissowska *et al.*, 2003; De Stefani *et al.*, 2007), manufactured cigarettes (De Stefani *et al.*, 1992, 2007) or low-tar cigarettes (Franceschi *et al.*, 1992). Two studies from India (Znaor *et al.*, 2003; Sapkota *et al.* 2007) revealed higher risks of *bidi* smoking related to cigarettes smoking.

(d) Sex

Sex-specific effects were analysed in four cohort studies (IARC 2004a; Table 2.31 online). In three cohort studies (Hammond & Seidman, 1980; Akiba & Hirayama, 1990; Freedman *et al.*, 2007a) a higher relative risk was found for male smokers than for female smokers; however, Ide *et al.* (2008) detected a higher risk among women in a study with a small number of cases.

In three case–control studies (Blot *et al.*, 1988; Kabat *et al.*, 1994; Muscat *et al.*, 1996) the relative risks were higher for women than for men in all categories of intensity of smoking (number of cigarettes per day), cumulative exposure (cumulative tar consumption, pack–years, duration of smoking) and age at starting smoking, as well as for former smokers. However, the trends in men were always in the same direction and of the same order of magnitude. An exception to the pattern was that in one study (Merletti *et al.*, 1989) the relative risk for smoking filter-tipped cigarettes was higher than that for smoking untipped cigarettes for women.

Overall, the strength of association by sex was generally similar, especially when taking into account the fact that women generally underreport levels of smoking and that most studies included many fewer women than men.

(e) Ethnicity

Relative risks were reported separately for blacks and whites in a large case–control study from the USA (Day *et al.*, 1993). Relative risks adjusted for alcohol consumption, sex and other relevant variables were very similar for the number of cigarettes smoked per day, years of cigarette smoking, age at starting smoking and number of years since stopping smoking.

2.4 Cancer of the stomach

2.4.1 Overview of studies

In the previous *IARC Monograph* (IARC, 2004a) it was concluded that there was *sufficient evidence* that tobacco smoking causes cancer of the stomach. Three meta-analyses have since examined the evidence for gastric cancer in 42

independent cohort studies published between 1958 and July 2007 (Ladeiras-Lopes *et al.*, 2008), in 46 case–control studies published between 1997 and June 2006 (La Torre *et al.*, 2009), and in 10 cohort and 16 case–control studies conducted in Japanese populations published between 1966 and March 2005 (Nishino *et al.*, 2006; Table 2.36 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.36.pdf). For current smokers compared to never smokers, the risk for stomach cancer was found to be statistically significantly increased by 53% (Ladeiras-Lopes *et al.*, 2008), 56% (Nishino *et al.*, 2006), and 57% when considering high quality case–control studies (La Torre *et al.*, 2009), with moderate to high heterogeneity.

Since the previous *IARC Monograph* (IARC, 2004a), the association between cigarette smoking and stomach cancer risk (15 studies) and mortality (4 studies) has been examined in 19 cohort studies (Table 2.37 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.37.pdf). Eleven of these were conducted in Asia (Sasazuki *et al.*, 2002; Jee *et al.*, 2004; Koizumi *et al.*, 2004; Wen *et al.*, 2004; Fujino *et al.*, 2005; Sauvaget *et al.*, 2005; Tran *et al.*, 2005; Kurosawa *et al.*, 2006; Kim *et al.*, 2007; Sung *et al.*, 2007; Shikata *et al.*, 2008), seven in Europe (Simán *et al.*, 2001; González *et al.*, 2003; Doll *et al.*, 2005; Lindblad *et al.*, 2005; Sjödahl *et al.*, 2007; Batty *et al.*, 2008; Zendehdel *et al.*, 2008) and one in the USA (Freedman *et al.*, 2007a). Only the updated British Doctors' study (Doll *et al.*, 2005) and the most recent studies (Shikata *et al.*, 2008; Zendehdel *et al.*, 2008) were not included in the meta-analysis of cohort studies (Ladeiras-Lopes *et al.*, 2008). Elevated risks in current smokers were found in all studies. The reported association of current smoking with mortality in the four cohort studies conducted in Taiwan, China (Wen *et al.*, 2004), Japan (Kurosawa *et al.*, 2006) and the United Kingdom (Doll *et al.*, 2005; Batty *et al.*, 2008) was comparable to that with incidence.

In addition, the association between smoking and stomach cancer risk has been reported in 37 case–control studies since the previous *IARC Monograph*, of which 22 are hospital-based and 15 population-based. With the exception of three studies (Campos *et al.*, 2006; García-González *et al.*, 2007; Suwanrungruang *et al.*, 2008; Table 2.38 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.38.pdf), all these studies were included in the meta-analysis conducted by (La Torre *et al.*, 2009).

2.4.2 Factors affecting risk

(a) Intensity and duration

Clear evidence has been provided by the meta-analyses as well as by the additional cohort studies that the risk for stomach cancer increases significantly with increasing daily cigarette consumption, duration or pack–years of smoking, although individual studies did not always find statistically significant dose–response relationships. In one meta-analysis based on 21 cohort studies, the risk for stomach cancer increased statistically significantly by 53% with consumption of approximately 20 cigarettes per day (Ladeiras-Lopes *et al.*, 2008). Using trend estimation analysis as proposed by Greenland & Longnecker (1992), the authors found an increase in relative risk from 1.3 for the lowest consumption to 1.7 for smoking 30 cigarettes per day.

(b) Cessation of smoking

Risk for stomach cancer has been generally found to be lower in former smokers than in current smokers. In six of the cohort studies decreasing risk with increasing years since stopping smoking was found although none found statistically significant dose–response relationships (González *et al.*, 2003; Koizumi *et al.*, 2004; Sauvaget *et al.*, 2005; Freedman *et al.*, 2007a; Kim *et al.*, 2007; Zendehdel *et al.*, 2008). Risk in former smokers was comparable to never smokers after quitting for 5 years (Kim *et al.*,

2007), 10 years (González *et al.*, 2003; Sauvaget *et al.*, 2005; Freedman *et al.*, 2007a) or 15 years (Koizumi *et al.*, 2004).

2.4.3 Subsites

The effect of current smoking on the risk for stomach cancer by subsite was assessed in ten cohort studies. Elevated risks were found for both cardia and non-cardia cancers. In six studies higher risks were found for cancer of the gastric cardia than for cancer of the distal stomach (Simán *et al.* 2001; González *et al.*, 2003; Freedman *et al.*, 2007a; Sung *et al.*, 2007; Shikata *et al.*, 2008; Zendehdel *et al.*, 2008), three studies found no difference (Sasazuki *et al.*, 2002; Lindblad *et al.*, 2005; Tran *et al.*, 2005), and in one study higher risk for cancer in the antrum rather than the body or the cardia was found (Koizumi *et al.*, 2004). A meta-analysis yielded statistically significant summary relative risks of 1.87 for cardia cancers and 1.60 for non-cardia cancers based on nine cohort studies (Ladeiras-Lopes *et al.*, 2008). However, there was substantial heterogeneity across studies for cardia cancers. For case–controls studies, the corresponding odds ratios were 2.05 (95%CI: 1.50–2.81) and 2.04 (95%CI: 1.66–2.50), respectively, with greater heterogeneity for non-cardia cancers. Criteria for the classification by subsite were not always described (Simán *et al.*, 2001; Koizumi *et al.*, 2004; Lindblad *et al.*, 2005; Tran *et al.*, 2005) and some studies included tumours located in the upper third of the stomach in the group of cardia cancer (Sasazuki *et al.*, 2002; Sung *et al.*, 2007; Shikata *et al.* 2008).

In three studies risk estimates for smoking associated stomach cancer were estimated by histological type (Sasazuki *et al.*, 2002; Koizumi *et al.*, 2004; Shikata *et al.*, 2008). The relative risks were 2.1 (95%CI: 1.2–3.6), 1.6 (95%CI: 1.1–2.3) and 2.3 (95%CI: 1.3–4.1) for the differentiated type, respectively, and 0.6 (95%CI: 0.3–1.1), 2.1 (95%CI: 1.1–4.1), and 1.3 (95%CI: 0.5–3.5) for the non-differentiated type, respectively.

2.4.4 Population characteristics

In four of the additional cohort studies risk was reported separately for men and women (González *et al.*, 2003; Jee *et al.*, 2004; Fujino *et al.*, 2005; Kim *et al.*, 2007), in three studies only for men (Koizumi *et al.*, 2004; Tran *et al.*, 2005; Sung *et al.*, 2007) and in one mortality study for men as well as for women (Wen *et al.*, 2004). Generally, the relative risks were smaller in women than in men. For all stomach cancers, risk in current smokers compared to never smokers was found to be significantly increased by 62% in men (based on 18 studies) and by 20% in women (based on nine studies) in the meta-analysis of cohort studies (Ladeiras-Lopes *et al.*, 2008). The men–women differences were independent of exposure level but could be explained by the sex difference in the distribution by histological type and other factors associated with socioeconomic status.

Ethnicity does not appear to modify the effect of smoking on stomach cancer risk. In the meta-analysis of case–control studies risk in current smokers was increased by 78% in Caucasians and by 48% in Asians (La Torre *et al.*, 2009). The summary risk based on the cohort studies increased by 46% and 47% in Caucasian and Asian studies, respectively. In a meta-regression analysis including the variables sex, population, and fruit and vegetable consumption, sex but not origin of the population showed significant differences in risk estimates (Ladeiras-Lopes *et al.*, 2008).

2.4.5 Bias and confounding

Generally, most cohort studies have relied on baseline information and did not update the exposure information, possibly leading to misclassification of smoking status. Most of

the recent cohort studies have accounted for confounding by alcohol consumption (Fujino *et al.*, 2005; Lindblad *et al.*, 2005; Sjödahl *et al.*, 2007; Sung *et al.*, 2007) as well as fruit and vegetable consumption (González *et al.*, 2003; Koizumi *et al.*, 2004; Freedman *et al.* 2007a) and still observed significantly increased risk of stomach cancer in current smokers.

2.4.6 Helicobacter pylori infection

The association between tobacco smoking and stomach cancer could be confounded or modified by the effect of *H. pylori* infection, an established risk factor for stomach cancer. In three case–control studies (Zaridze *et al.*, 2000; Brenner *et al.*, 2002; Wu *et al.* 2003), and two cohort studies (Simán *et al.*, 2001; Shikata *et al.*, 2008) the joint effects and possible interaction between *H. pylori* status and smoking in relation to risk for stomach cancer was investigated. Among subjects who had *H. pylori* infection, the risk for stomach cancer was higher in current smokers than in non-smokers by 1.6 to 2.7 fold, providing evidence for a causal effect of tobacco smoking independently of *H. pylori* infection. Smoking was associated with risk elevations of the same order of magnitude among subjects without *H. pylori* infection. Smoking and *H. pylori* therefore may act synergistically, leading to very high risks in current smokers with *H. pylori* infection compared to non-smokers without *H. pylori* infection. In one study that examined risk by subsite an effect of smoking independent of *H. pylori* infection for gastric cardia as well as distal gastric cancer was found (Wu *et al.*, 2003). In none of the studies was there statistically significant evidence for interaction.

2.5 Cancer of the pancreas

2.5.1 Overview of studies

Previous *IARC Monographs* (IARC, 1986, 2004a) concluded that exposure to tobacco smoke caused cancer of the pancreas. Additional evidence has come from a pooled analysis of eight cohort studies with almost 1500 incident cases of pancreatic cancer and an equal number of controls (Lynch *et al.*, 2009) as well as a meta-analysis of 82 independent studies (42 case–control studies, 40 cohort studies) published between 1950 and 2007 (Iodice *et al.*, 2008; Table 2.39 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.39.pdf). In the meta-analysis 74% and 20% significant increased risks for current and former smokers, respectively, were found with significant heterogeneity of effect regarding current smoking across studies. Adjustment for confounders explained some of the heterogeneity (Iodice *et al.*, 2008). A similar significant risk elevation of 77% for current smokers was found in the pooled analysis, without study heterogeneity (Lynch *et al.*, 2009). For former smokers, risk was increased non-significantly by 9%.

Since the previous *IARC Monograph* (IARC, 2004a), a total of 15 cohort studies have reported on the association between cigarette smoking and pancreatic cancer incidence (8 studies) and mortality (5 studies) or both (one study) (Table 2.40 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.40.pdf), two of which were included in the pooled analysis (Coughlin *et al.*, 2000; Vrieling *et al.*, 2009). Excluding case–control studies that did not report odds ratios for current smokers, there were three additional case–control studies (Duell *et al.*, 2002; Inoue *et al.*, 2003; Alguacil & Silverman, 2004; Table 2.41 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.41.pdf). The effect of cigar and pipe smoking on pancreatic cancer was

also examined in the ACS Cancer Prevention Study II regarding mortality (Shapiro *et al.*, 2000; Henley *et al.*, 2004) and in the Kaiser Permanente Medical Care Program regarding incidence (Iribarren *et al.*, 1999). All the additional studies showed an increased risk for pancreatic cancer associated with tobacco smoking, generally higher in current than in former smokers. The reported risk estimates were not always statistically significant, predominantly due to the small size of some studies and therefore lack of statistical precision.

2.5.2 Factors affecting risks

(a) Intensity and duration

Clear evidence has been provided by the meta-analysis, the pooled analysis as well as the additional studies that the risk for cancer of the pancreas increases significantly with increasing daily cigarette consumption, duration and pack–years of smoking (Coughlin *et al.*, 2000; Gapstur *et al.*, 2000; Nilsen & Vatten, 2000; Nilsson *et al.*, 2001; Isaksson *et al.*, 2002; Doll *et al.*, 2005; Yun *et al.*, 2005; Ansary-Moghaddam *et al.*, 2006; Gallicchio *et al.*, 2006; Vrieling *et al.*, 2009). In the meta-analysis risk of pancreatic cancer increased significantly by 62% with an increase of 20 cigarettes per day (based on 45 studies) and by 16% with a 10-year increase in smoking duration (based on 16 studies), but with significant study heterogeneity. In the pooled analysis, the excess odds ratio per pack–years generally declined with increasing smoking intensity (Lynch *et al.*, 2009).

(b) Cessation of smoking

A reduction in risk in former smokers who had stopped smoking for at least 10 years was found in the meta-analysis (Iodice *et al.*, 2008) and the pooled study (Lynch *et al.*, 2009). In some cohort studies risk was already comparable to never smokers five years after quitting (Boyle *et al.*, 1996; Fuchs *et al.*, 1996; Nilsen & Vatten, 2000; Vrieling *et al.*, 2009).

(c) Types of tobacco

In non–cigarette smokers, mortality from pancreatic cancer was increased although not statistically significantly so in cigar smokers in the CPS-II cohort study (Shapiro *et al.*, 2000) as well as a large case–control study (Alguacil & Silverman, 2004) but was less clearly elevated in the smaller Kaiser Permanente cohort study (Iribarren *et al.*, 1999). There was a significantly increased mortality for current cigar smokers who reported inhaling cigar smoke (Shapiro *et al.*, 2000). Pipe smoking was also found to be associated with an increased risk of cancer of the pancreas, which was stronger in those who reported that they inhaled the smoke (Henley *et al.*, 2004). A limitation of the cohort studies is that smoking habits were reported only at baseline, misclassification of smoking exposure is likely to underestimate the associated risks. In the meta-analysis there was a significant increase in risk of 47% associated with current cigar and/or pipe smoking (18 studies) and a non-significant risk elevation of 29% with former cigar and/or pipe smoking (5 studies) (Iodice *et al.*, 2008).

2.5.3 Population characteristics

The effect of sex on pancreatic cancer risk was investigated in two cohort studies (Nilsen & Vatten, 2000; Larsson *et al.*, 2005) and on pancreatic cancer mortality in four cohort studies (Coughlin *et al.*, 2000; Gapstur *et al.*, 2000; Nilsson *et al.*, 2001; Lin *et al.*, 2002a). The relative risks were comparable between men and women and no consistent evidence for an effect modification by sex was observed.

Ethnicity does not appear to modify the association of smoking with pancreatic cancer risk. The roughly twofold elevated risk in current smokers compared to never smokers was observed both in studies of Caucasians (Lynch *et al.*, 2009) and of Asians (Lin *et al.*, 2002a; Jee *et al.*, 2004; Yun *et al.*, 2005; Li *et al.*, 2006). In populations of the Asia-Pacific Region, there

was also no difference in the strength of association between Asia and Australia/New Zealand (Ansary-Moghaddam *et al.*, 2006).

2.5.4 Confounding factors

In two large cohort studies the risk estimates for pancreatic cancer associated with cigarette smoking were not substantially influenced by adjustment for further potential confounding factors, including diabetes, body mass index (BMI), alcohol and dietary intake (Coughlin *et al.*, 2000; Vrieling *et al.*, 2009).

2.6 Cancer of the colorectum

2.6.1 Overview of studies

In the previous *IARC Monograph* (IARC, 2004a) it was not possible to conclude that the association between tobacco smoking and colorectal cancer is casual, principally because of concern about confounding by other risk factors. That evaluation was based on a total of 60 epidemiologic studies, although only few were specifically designed to study the effects of smoking. Studies have however shown consistently that cigarette smoking is a risk factor for colorectal adenomatous polyps, which are recognized precursor lesions of colorectal cancer (Hill, 1978). To explain this discrepancy, Giovannucci *et al.* (1994) hypothesized that a long induction period is required for tobacco to play a role in colorectal carcinogenesis, which would not be captured by studies with shorter follow-up time.

Four recent meta-analyses consistently showed a strong association between cigarette smoking and colorectal cancer (Botteri *et al.*, 2008a; Liang *et al.*, 2009; Huxley *et al.*, 2009; Tsoi *et al.*, 2009).

2.6.2 Cohort studies

Since the previous *IARC Monograph* (IARC, 2004a), 22 additional cohort studies have investigated the association between tobacco smoke and colorectal cancer (Table 2.42 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.42.pdf). [Studies that did not provide point estimates of risk (Andersen *et al.*, 2009; Hansen *et al.*, 2009; Murphy *et al.*, 2009) and included prevalent colorectal cancer in patients with other diagnosis (Chan *et al.*, 2007) are excluded from this review]. Seven of the studies were conducted in Europe, nine in Asia and five in the USA. In eleven studies, risk estimates were reported solely for colorectal cancer (Tiemersma *et al.*, 2002a; Limburg *et al.*, 2003; Otani *et al.*, 2003; Colangelo *et al.*, 2004; Sanjoaquin *et al.*, 2004; Lüchtenborg *et al.*, 2005a; Kim *et al.*, 2006; Akhter *et al.*, 2007; Huxley, 2007a; Kenfield *et al.*, 2008; Hannan *et al.*, 2009), five studies separately for colon cancer and rectal cancer (Shimizu *et al.*, 2003; Wakai *et al.*, 2003; Jee *et al.*, 2004; Yun *et al.*, 2005; Batty *et al.*, 2008) and five studies both for colorectal cancer as well as for colon and rectal cancers (Terry *et al.*, 2002a; van der Hel *et al.*, 2003a; Doll *et al.*, 2005; Paskett *et al.*, 2007; Tsong *et al.*, 2007; Gram *et al.*, 2009). Six studies were restricted to women (Terry *et al.*, 2002a; Limburg *et al.*, 2003; van der Hel *et al.*, 2003a; Paskett *et al.*, 2007; Kenfield *et al.*, 2008; Gram *et al.*, 2009), and two studies to men (Doll *et al.*, 2005; Yun *et al.*, 2005; Akhter *et al.*, 2007). One study reported both colorectal incidence and mortality (Limburg *et al.*, 2003) and three studies only reported colorectal cancer mortality (Doll *et al.*, 2005; Huxley, 2007a; Batty *et al.*, 2008; Kenfield *et al.*, 2008).

(a) Smoking status

Virtually all studies reported elevated risk associated with smoking, although results were not always statistically significant. The largest meta-analysis based on 36 prospective studies

with data from a total of 3007002 subjects found that compared to never smokers, current smokers had a 15% significantly higher risk of developing colorectal cancer and 27% significantly higher risk of colorectal cancer mortality (Liang *et al.*, 2009; Table 2.43 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.43.pdf). In former smokers, colorectal cancer risk was also significantly elevated by 20% whereas colorectal cancer mortality was non-significantly increased by 20%. The risk estimates were not significantly different between colon and rectal cancer for current smokers (RR, 1.10 versus 1.19) and for former smokers (RR, 1.10 versus 1.20). There was no heterogeneity among colorectal cancer studies and no evidence for publication bias. Comparable risk elevations in current and former smokers were found in the other meta-analyses. For current smokers, the risk for colorectal cancer increased significantly by 16% when using data from 22 cohort studies (Huxley *et al.*, 2009), by 20% based on 28 cohort studies (Tsoi *et al.*, 2009), and by 7% based on data from 45 cohort and case–control studies (Botteri *et al.*, 2008a). In the latter meta-analysis a 17% significantly higher risk of colorectal cancer in former smokers was found.

(b) *Intensity of smoking*

All but three of the recent 21 cohort studies (van der Hel *et al.*, 2003a; Jee *et al.*, 2004; Sanjoaquin *et al.*, 2004) investigated dose–response relationships, using at least one of number of cigarettes smoked, duration of smoking, pack–years of smoking, age at smoking initiation, time since smoking cessation. In two further studies (Tiemersma *et al.*, 2002a; Batty *et al.*, 2008) these parameters were examined separately in current and former smokers, as by Chao *et al.* (2000). Statistically significant dose–response trends with amount smoked daily were reported for colorectal cancer (Lüchtenborg *et al.*, 2005a; Akhter *et al.*, 2007; Paskett *et al.*, 2007; Kenfield *et al.*, 2008), for colon cancer (Paskett *et al.*, 2007), and for rectal cancer (Paskett *et al.*, 2007; Tsong *et al.*, 2007). The dose–response of daily cigarette consumption and colorectal cancer was assessed in two meta-analyses (Liang *et al.*, 2009; Tsoi *et al.*, 2009) and both found statistically significant relationships. Based on eleven studies, Liang *et al.* (2009) found that risk for colorectal cancer increased significantly by 17% with an increase of 20 cigarettes/day and by 38% with an increase of 40 cigarettes/day, while colorectal cancer mortality increased by 41% and 98%, respectively (Table 2.43 online). The risk elevation associated with an increase of 20 cigarettes/day was greater for rectal than for colon cancer (13% versus 3%) but this difference was not statistically significant.

(c) *Duration of smoking*

In addition to two previously reported studies (Hsing *et al.*, 1998; Chao *et al.*, 2000), thirteen studies have examined duration of smoking and colorectal cancer risk. A statistically significant trend of increasing risk with increasing duration was found for colorectal (Limburg *et al.*, 2003; Kim *et al.*, 2006; Paskett *et al.*, 2007; Gram *et al.*, 2009), for colon cancer (Paskett *et al.*, 2007) and for rectal cancer (Terry *et al.*, 2002a; Paskett *et al.*, 2007; Tsong *et al.*, 2007). In one study, increasing duration of smoking was significantly associated with risk for colorectal cancer solely in former smokers (Tiemersma *et al.*, 2002a). Based on eight studies (Terry *et al.*, 2002a; Tiemersma *et al.*, 2002a; Limburg *et al.*, 2003; Lüchtenborg *et al.*, 2005a; Kim *et al.*, 2006; Akhter *et al.*, 2007; Paskett *et al.*, 2007; Tsong *et al.*, 2007), a meta-analysis for duration of smoking and colorectal cancer incidence yielded highly significant results (Liang *et al.*, 2009). Risk was increased by 9.4% with a 20-year increase in smoking duration and 19.7% with a 40-year increase. Smoking duration was also significantly associated with risk for rectal cancer but not for colon cancer. In another meta-analysis where dose–response relationship was modelled, a nonlinear increase in risk with

increasing duration was observed (Botteri *et al.*, 2008a). The risk started to increase after approximately 10 years of smoking and reached statistical significance after 30 years.

(d) Pack–years

Since the previous *IARC Monograph*, the association of colorectal cancer with pack–years of cigarette smoking has been evaluated in six studies (Limburg *et al.*, 2003; Otani *et al.*, 2003; Shimizu *et al.*, 2003; Wakai *et al.*, 2003; Kim *et al.*, 2006; Gram *et al.*, 2009). In addition to the previously reported significant results (Giovannucci *et al.*, 1994; Heineman *et al.*, 1994; Chao *et al.*, 2000; Stürmer *et al.*, 2000), a statistically significant trend of increasing risk with increasing pack–years was found for colorectal cancer in two studies (Limburg *et al.*, 2003; Gram *et al.*, 2009), and for colon cancer in one study (Gram *et al.*, 2009). In their dose–response analysis of pack–years and colorectal incidence, Liang *et al.* (2009) included five studies (Giovannucci *et al.*, 1994; Stürmer *et al.*, 2000; Limburg *et al.*, 2003; Otani *et al.*, 2003; Kim *et al.*, 2006) and found a statistically significant trend of increasing risk with increasing pack–years of smoking for colorectal cancer but not specifically for colon or rectal cancer. Risk for colorectal cancer increased by 27% for an increase of 35 pack–years and by 50% for an increase of 60 pack–years.

(e) Age at initiation

In nine of the cohort studies the age at smoking initiation in relation to colorectal cancer (eight studies) or colon and rectal cancer (four studies) was investigated. In four studies a statistically significant trend of increasing risk with decreasing age at initiation of smoking for colorectal cancer was found (Limburg *et al.*, 2003; Kim *et al.*, 2006; Akhter *et al.*, 2007; Gram *et al.*, 2009) and for colon cancer (Gram *et al.*, 2009) and rectal cancer (Tsong *et al.*, 2007). In one meta-analysis (Liang *et al.*, 2009), a highly significant association was found for age at smoking initiation and colorectal cancer incidence based on six studies (Limburg *et al.*, 2003; Kim *et al.*, 2006; Akhter *et al.*, 2007; Paskett *et al.*, 2007; Tsong *et al.*, 2007; Gram *et al.*, 2009). Risk for colorectal cancer was reduced by 2.2% for a 5-year delay in smoking initiation and by 4.4% for a 10-year delay.

(f) Smoking cessation

The effect of smoking cessation by years since stopping was assessed in seven studies, six for colorectal cancer (Tiemersma *et al.*, 2002a; Lüchtenborg *et al.*, 2005a, 2007; Paskett *et al.*, 2007; Kenfield *et al.*, 2008; Gram *et al.*, 2009; Hannan *et al.*, 2009) and three for colon and/or rectal cancer (Wakai *et al.*, 2003; Paskett *et al.*, 2007; Gram *et al.*, 2009). In one study a statistically significant trend in risk reduction with years since quitting was found both overall as well as separately for men and for women (Hannan *et al.*, 2009).

(g) Population characteristics

It has been suggested that the association between smoking and colorectal cancer may be stronger in men than in women. In the three recent cohort studies reporting sex–specific results (Shimizu *et al.*, 2003; Wakai *et al.*, 2003; Colangelo *et al.*, 2004), this was only observed in studies in Japan (Shimizu *et al.*, 2003; Wakai *et al.*, 2003), but could be attributed to the very low prevalence of smoking in women. The studies restricted to women have generally shown associations with cigarette smoking that were of comparable magnitude to those observed in men (Terry *et al.*, 2002a; Limburg *et al.*, 2003; van der Hel *et al.*, 2003a; Paskett *et al.*, 2007; Kenfield *et al.*, 2008; Gram *et al.*, 2009).

Recent studies have been carried out either in Europe and in USA, with predominantly Caucasian study subjects, or in Asia, mostly in Japan and in the Republic of Korea. The results from these studies suggest no differences in the association between tobacco smoking and

colorectal cancer between different ethnic groups.

(h) Subsites

Smoking and risks for colon cancer and for rectal cancer were investigated in eleven of the 21 additional studies. Risk patterns are generally consistent between colon and rectal cancer (Otani *et al.*, 2003; van der Hel *et al.*, 2003a; Wakai *et al.*, 2003; Jee *et al.*, 2004; Yun *et al.*, 2005; Batty *et al.*, 2008). In some studies, dose–response relationships were stronger for rectal cancer than for colon cancer (Terry *et al.*, 2002a; Paskett *et al.*, 2007) or were statistically significant only for rectal cancer (Shimizu *et al.*, 2003; Doll *et al.*, 2005; Tsong *et al.*, 2007). In a meta-analysis (Liang *et al.*, 2009) the association was stronger for rectal cancer than for colon cancer in the subset of cohort studies that differentiated cancer by site. Most dose–response variables were not associated with colon cancer incidence whereas associations were stronger for rectal cancer incidence and statistically significant with longer duration of smoking, albeit based only on a small number of studies. In one cohort study the increased risk associated with smoking was more apparent for proximal than for distal colon cancer (Lüchtenborg *et al.*, 2005a), which was not found in an earlier study (Heineman *et al.*, 1994).

(i) Confounding and effect modification

Smokers have been shown to be more likely than non-smokers to be physically inactive, to use alcohol, to have lower consumption of fruits and vegetables and higher consumption of fat and meat, and they are less likely to be screened for colorectal cancer (Le Marchand *et al.*, 1997; Ghadirian *et al.*, 1998; Nkondjock & Ghadirian, 2004; Reid *et al.*, 2006b; Mutch *et al.*, 2009).

Few potential confounders were considered in the cohort studies evaluated in the previous *IARC Monograph* (IARC, 2004a). Of the cohort studies published since, all except three (van der Hel *et al.*, 2003a; Jee *et al.*, 2004; Doll *et al.*, 2005) considered two or more potential confounders. In eleven of the recent studies adjustments were made for physical activity, alcohol consumption, overweight/obesity (Terry *et al.*, 2002a; Limburg *et al.*, 2003; Otani *et al.*, 2003; Wakai *et al.*, 2003; Yun *et al.*, 2005; Akhter *et al.*, 2007; Ashktorab *et al.*, 2007; Paskett *et al.*, 2007; Tsong *et al.*, 2007; Kenfield *et al.*, 2008; Hannan *et al.*, 2009), and seven also adjusted for dietary habits (e.g. intake of fruits and vegetables, dietary fibres, fat, red meat). Among the studies with the latter adjustments, eight (Giovannucci *et al.*, 1994; Chao *et al.*, 2000; Stürmer *et al.*, 2000; Limburg *et al.*, 2003; Yun *et al.*, 2005; Akhter *et al.*, 2007; Paskett *et al.*, 2007; Hannan *et al.*, 2009) found significant dose–response relationships with at least one of the smoking variables. In two studies a significant association of smoking with colorectal cancer risk was observed after accounting for history of colonoscopy (Paskett *et al.*, 2007; Hannan *et al.*, 2009). Risk factors in multivariable analyses in several studies were level of education, use of menopausal hormone therapy, family history and regular aspirin use. The association between smoking and colorectal cancer was not modified by these other characteristics, or by alcohol consumption in two studies (Otani *et al.*, 2003; Tsong *et al.*, 2007). Therefore, confounding factors do not seem to affect the observed significant increase in risk for colorectal cancer associated with tobacco smoking and the dose–response relationships with smoking variables.

When considering other types of smoking, it is generally found that cigar and pipe smoking are less associated with socioeconomic class and other life-style habits than cigarette smoking. Therefore, it is logical to assume that, for these types of smoking, risk associations derived from epidemiologic studies may be less prone to potential confounding. In all the cohort studies reviewed in the previous *IARC Monograph* (IARC, 2004a) an elevated, though not always statistically significant, risk was consistently reported for cancers of the colon and the rectum

associated with exclusive pipe and/or cigar smoking.

Infection with JC virus has been proposed as a potential risk factor for colon cancer (Rollison *et al.*, 2009) but results still need further validation.

Three cohort studies assessed possible modifying effects by genetic susceptibility. Rapid acetylator phenotype (as determined by polymorphisms of the *NAT2* gene involved in metabolism of heterocyclic aromatic amines) was found to increase the risk for colorectal cancer in smokers, in one (van der Hel *et al.*, 2003a) but not in another study (Tiemersma *et al.*, 2002a). For genes involved in the metabolism of polycyclic aromatic hydrocarbons such as *GSTM1* or *GSTT1,* no statistical contribution to the risk of colorectal cancer associated with smoking was observed (Tiemersma *et al.*, 2002a; Lüchtenborg *et al.*, 2005a).

2.6.3 Case–control studies

Thirty-one case–control studies were included in the previous *IARC Monograph* (IARC, 2004a). Although results were inconsistent with respect to risk association in ever versus former and current smokers, a dose–response relationship with smoking variables was found in some studies. Since then, seventeen case–control studies investigating the association between tobacco smoke and colorectal cancer risk have been published, seven carried out in Asia, four in Europe, five in North America and one in Hawaii (Table 2.44 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.44.pdf). Six studies reported solely for colorectal cancer (Ateş *et al.*, 2005; Chia *et al.*, 2006; Verla-Tebit *et al.*, 2006; Lüchtenborg *et al.*, 2007; Steinmetz *et al.*, 2007; Wu *et al.*, 2009b), four separately for colon and rectal cancer (Ji *et al.*, 2002; Sharpe *et al.*, 2002; Minami & Tateno, 2003; Goy *et al.*, 2008), two for colorectal cancer as well as for colon and rectal cancer (Ho *et al.*, 2004; Gao *et al.*, 2007; Wei *et al.*, 2009), three for colon cancer only (Diergaarde *et al.*, 2003; Kim *et al.*, 2003; Hu *et al.*, 2007) and one for rectal cancer only (Slattery *et al.*, 2003). Nine of the studies reported risk estimates separately for men and for women.

(a) Smoking status

Most case–control studies considered the effects of current and former smoking separately. A positive association between smoking and colorectal cancer was found in virtually all the studies, although the results were generally not statistically significant. Statistically significant increased risk was reported in current smokers for colorectal cancer (Chia *et al.*, 2006; Wu *et al.*, 2009b), for rectal cancer (Slattery *et al.*, 2003; Ho *et al.*, 2004), and in former smokers for colorectal cancer both in men and women combined (Chia *et al.*, 2006) and in women only (Lüchtenborg *et al.*, 2007). Five studies, which did not focus on the main effects of smoking, only evaluated risks for ever smoking (Diergaarde *et al.*, 2003; Kim *et al.*, 2003; Ateş *et al.*, 2005; Gao *et al.*, 2007; Hu *et al.*, 2007); none of these reported significant risk estimates.

(b) Intensity of smoking

Nine case–control studies investigated dose–response relationships considering at least one smoking variable. Number of cigarettes smoked daily was evaluated in seven studies, three for colorectal cancer (Verla-Tebit *et al.*, 2006; Lüchtenborg *et al.*, 2007; Wu *et al.*, 2009b), two for colon and rectal cancer (Ji *et al.*, 2002; Minami & Tateno, 2003), one for rectal cancer (Slattery *et al.*, 2003) and one for colorectal cancer and both subsites (Ho *et al.*, 2004). Statistically significant positive trends of increasing risk with increasing number of cigarettes smoked daily were found for colorectal cancer in only one study (Wu *et al.*, 2009b).

(c) *Duration of smoking, pack–years, age at initiation, smoking cessation*

Duration of smoking was examined in several studies in relation to colorectal cancer (Ho *et al.*, 2004; Chia *et al.*, 2006; Verla-Tebit *et al.*, 2006; Lüchtenborg *et al.*, 2007; Wu *et al.*, 2009b) and/or to colorectal cancer by subsite (Ji *et al.*, 2002; Minami & Tateno, 2003; Ho *et al.*, 2004). A statistically significant trend with increasing number of years smoked was found in two of the five studies of colorectal cancer (Chia *et al.*, 2006; Wu *et al.*, 2009b). In one study, increasing duration of smoking was significantly associated with risk for rectal cancer in ever smokers but not in current smokers (Ho *et al.*, 2004). In only one earlier case–control study was a significant association in ever smokers with increasing number of years of smoking for colon as well as rectal cancer found (Newcomb *et al.*, 1995).

Duration of smoking exposure was assessed by pack–years of smoking in seven studies (Ji *et al.*, 2002; Slattery *et al.*, 2003; Chia *et al.*, 2006; Verla-Tebit *et al.*, 2006; Lüchtenborg *et al.*, 2007; Goy *et al.*, 2008; Wu *et al.*, 2009b) and by age at smoking initiation in three studies (Ji *et al.*, 2002; Slattery *et al.*, 2003; Wu *et al.*, 2009b). All four studies that evaluated pack–years of smoking with respect to colorectal cancer risk found statistically significant associations. Two studies found a significant association with increasing pack–years in men and women combined; when investigated separately, the increasing trend was statistically significant only in women (Verla-Tebit *et al.*, 2006) or only in men (Wu *et al.*, 2009b). In one study a statistically significant trend with pack–years of smoking in both men and women was found only with non-filtered cigarettes (Lüchtenborg *et al.*, 2007); the relative risk was significant for colon as well as rectal cancer and was greater for rectal cancer.

In two studies a non-significant trend of decreasing risk with increasing time since stopped smoking was found (Verla-Tebit *et al.*, 2006; Lüchtenborg *et al.*, 2007).

(d) *Subsites and molecular subtypes*

A stronger association between tobacco smoking and rectal cancer compared with colon cancer has generally been observed in the studies that reported risk estimates by cancer site. In a recent meta-analysis including both cohort and case–control studies, higher smoking-related risk estimates for rectal cancer were found than for proximal and distal colon cancer (Botteri *et al.*, 2008a). Stronger relative risk in ever smokers, but not in current smokers, was found for proximal compared to distal tumours in one recent study (Hu *et al.*, 2007).

Colorectal cancer is a multipathway disease. A molecular approach to its classification utilizes: (1) the type of genetic instability, specifically microsatellite instability, and (2) the presence of DNA methylation or the CpG island methylator phenotype (CIMP) (Jass, 2007). Smoking has been associated with microsatellite instability in sporadic colon cancer. Higher risk for microsatellite-unstable than for microsatellite-stable tumours was found in four studies (Slattery *et al.*, 2000; Yang *et al.*, 2000; Chia *et al.*, 2006; Campbell *et al.*, 2009). The observed twofold risk elevation for colorectal cancer showing microsatellite instability is similar in order of magnitude to that found for colorectal polyps. In only one small study similar risk estimates for stable and unstable tumours were found (Diergaarde *et al.*, 2003). Microsatellite instability is characteristic of hereditary nonpolyposis colorectal cancer syndrome and smoking has been associated with colorectal cancer in patients with this syndrome (Watson *et al.*, 2004; Diergaarde *et al.*, 2007). Among sporadic colorectal tumours with microsatellite instability, about 11–28% carry somatic genetic mutations. In addition, the association of colon cancer with smoking was increased two to threefold when widespread CIMP and/or *BRAF* mutation, irrespective of microsatellite instability

status, was present (Samowitz *et al.*, 2006). These data indicate that the association with MSI-high tumours may be attributed to the association of smoking with CIMP and *BRAF* mutation.

(e) Effect modification

Effect modification by genetic polymorphisms in enzymes metabolizing tobacco smoke constituents could provide further evidence for a causal association between smoking and colorectal cancer. Most studies that have investigated modification of colorectal cancer risk associated with smoking by genetic polymorphisms of xenobiotic enzymes were too small to be informative (Inoue *et al.*, 2000; Smits *et al.*, 2003; Jin *et al.*, 2005; Tranah *et al.*, 2005; van den Donk *et al.*, 2005; Tijhuis *et al.*, 2008). Studies on the possible differential effect by acetylation status have reported stronger association of tobacco smoking (in terms of pack–years) with colorectal cancer risk in slow acetylators phenotypes (Lilla *et al.*, 2006), and with rectal cancer in rapid acetylators phenotypes (Curtin *et al.*, 2009). Furthermore, *CYP1A1* and *GSTM1* variant alleles were found to greatly affect colon cancer or rectal cancer risk in smokers (Slattery *et al.*, 2004).

2.6.4 Colorectal polyps

Colorectal adenomas and possibly some hyperplastic polyps are considered precursors of colorectal cancer. The epidemiologic evidence on the relationship between cigarette smoking and colorectal polyps has been generally consistent. Since the previous *IARC Monograph* (IARC, 2004a), twelve further independent studies have investigated this association (Table 2.45 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.45.pdf). All studies found a significantly increased risk for polyps in association with one or more smoking variables. A recent meta-analysis including 42 studies reported a statistically significant positive association between smoking and colorectal adenomas (Botteri *et al.*, 2008b). The meta-analysis, which included several studies that did not explicitly report relative risks for tobacco smoking (Cardoso *et al.*, 2002; Voskuil *et al.*, 2002; Sparks *et al.*, 2004; Gong *et al.*, 2005; Jiang *et al.*, 2005; Kim *et al.*, 2005; Mitrou *et al.*, 2006; Otani *et al.*, 2006; Skjelbred *et al.*, 2006), found a twofold risk elevation for colorectal adenomas in current smokers and a 50% increase in former smokers. The association had been previously found to be equally strong in men and women. In one of two recent studies, there was no difference in the results for men and women separately (Tranah *et al.*, 2004) but significantly greater effects in women were found in the other (Hermann *et al.*, 2009).

Significant positive trends with number of cigarettes per day were found in four (Ji *et al.*, 2006; Larsen *et al.*, 2006; Stern *et al.*, 2006; Shrubsole *et al.*, 2008) of five studies (Tiemersma *et al.*, 2004). Dose–response with duration of smoking was assessed in four studies (Ji *et al.*, 2002; Tiemersma *et al.*, 2004; Stern *et al.*, 2006; Shrubsole *et al.*, 2008) and with pack–years of smoking in five studies (Hoshiyama *et al.*, 2000; Ulrich *et al.*, 2001; Tranah *et al.*, 2004; Ji *et al.*, 2006; Shrubsole *et al.*, 2008; Omata *et al.*, 2009). All nine studies found statistically significant trends, which were consistent with those for adenomas and hyperplastic polyps when reported separately (Ulrich *et al.*, 2001; Ji *et al.*, 2006; Shrubsole *et al.*, 2008). Ever smokers were estimated to have a 13% (95%CI: 9–18%) increasing risk of presenting with adenomatous polyps for every additional 10 pack–years smoked in comparison to never smokers, based on data from 19 studies (Botteri *et al.*, 2008b).

Decreasing risks with years since quitting smoking were found in four studies (Ulrich *et al.*, 2001; Tiemersma *et al.*, 2004; Ji *et al.*, 2006; Shrubsole *et al.*, 2008), statistically significant so in the latter three studies. In comparison to never smokers, former smokers retained moderately elevated risk for colorectal polyps even 20

years after quitting smoking. One study examined both dose metrics (cigarettes per day, duration, and pack–years) and recency of tobacco use: in subjects who had quit smoking for at least 20 years, only the heaviest users of tobacco still had modest excess risks (Ji *et al.*, 2006).

It has been proposed that the association between cigarette smoking and polyps may be stronger with non-progressing adenomas, such as those that are smaller and less villous but the hypothesis is not supported in most studies (Anderson *et al.*, 2003; Toyomura *et al.*, 2004; Ji *et al.*, 2006; Skjelbred *et al.*, 2006). In one study a clearly higher risk for large and multiple adenomas in every anatomic site of the colon was found in a dose–response manner (Toyomura *et al.*, 2004). A meta-analysis found that the combined risk estimate for high-risk adenomas associated with smoking was greater than that for low-risk adenomas and that the difference was statistically significant for current smokers but not former smokers (Botteri *et al.*, 2008b). In addition, a stronger association of smoking with hyperplastic polyps than with adenomas was found in some studies (Ulrich *et al.*, 2001; Ji *et al.*, 2006; Shrubsole *et al.*, 2008) but not in another (Erhardt *et al.*, 2002). The risk associated with smoking may be even higher in subjects presenting with concurrent benign hyperplastic and adenomatous polyps (Ji *et al.*, 2006; Shrubsole *et al.*, 2008).

Relative risk estimates for tobacco smoking and polyps generally range between 2 and 3 whereas those for colorectal cancer range between 1.2 and 1.4. One possible explanation is the effect dilution due to the inclusion of a high proportion of individuals with precursor lesions in the unscreened control groups in most colorectal cancer studies (Terry & Neugut, 1998). Some indirect evidence for this hypothesis is provided by the meta-analysis of colorectal adenomas, which showed that the smoking-associated risk for adenomas was significantly higher in studies including subjects who had undergone complete colonoscopy in comparison to those in which some or all controls had undergone incomplete examination (i.e. only sigmoidoscopy) (Abrams *et al.*, 2008; Botteri *et al.*, 2008b).

It is also possible that smoking is associated with a subset of colorectal cancers so that relative risk estimates for colorectal cancer as a whole are diluted. The pattern of risk observed for colorectal cancer by microsatellite instability status and for type of colorectal polyps suggests that the traditional (non-serrated) adenoma-carcinoma sequence may proceed through a hyperplastic polyps-mixed polyps-serrated adenoma progression and that smoking may be more strongly related to the development of these subtypes (Jass *et al.*, 2000; Hawkins & Ward, 2001). More recently, a *BRAF* mutation was shown to be a specific marker for the serrated polyp neoplasia pathway originating from a hyperplastic polyp, in which the CIMP-high develops early and the microsatellite instability carcinoma develops late (O'Brien *et al.*, 2006). The findings of strong associations between smoking and colon cancer with CIMP and/or BRAF mutation, irrespective of microsatellite status, are compatible with this observation (Samowitz *et al.*, 2006).

2.7 Hepatocellular carcinoma

2.7.1 Overview of studies

In the previous *IARC Monograph* (IARC, 2004a), a causal relationship between liver cancer (hepatocellular carcinoma) and smoking was established. Two case–control and one cohort studies have been published since (Table 2.46 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.46.pdf). Overall, most cohort studies and the largest case–control studies, most notably those that included community controls, showed a moderate association between tobacco smoking and risk for hepatocellular carcinoma.

Confounding from alcohol has been addressed in the best studies. The association between alcohol drinking and hepatocellular carcinoma is strong, and alcohol intake is frequently misclassified, leading to potential residual confounding. However an association with smoking has been demonstrated also among non-drinkers.

A meta-analysis was based on 38 cohort studies and 58 case–control studies (Lee *et al.*, 2009). Compared to never smokers, the meta-relative risks adjusted for appropriate confounders were 1.51 (95%CI: 1.37–1.67) for current smokers and 1.12 (0.78–1.60) for former smokers. The increased liver cancer risk among current smokers appeared to be consistent in strata of different regions, study designs, study sample sizes, and publication periods. The association with smoking was observed in non-alcohol-drinkers (RR, 1.34; 95%CI: 0.92–1.94 in men and 1.31; 95%CI: 0.70–2.44 in women). Further supportive evidence is provided by the association between smoking and liver cancer observed among Chinese women and Japanese women, in whom alcohol drinking is extremely rare (Li *et al.*, 2011). One difficulty is that sometimes studies do not specify the histology of liver cancer (hepatocellular versus intra-hepatic biliary tract).

In the update of the Whitehall study (Batty *et al.*, 2008) (a cohort of 17363 government employees in London, followed-up for 38 years), the hazard ratio for death from liver cancer was 1.03 (0.49–2.16) in former smokers and 1.43 (0.69–2.95) in current smokers (based on 57 deaths). In the 50-year follow-up of the British doctors cohort (Doll *et al.*, 2005), there were 74 deaths from liver cancer. Death rates per 100000 per year were 4.4 in never smokers, 10.7 in smokers of 1–14 cigarettes/day, 2.6 in smokers of 15–24 cigarettes/day, and 31.3 in smokers of ≥ 25 cigarettes/day.

2.7.2 Factors affecting risks

(a) Dose–response relationship

Most studies, including the recent ones (Table 2.46 online), show a dose–response relationship with the number of cigarettes smoked and with smoking duration, with exceptions such as Franceschi *et al.* (2006) and some older studies from Asia. Relative risk estimates increased to 2.0 after 20 years of smoking.

(b) Cessation

Though former smokers tend to have lower relative risks than current smokers, there were no consistent patterns of risks after cessation, including in the recent studies (Table 2.46 online).

2.7.3 Interaction with hepatitis B or C

Infection with hepatitis B virus (HBV) is one of the major causes of liver cancer worldwide, whereas hepatis C virus (HCV) infection causes a large fraction of liver cancer in Japan, Northern Africa and southern Europe. While many studies, most notably from Asia, have found no attenuation of the association between smoking and liver cancer after adjustment/stratification for markers of HBV or HCV infection, an apparent interaction between smoking and HBV or HCV infection has been reported. The increase in risk for liver cancer associated with cigarette smoking appears to be greater among HBV carriers than among uninfected persons in some studies (Tu *et al.*, 1985), but not in others (Kuper *et al.*, 2000a). Two recent reports (Franceschi *et al.*, 2006; Hassan *et al.*, 2008a) studied possible interactions between smoking and hepatitis virus infection and both reported an apparent interaction between smoking and hepatitis C infection. Interactions between smoking and hepatitis B infection were not found among men in one study (Hassan *et al.*, 2008a) and the rarity of HBsAg prevented the evaluation of HBV and smoking in the other (Franceschi *et al.*, 2006;

Table 2.46 online). In the meta-analysis by Lee *et al.* (2009) adjustment for HBV reduced the relative risks in both men and women, while adjustment for HCV did not change the risk in women and increased it in men.

2.8 Renal cell carcinoma

2.8.1 Overview of studies

The previous *IARC Monograph* (IARC, 2004a) concluded that renal-cell carcinoma is associated with tobacco smoking in both men and women. Four case–control studies and no cohort studies have become available since then (Table 2.47 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.47.pdf). Overall these confirm the previous evidence, though with some conflicting results. In particular, both the study by Hu *et al.* (2005) in Canada and the multicentre European study by Brennan *et al.* (2008) do not show a clear effect of smoking. In contrast, the study by Theis *et al.* (2008) shows an increased risk with smoking duration (irregular, levelling-off after 40 years) and a statistically significant dose–response relationship with pack–years.

In the update of the Whitehall study (Batty *et al.*, 2008) (a cohort of 17363 government employees in London, followed for 38 years), the hazard ratio for deaths from kidney cancer was 0.64 (0.32–1.26) for former smokers, and 1.29 (0.69–2.41) for current smokers (based on 68 deaths). In the 50-year follow-up of the British doctor cohort (Doll *et al.*, 2005) there were 140 deaths from kidney cancer. Mortality rates per 100000 per year were 9.3 in never smokers, 16.4 in smokers of 1–14 cigarettes/day, 16.6 in smokers of 15–24 cigarettes/day, and 15.5 in smokers of ≥ 25 cigarettes/day (age-adjusted).

Hunt *et al.* (2005) performed a meta-analysis based on 19 case–control studies and 5 cohort studies (total 8032 cases in case–control and 1326 in cohort studies). The relative risk for smoking men was 1.54 (1.42–1.68), and for smoking women was 1.22 (1.09–1.36). A dose–response relationship was found in both men and women. The association observed was more convincing in population-based compared to hospital-based studies.

2.8.2 Confounding

Hypertension is a well established risk factor for kidney cancer but the association with smoking is only indirect. Potential confounding from hypertension was considered only by Brennan *et al.* (2008).

Other potential confounders such as BMI have been appropriately addressed in most studies.

2.8.3 Cessation

Most studies reviewed in the previous *Monograph* showed a lower risk for former smokers compared to current smokers, with a significant negative trend with increasing number of years since quitting (IARC, 2004a). In case–control study on smoking cessation and renal-cell carcinoma, the decrease in risk became significant only after 30 years of quitting (Parker *et al.*, 2003). In the meta-analysis (Hunt *et al.*, 2005), former smokers were at reduced risk after 10 years or more of quitting. A clear decline in risk after cessation was also reported by Theis *et al.* (2008). [The Working Group noted the poor quality of the study, considering the low response rate among controls.]

2.9 Cancer of the lower urinary tract (including cancer of the bladder, ureter, and renal pelvis)

2.9.1 Overview of studies

The previous *IARC Monograph* (IARC, 2004a) clearly identified a causal relationship of smoking with transitional-cell carcinomas and squamous-cell carcinomas of the bladder, ureter and renal pelvis both in men and women. Two new case–control studies (Cao *et al.*, 2005; Samanic *et al.*, 2006; Table 2.48 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.48.pdf) and two cohort studies (Bjerregaard *et al.*, 2006; Alberg *et al.*, 2007; Table 2.49 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.49.pdf) have been reported since then in addition to updates of cohort studies with longer follow-up.

In the update of the Whitehall study (Batty *et al.*, 2008) (a cohort of 17363 government employees in London, followed-up for 38 years), the hazard ratio for death from bladder cancer was 0.98 (0.62–1.54) in former smokers and 1.66 (1.06–2.59) in current smokers (based on 164 deaths). In the 50-year follow-up of the British doctors cohort (Doll *et al.*, 2005), there were 220 deaths from bladder cancer. Death rates per 100000 per year were 13.7 in never smokers, 37.7 in smokers of 1–14 cigarettes/day, 31.8 in smokers of 15–24 cigarettes/day, and 51.4 in smokers of ≥ 25 cigarettes/day. All the new studies confirm the existence of a dose–response relationship with the number of cigarettes smoked and with duration, and a decline in relative risk with time since quitting smoking, compared to non-quitters.

2.9.2 Types of tobacco

The risk of lower urinary tract cancer was more strongly associated with smoking air-cured (black) tobacco than smoking flue-cured (blond) tobacco in several studies (IARC, 2004a). The stronger association with air-cured (black) than blond tobacco among current smokers has not been clearly confirmed in a re-analysis of the Spanish multicentre case–control study (Samanic *et al.*, 2006). Relative risks in current smokers were 7.3 (4.9–10.9) in black tobacco smokers and 5.8 (3.4–10.0) in blond tobacco smokers; in former smokers, 4.2 (2.9–6.0) for black tobacco and 1.8 (1.0–3.2) for blond tobacco (Table 2.48 online). The effect of cessation was more pronounced in blond tobacco smokers than in black tobacco smokers, suggesting potentially different mechanisms of action of the two types of tobacco. Air-cured (black) tobacco is richer in arylamines.

2.9.3 Gene–environment interactions

A large number of studies have considered gene–environment interactions between tobacco smoking and genetic polymorphisms, including DNA repair genes (Vineis *et al.*, 2009) and genes involved in carcinogen metabolism (Malats, 2008; Dong *et al.*, 2008). Overall, there is evidence that the slow acetylator variant of the *NAT2* gene is involved in bladder carcinogenesis and may interact with smoking. The meta-relative risk for *NAT2* slow acetylator and bladder cancer was 1.46 (95%CI: 1.26–1.68; $P = 2.5 \times 10^{-7}$), based on 36 studies and 5747 cases (Dong *et al.*, 2008). Similar but weaker evidence has been provided for *GSTM1* (Malats, 2008).

The extent of interaction between *NAT2* variants and smoking is still unclear. In one study the *NAT2* acetylation status was found to modulate the association of bladder cancer and cigarette smoking through smoking intensity and not smoking duration (Lubin *et al.*, 2007). Studies are not consistent concerning the three-way association between smoking intensity, *NAT2* and bladder cancer. Some studies found greater effects at a lower level of exposure and others the opposite (Malats, 2008). Genome-wide

association studies have indicated 8q24 as a region that may confer high risk for bladder cancer (Kiemeney *et al.*, 2008).

2.10 Myeloid leukaemia (acute and chronic)

Myeloid leukaemia in adults was observed to be causally related to cigarette smoking in the previous *IARC Monograph* (IARC, 2004a). Risk increased with amount of tobacco smoked in a substantial number of adequate studies, with evidence of a dose–response relationship. Biological plausibility for a causal relationship of smoking with myeloid leukaemia is provided by the finding of known leukaemogens in tobacco smoke, one of which (benzene) is present in relatively large amounts. No evidence was found for an association with acute lymphocytic leukaemia.

One recently published cohort study included information on acute and chronic myeloid leukaemias (Fernberg *et al.*., 2007), based on 372 incident cases. A weak association was found between acute myeloid leukaemia and intensity of smoking, and a statistically significant association with current smoking (RR, 1.5; 95%CI: 1.06–2.11). No association was found with chronic myeloid leukaemia.

In the update of the Whitehall study (Batty *et al.*., 2008) (a cohort of 17363 government employees in London, followed-up for 38 years), the hazard ratio for mortality from myeloid leukaemias (acute plus chronic) was 5.08 (95%CI: 1.78–14.5) for current smokers, and 3.84 (95%CI: 1.35–11.0) for former smokers (based on 66 deaths). In the 50-year follow-up of the British doctors cohort (Doll *et al.*., 2005), there were 100 deaths from myeloid leukaemias. The mortality rates per 100000 per year were 6.3 in never smokers, 2.8 in smokers of 1–14 cigarettes/day, 14.0 in smokers of 15–24, and 18.3 in smokers of ≥ 25 cigarettes/day (age-adjusted).

2.11 Other leukaemias and lymphomas

2.11.1 Non-Hodgkin lymphoma

Six cohort studies have been published on the association between non-Hodgkin lymphoma and smoking, all reviewed in the previous *IARC Monograph* (IARC, 2004a). In five of these, no increased risk among smokers was evident (Doll *et al.*, 1994; McLaughlin *et al.*, 1995; Adami *et al.*, 1998; Herrinton & Friedman, 1998; Parker *et al.*, 2000). However, in one study, men who had ever smoked cigarettes had a twofold increase in risk for non-Hodgkin lymphoma, and the risk was still higher among the heaviest smokers (Linet *et al.*, 1992). Data from case–control studies generally also fail to support an effect of smoking on the incidence of non-Hodgkin lymphoma (Peach & Barnett, 2001; Stagnaro *et al.*, 2001; Schöllkopf *et al.*, 2005; Bracci & Holly, 2005; Table 2.50 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.50.pdf). Reanalysis of data of an Italian study (Stagnaro *et al.*, 2004) found a statistically significant association (OR, 1.4; 95%CI: 1.1–1.7) for blond tobacco exposure and non-Hodgkin lymphoma risk.

Three studies and a pooled analysis have examined histological subtypes of non-Hodgkin lymphoma. In one cohort study in women, smoking was associated with increased risk for follicular non-Hodgkin lymphoma (Parker *et al.*, 2000). Similarly, two other studies reported a weak positive association between smoking and risk for follicular lymphoma, but no effect for other histological types (Herrinton & Friedman, 1998; Stagnaro *et al.*, 2001). A large pooled analysis based on nine North-American and European case–control studies found an overall odds ratio of 1.07 (95%CI: 1.0–1.15) for smokers; the association was particularly strong for follicular lymphoma (OR, 1.31; 95%CI: 1.12–1.52) (Morton *et al.*, 2005).

2.11.2 Hodgkin lymphoma

In the previous *IARC Monograph* (IARC, 2004a) seven studies on the association between Hodgkin lymphoma and smoking were examined and null or weakly positive associations were noted. Among studies published since, a positive association was observed in two case–control (Willett *et al.*, 2007; Kanda *et al.*, 2009) and three cohort studies (Nieters *et al.*, 2006; Lim *et al.*, 2007; Nieters *et al.*, 2008), while one study found no clear association (Monnereau *et al.*, 2008). Several other recent studies also reported a positive association, but with some internal inconsistencies. In a European multicentre case–control study, no association was observed between tobacco and Hodgkin lymphoma for subjects below age 35 years, whereas for older subjects, ever-smokers experienced a doubled risk of Hodgkin lymphoma as compared to never smokers (Besson *et al.*, 2006). In contrast, a positive association was observed in young adults participating in the International Twin Study (Cozen *et al.*, 2009). A positive association was observed in a Scandinavian case–control study, but without a clear dose–response (Hjalgrim *et al.*, 2007). In a case–control study addressing infectious precursors, particularly Epstein-Barr virus (EBV), an increased risk for EBV-positive Hodgkin lymphoma was found among current smokers (Glaser *et al.*, 2004; Table 2.50 online).

Several of the above studies found positive associations for Hodgkin lymphoma while also demonstrating null or inverse associations with non-Hodgkin lymphoma (Nieters *et al.*, 2006; Lim *et al.*, 2007; Nieters *et al.*, 2008; Kanda *et al.*, 2009).

2.11.3 Multiple myeloma

In the previous *IARC Monograph* (IARC, 2004a), the large majority of studies on tobacco smoking and risk for multiple myeloma evaluated showed no clear association. More recently, two case–control studies found a positive association (Vlajinac *et al.*, 2003; Nieters *et al.*, 2006), whereas no clear association was observed in another case–control study (Monnereau *et al.*, 2008) or in a cohort study in Sweden (Fernberg *et al.*, 2007; Table 2.51 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.51.pdf).

2.12 Cancer of the breast

Approximately 150 epidemiological studies have been published on the relationship between breast cancer and active and passive smoking. The results from these studies have been comprehensively examined in peer-reviewed literature (Palmer & Rosenberg, 1993; Terry *et al.*, 2002a; Johnson *et al.*, 2002; Johnson, 2005; Terry & Goodman, 2006; Miller *et al.*, 2007). The previous *IARC Monograph* (IARC, 2004a) considered studies conducted through June 2002 and concluded that there is evidence suggesting lack of carcinogenicity of tobacco smoking in humans for cancers of the female breast.

Other consensus reviews have drawn different conclusions, based partly on the availability of new data, and partly on differences in interpretation:

- The 2001 US Surgeon General Report on Women and Smoking (Department of Health & Human Services, 2001) concluded that tobacco smoking does not appear to appreciably affect breast cancer risk overall. However, several issues were not entirely resolved, including whether starting to smoke at an early age increases risk, whether certain subgroups defined by genetic polymorphisms are differentially affected by smoking, and whether exposure to second-hand smoke affects risk.
- The 2004 US Surgeon General report on "The Health Consequences of Smoking" (Department of Health & Human

Services, 2004) concluded the evidence is suggestive of no causal relationship between tobacco smoking and breast cancer.

- The 2009 Canadian Expert Panel on Tobacco Smoke and Breast Cancer Risk (Collishaw *et al.*, 2009) concludes that based on the weight of evidence from epidemiological and toxicological studies and understanding of biological mechanisms, the associations between tobacco smoking and both pre- and post-menopausal breast cancer are consistent with causality.

The lack of agreement in the conclusions from these groups is not surprising, given that the observed associations are weaker and less consistent for breast cancer than for other tobacco-related cancers. Furthermore, several methodological considerations could either obscure a small increase in risk caused by tobacco smoking, or alternatively introduce a spurious association where no causal relationship exists.

2.12.1 Methodological and related issues

The principal concerns about studies of tobacco smoking and breast cancer are the following: timing of exposure, the relevant disease endpoint, the potential for confounding by factors associated with both smoking and the occurrence/detection of breast cancer, the hypothesis that tobacco smoking may have opposing effects on breast cancer risk (protective and detrimental), and the hypothesis that some women may be genetically more susceptible to develop breast cancer from smoking, and that increased risk in these subgroups may be obscured in analyses of average risk in the population.

(a) Misclassification of exposure

Self-reported information on tobacco smoking is generally considered more reliable than questionnaire information on exposure to second-hand tobacco smoke. However, studies of tobacco smoking have not uniformly considered the duration of smoking (years), the average amount smoked (cigarettes/day), or the timing of initiation in relation to first full-term pregnancy. Only one (Al-Delaimy *et al.*, 2004) of the seven available cohort studies updated the information on smoking behaviour during follow-up. Whereas some exposure variables, such as age at initiation and age at first full-term pregnancy remain constant over time, others, such as smoking status, duration and age at cessation do not. Furthermore, the average age at initiation and duration of smoking are highly correlated with birth cohort and attained age. While the number of years of smoking before first full term pregnancy has been proposed as a potentially relevant measure of exposure, the range of this variable is constrained except among women whose first pregnancy occurs at an older age, which is itself an independent risk factor for breast cancer.

(b) Specificity of disease endpoints

Breast cancer is not a single disease. Accordingly, some researchers have postulated that exposure to tobacco smoke (from tobacco smoking or second-hand tobacco smoke) could differentially affect certain clinical subtypes of breast such as pre- or post-menopausal cancers or tumours with or without hormonal receptors. It is also possible that smoking might affect the survival of women with breast cancer, whether or not it affects incidence rates. Most published studies have measured incidence rates as the endpoint, although some have measured mortality rates or effects on survival.

(c) Confounding

Alcohol consumption is positively correlated with tobacco smoking (Marshall *et al.*, 1999) and is an established cause of breast cancer (IARC, 2010a; *Monograph* on Consumption of Alcoholic Beverages in this Volume). Most epidemiologic studies attempt to control for alcohol consumption using questionnaire information on usual drinking patterns. This approach is vulnerable to residual confounding, because self-reported data on lifetime alcohol consumption leave room for misclassification. Potential confounding by alcohol consumption is of greater concern for current than for former smokers, since, on average, current smokers drink more than former smokers (Reynolds *et al.*, 2004a, b). One study by the Collaborative Group on Hormonal Factors and Breast Cancer (Hamajima *et al.*, 2002) controlled rigorously for alcohol consumption by restricting the analysis of smoking and breast cancer to women who reported drinking no alcohol.

Conversely, mammography screening can be a negative confounder in studies of tobacco smoking and breast cancer incidence. Few studies of tobacco smoking in relation to breast cancer have controlled for mammography screening. Current smokers report a lower frequency of mammographic screening than never-smokers, whereas health conscious former smokers report higher screening rates (Gross *et al.*, 2006). Mammography screening affects the detection rather than the occurrence of breast cancer; it detects some tumours that might otherwise never have been recognized and allows earlier diagnosis of others, thereby increasing breast cancer incidence in the short-term. The consequence of uncontrolled confounding by mammography screening would be to underestimate an association between current smoking and breast cancer incidence, and to overestimate the association in former smokers. Confounding by screening would be expected to have the opposite effect in studies of breast cancer mortality.

Other correlates of tobacco smoking might also confound a potential association between tobacco smoking and breast cancer, although their net effect is likely to be smaller and harder to predict than confounding by alcohol and mammography screening. Women who smoke undergo menopause about two to three years earlier than never-smokers (Baron *et al.*, 1990). The effect of this may be partly or wholly offset by the greater likelihood of girls who experience early menarche to initiate smoking in early adolescence (Jean *et al.*, 2011). There is no documentation that smokers and never-smokers differ with respect to average years of ovulation. Tobacco smoking also has a complex relationship to body mass index. Post-menopausal women who smoke are less likely to be overweight or obese than former or never smokers, but overweight adolescent girls are more likely to begin smoking for weight control (Fine *et al.*, 2004). Similarly complex relationships exist between smoking and physical activity. Current smokers report less physical activity than either former or never smokers (Kaczynski *et al.*, 2008; Trost *et al.*, 2002), but only a small proportion of the population engages in the vigorous physical activity that is needed to protect against breast cancer. The socioeconomic correlates of smoking have changed over time. Women who attended college during the 1960s and 1970s were more likely to initiate smoking than less educated women, but subsequently college-educated women have been more likely to quit. Thus, the potential for confounding by reproductive patterns and use of post-menopausal hormone treatment varies by birth cohort and differs for current and former smokers.

Most epidemiological studies have attempted to control for factors that might confound the relationship between breast cancer and tobacco smoking using questionnaire information collected on these factors. None of the published

studies have been able to control for all of the potential confounders, however. Most studies lack data on screening behaviour and have limited information on alcohol consumption, use of post-menopausal hormones, and physical activity.

(d) Potential anti-estrogenic effects of tobacco smoking

Indirect evidence suggests that tobacco smoking may have anti-estrogenic effects that might offset the adverse effects of tobacco smoke carcinogens on breast cancer risk. Baron *et al.* (1990) pointed to observations suggesting lower estrogen activity levels in women who smoke compared to those who do not. Smokers have lower risk of endometrial cancer (Department of Health & Human Services, 2004), higher risk of osteoporosis (Jensen *et al.*, 1985; Jensen & Christiansen, 1988), earlier age at natural menopause (Baron *et al.*, 1990) and lower mammography density (Roubidoux *et al.*, 2003) than women who do not smoke. Smoking also attenuates the effects of hormone replacement therapy (HRT) on lipid profiles (Jensen & Christiansen, 1988) and serum estrone (McDivit *et al.*, 2008). No difference in serum concentrations of estradiol and estrone between post-menopausal smokers and non-smokers have been reported in several studies (Cassidenti *et al.*, 1992; Khaw *et al.*, 1988; Berta *et al.*, 1991; Longcope *et al.*, 1986; Berta *et al.*, 1992; Cauley *et al.*, 1989; Friedman *et al.*, 1987; Key *et al.*, 1991). However, smokers have been observed to have higher levels of androgens (Cassidenti *et al.*, 1992) (specifically androstenedione) (Khaw *et al.*, 1988; Cauley *et al.*, 1989; Friedman *et al.*, 1987; Key *et al.*, 1991), prolactin (Berta *et al.*, 1991), and unbound serum estradiol (Cassidenti *et al.*, 1992).

(e) Genetically susceptible subgroups

Certain subgroups of women may have greater risk of breast cancer when exposed to tobacco smoke because of genetic or other factors affecting cancer susceptibility. Potential interactions between inherited polymorphisms and tobacco smoking have been studied for selected candidate genes that affect carcinogen metabolism, modulation of oxidative damage, immune responses, and DNA repair (see Sections 2.12.4b and 4.2).

2.12.2 Analytical studies

Over 130 epidemiological studies on tobacco smoking and breast cancer were reviewed.

(a) Incidence in current and former smokers

Since the previous *IARC Monograph* (IARC, 2004a), seven reports on cohort studies (Al-Delaimy *et al.*, 2004; Reynolds *et al.*, 2004a; Gram *et al.*, 2005; Hanaoka *et al.*, 2005; Olson *et al.*, 2005; Cui *et al.*, 2006; Ha *et al.*, 2007) have been published on breast cancer incidence in relation to tobacco smoking (Table 2.52 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.52.pdf). Breast cancer incidence was significantly associated with current tobacco smoking in three studies (Reynolds *et al.*, 2004a; Olson *et al.*, 2005; Cui *et al.*, 2006), with relative risk estimates among the larger studies ranging from 1.12 (95%CI: 0.92–1.37) (Al-Delaimy *et al.*, 2004) to 1.32 (95%CI:1.10–1.57) (Reynolds *et al.*, 2004a). Former smoking was significantly associated with risk in only one cohort (Al-Delaimy *et al.*, 2004), with relative risk estimates across all of the cohorts ranging from 1.00 (95%CI: 0.93–1.08) (Cui *et al.*, 2006) to 1.18 (95%CI: 1.02–1.36) (Al-Delaimy *et al.*, 2004). The association with breast cancer is stronger in current than in former smokers in four of the seven cohort studies (Reynolds *et al.*, 2004a; Hanaoka *et al.*, 2005; Olson *et al.*, 2005; Cui *et al.*, 2006), although the confidence intervals overlap widely in all but one (Cui *et al.*, 2006). [The Working group noted that three cohort studies (Gram *et al.*, 2005; Hanaoka *et al.*, 2005; Olson *et al.*, 2005) provided data on both

the age-adjusted and the multivariate-adjusted risk estimates for current and former smoking. None of these showed attenuation of the estimate associated with current smoking, and two (Hanaoka *et al.*, 2005; Olson *et al.*, 2005) reported somewhat stronger estimates when adjusted for established risk factors besides age. None of the studies adjusted for the frequency of mammography screening. Residual confounding by screening and incomplete control for other risk factors would be expected to cause underestimation of the association with current smoking, and overestimation of the association with former smoking.]

Since the previous *IARC Monograph* (IARC, 2004a), a total of 12 case–control studies on tobacco smoking and breast cancer incidence have been published (Table 2.53 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.53.pdf). Results from the case–control studies are less consistent than those from the cohort studies. Six studies (Li *et al.*, 2004; Mechanic *et al.*, 2006; Magnusson *et al.*, 2007; Prescott *et al.*, 2007; Roddam *et al.*, 2007; Slattery *et al.*, 2008) differentiated between current and former smokers, while the six other reports (Band *et al.*, 2002; Lash & Aschengrau, 2002; Gammon *et al.*, 2004; Rollison *et al.*, 2008; Ahern *et al.*, 2009; Young *et al.*, 2009) specify only ever or never smokers. Only one study (Li *et al.*, 2004) reported a borderline significant increase in risk associated with current smoking, and two studies (Band *et al.*, 2002; Rollison *et al.*, 2008) with ever smoking.

None of the six case–control studies that presented data on breast cancer incidence separately for current and former smokers found a significant difference in risk between the two smoking categories; the relative risk estimates were higher for former than for current smokers in four of the studies (Mechanic *et al.*, 2006; Prescott *et al.*, 2007; Roddam *et al.*, 2007; Slattery *et al.*, 2008) and identical in the fifth (Magnusson *et al.*, 2007).

(b) Years of cessation

When the relative risk for breast cancer incidence in former smokers is examined by years since cessation in cohort studies (Table 2.54 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.54.pdf), the point estimates do not consistently decrease with longer time since cessation. In none of the four cohort studies (London *et al.*, 1989b; Egan *et al.*, 2002; Reynolds *et al.*, 2004a; Cui *et al.*, 2006) and in only one (Li *et al.*, 2005) of the five case–control studies (Chu *et al.*, 1990; Gammon *et al.*, 1998; Johnson *et al.*, 2000; Kropp & Chang-Claude, 2002; Li *et al.*, 2005) that formally tested for trend (Table 2.55 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.55.pdf) was there a statistically significant decrease in relative risk observed with longer time since cessation. Only one study has reported data on breast cancer mortality in relation to years since quitting or age at cessation (Calle *et al.*, 1994). A statistically significant inverse trend in the relative risk estimates was reported with both years since quitting (p trend = 0.04) and younger age at cessation (p trend = 0.02). [The Working Group noted that the inverse trends in the relative risk of dying from breast cancer observed in this study are weaker than those observed with most other cancers designated as causally associated with smoking.]

(c) Duration of smoking and age at initiation

Tables 2.56–2.61 (see below for links) list the published epidemiologic studies that relate breast cancer incidence to duration of tobacco smoking, age at initiation and/or timing relative to first full term pregnancy.

Longer duration of smoking is associated with higher breast cancer incidence in five of seven cohort studies (Table 2.56 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.56.pdf). A similar trend is seen inconsistently among the 33 case–control

studies that report relative risk estimates by duration of smoking (Table 2.57 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.57.pdf). Among the 18 studies that reported a formal test of trend, eight studies (Gammon *et al.*, 1998; Johnson *et al.*, 2000; Reynolds *et al.*, 2004a; Gram *et al.*, 2005; Li *et al.*, 2005; van der Hel *et al.*, 2005; Cui *et al.*, 2006; Mechanic *et al.*, 2006) reported a statistically significant or borderline increase in the relative risk of incident breast cancer with the duration of smoking; seven studies (Ewertz, 1990; Palmer *et al.*, 1991; Egan *et al.*, 2002; Al-Delaimy *et al.*, 2004; Lissowska *et al.*, 2006; Magnusson *et al.*, 2007; Prescott *et al.*, 2007) reported no trend, and one study (Brinton *et al.*, 1986) reported an inverse relationship.

Thirty studies, including cohort (Tables 2.58 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.58.pdf) and case–control studies (Table 2.59 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.59.pdf) related breast cancer incidence to age at smoking initiation. Fifteen of these (Chu *et al.*, 1990; Ewertz, 1990; Palmer *et al.*, 1991; Nordlund *et al.*, 1997; Gammon *et al.*, 1998; Johnson *et al.*, 2000; Egan *et al.*, 2002; Kropp & Chang-Claude, 2002; Gram *et al.*, 2005; Cui *et al.*, 2006; Lissowska *et al.*, 2006; Ha *et al.*, 2007; Lissowska *et al.*, 2007; Magnusson *et al.*, 2007; Prescott *et al.*, 2007; Slattery *et al.*, 2008) reported a formal test of trend. Among these, only two (Gram *et al.*, 2005; Ha *et al.*, 2007) found a statistically significant or borderline significantly higher risk in women who began smoking at a younger ages; twelve studies (Chu *et al.*, 1990; Ewertz, 1990; Palmer *et al.*, 1991; Nordlund *et al.*, 1997; Gammon *et al.*, 1998; Johnson *et al.*, 2000; Egan *et al.*, 2002; Cui *et al.*, 2006; Lissowska *et al.*, 2006; Magnusson *et al.*, 2007; Prescott *et al.*, 2007; Slattery *et al.*, 2008) found no relationship with age at initiation, and one (Kropp & Chang-Claude, 2002) reported higher risk among women who began smoking later. [The Working Group noted that at least two studies (Cui *et al.*, 2006; Slattery *et al.*, 2008) appear to have included never-smokers in the tests of trend and that the categories that define age at initiation differ across studies.]

The relative risk of incident breast cancer according to the timing of smoking initiation relative to first full-term pregnancy was reported in 21 studies, of cohort (Table 2.60 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.60.pdf) and case–control (Table 2.61 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.61.pdf) design. For nine studies (Hunter *et al.*, 1997; Egan *et al.*, 2002; Al-Delaimy *et al.*, 2004; Reynolds *et al.*, 2004a; Li *et al.*, 2005; Cui *et al.*, 2006; Prescott *et al.*, 2007; Rollison *et al.*, 2008; Young *et al.*, 2009) categorical data on years of smoking before first pregnancy are presented, whereas for 12 (Lash & Aschengrau, 1999; Innes & Byers, 2001; Band *et al.*, 2002; Kropp & Chang-Claude, 2002; Lash & Aschengrau, 2002; Fink & Lash, 2003; Lawlor *et al.*, 2004; Gram *et al.*, 2005; Olson *et al.*, 2005; Lissowska *et al.*, 2006; Magnusson *et al.*, 2007; Slattery *et al.*, 2008) whether smoking was initiated before or after the initial pregnancy was considered. Breast cancer incidence is consistently higher when smoking began before or during first pregnancy in most (Hunter *et al.*, 1997; Lash & Aschengrau, 1999; Innes & Byers, 2001; Band *et al.*, 2002; Egan *et al.*, 2002; Al-Delaimy *et al.*, 2004; Reynolds *et al.*, 2004a; Gram *et al.*, 2005; Li *et al.*, 2005; Olson *et al.*, 2005; Cui *et al.*, 2006; Slattery *et al.*, 2008; Young *et al.*, 2009) but not all (Kropp & Chang-Claude, 2002; Lash & Aschengrau, 2002; Fink & Lash, 2003; Prescott *et al.*, 2007) studies that tested this. [The Working Group noted that the number of years of smoking before first pregnancy is highly correlated with age at first full-term pregnancy, which is itself an independent risk factor for breast cancer.]

It has been argued that some studies, and especially cohort studies, may underestimate

the true association between tobacco smoking and breast cancer risk by ignoring or underestimating lifetime exposure to second-hand tobacco smoke of those in the referent group (California Environmental Protection Agency, 2005; Johnson, 2005; Collishaw *et al.*, 2009). This criticism is based on the hypothesis that exposure to second-hand smoke may confer almost the same degree of breast cancer risk as tobacco smoking. Under this hypothesis, the inclusion of women exposed to second-hand smoke in the referent group dilutes the contrast between exposed and unexposed women in studies of tobacco smoking, and causes underestimation of the association between tobacco smoking and breast cancer. In several case–control studies the association between breast cancer and tobacco smoking strengthened when the referent group was defined as women with "never active, never-passive" exposure to tobacco smoke (Morabia *et al.*, 1996; Lash & Aschengrau, 1999; Johnson *et al.*, 2000; Kropp & Chang-Claude, 2002). In contrast, a stronger association between tobacco smoking and breast cancer risk, when women exposed only to second-hand smoke are excluded from the referent group, has not been observed in cohort studies (Egan *et al.*, 2002; Reynolds *et al.*, 2004a). Debate continues over whether the case–control studies should be considered "of highest quality" because they provide "lifetime exposure assessment" (Collishaw *et al.*, 2009) or whether the cohort studies are more credible, because prospectively-collected exposure data are not susceptible to the recall bias that can affect retrospective studies.

(d) Survival and mortality from breast cancer

The relationship between smoking and the natural history of breast cancer has been examined in several studies (Daniell, 1988; Ewertz *et al.*, 1991; Daniell *et al.*, 1993; Scanlon *et al.*, 1995; Yu *et al.*, 1997; Manjer *et al.*, 2000; Murin & Inciardi, 2001; Holmes *et al.*, 2007). In cross-sectional analyses, Daniell *et al.* (1993) found that smokers with breast cancer had more and larger lymph node metastases than non-smokers, after controlling for primary tumour size and other variables. Further, a case–control study (Murin & Inciardi, 2001) and a retrospective cohort study (Scanlon *et al.*, 1995) found smoking to be associated with an increased risk of developing pulmonary metastases from breast cancer. However, these studies could not definitively distinguish lung metastases from primary lung cancers.

Five cohort studies have focused specifically upon the association of tobacco smoking with either breast cancer survival (Ewertz *et al.*, 1991; Yu *et al.*, 1997; Manjer *et al.*, 2000; Holmes *et al.*, 2007) or breast cancer death rates (Calle *et al.*, 1994). A study of 1774 Danish women showed no association between smoking and breast cancer survival (Ewertz *et al.*, 1991), as did a study of 5056 women with breast cancer in the Nurse's Health Study (Holmes *et al.*, 2007). In contrast, follow-up of 792 women with in situ or invasive breast cancer detected in a screening study in Malmø, Sweden found a crude relative risk for smokers and ex-smokers, compared to never smokers, of 1.44 (95%CI: 1.01–2.06) and of 1.13 (95%CI: 0.66–1.94), respectively (Manjer *et al.*, 2000). The relative risk associated with smoking remained significant after adjustment for age and stage at diagnosis (RR, 2.14; 95%CI: 1.47–3.10). A study based on the ACS Cancer Prevention Study II reported an association between current smoking and increased breast cancer death rates after six years of follow-up (Table 2.56 online; Calle *et al.*, 1994). Risk of death attributed to breast cancer was positively and significantly related to the duration of current smoking reported at the time of enrolment. However, the authors acknowledge that mortality studies cannot exclude biases arising from the effect of smoking on overall death rates, which could increase the potential for prevalent breast cancer to be coded as the underlying cause of death on the death certificate (Calle *et al.*, 1994).

2.12.3 Subtypes

(a) Pre- versus post-menopausal

Since the previous *IARC Monograph* (IARC, 2004a), 19 case–control studies have published data on tobacco smoking in relation to pre- and post-menopausal breast cancer (Table 2.62 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.62.pdf). The results are inconsistent. Of the 12 studies that provide information separately for current smokers (Schechter *et al.*, 1985; Brinton *et al.*, 1986; Rohan & Baron, 1989; Ewertz, 1990; Baron *et al.*, 1996; Gammon *et al.*, 1998; Millikan *et al.*, 1998; Johnson *et al.*, 2000; Zheng *et al.*, 2002; Magnusson *et al.*, 2007; Slattery *et al.*, 2008), only five (Schechter *et al.*, 1985; Johnson *et al.*, 2000; Magnusson *et al.*, 2007; Slattery *et al.*, 2008) found a stronger association with pre- than with post-menopausal breast cancer. The other analyses show either similar associations (Brinton *et al.*, 1986; Ewertz, 1990; Baron *et al.*, 1996; Gammon *et al.*, 1998; Millikan *et al.*, 1998; Zheng *et al.*, 2002) or a stronger association with post-menopausal breast cancer (Rohan & Baron, 1989; Millikan *et al.*, 1998; Johnson *et al.*, 2000; Zheng *et al.*, 2002).

(b) Hormone receptor status

Two cohort studies (London *et al.*, 1989a; Manjer *et al.*, 2001), one case–control study (Morabia *et al.*, 1998) and a case series (Yoo *et al.*, 1997) have examined the association between quantitative measures of cigarette smoking and breast cancer risk according to estrogen receptor (ER) status. In one of the cohort studies (Manjer *et al.*, 2001), a statistically significant increased risk (RR, 1.6) of ER negative tumours associated with current smoking was found but no clear association between smoking and ER positive tumours, and no difference in the association with progestogen receptor (PR)-positive and PR-negative tumours. In the other three studies there was no clear difference in the association related to ER or PR receptor status.

2.12.4 Susceptible populations

More than 30 studies and meta-analyses (Alberg *et al.*, 2004; Terry & Goodman, 2006; Ambrosone *et al.*, 2008; Collishaw *et al.*, 2009) have evaluated whether a family history of breast cancer and/or inherited polymorphisms in various genes may confer greater susceptibility to develop breast cancer from exposure to tobacco smoke. These are described below in relation to the measure indicating potential susceptibility.

(a) Family history

In two studies, whether a family history of breast cancer modifies susceptibility to develop breast cancer from tobacco smoking has been examined. Couch *et al.* (2001) measured breast cancer incidence among female family members in a cohort of breast cancer cases diagnosed between 1944 and 1952 at the University of Minnesota. Sisters and daughters in families with at least three breast and/or ovarian cancers were at 2.4 fold higher risk for breast cancer (95%CI: 1.2–5.1) if they smoked compared to never-smokers. No dose–response was observed in relation to pack–years of smoking.

Suzuki *et al.* (2007) reported a statistically significant interaction between family history of breast cancer and smoking history in a hospital-based case–control study of 3861 breast cancer cases treated at a large cancer centre in Japan between 1988 and 2000. A family history of breast cancer in the absence of smoking was associated with a relative risk of 1.44 (95%CI: 1.21–1.71); the relative risk estimate was 1.95 (95%CI: 1.36–2.81) in women who reported < 30 pack–years of tobacco smoking, and 4.33 (95%CI: 1.65–11.40) in women who reported > 30 pack–years of smoking.

[The Working group noted that Japanese women who smoked during this time period

may have differed from never-smokers in other characteristics related to breast cancer. Besides its strong correlation with female smoking, "Westernization" might be associated with delayed childbearing, smaller families, higher body mass index, and greater use of post-menopausal hormones.]

(b) Genetic polymorphisms

Studies of breast cancer, smoking and low penetrance genetic polymorphisms are summarized in Table 2.63 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.63.pdf). The candidate genes in these studies are involved in carcinogen metabolism [*N*-acetyltransferases (*NAT1, NAT2*), cytochrome P450s (*CYP1A1, CYP1B1, CYP2E2*), GSTs], host responses to oxidative stress (superoxide dismutase) or to infectious organisms (myeloperoxidase and immunoglobulin binding protein) and DNA repair (O^6-methylguanine DNA methyltransferase, nucleotide excision repair).

The most consistent associations with breast cancer risk have been observed among long-term smokers with the *NAT2* slow acetylation genotype (Terry & Goodman, 2006). *NAT2* slow acetylation genotype is thought to confer less capability to detoxify tobacco smoke carcinogens and is associated with an increase in breast cancer risk (Ambrosone *et al.*, 1996, 2008). Approximately 50–60% of Caucasian women are reported to be slow acetylators.

Table 2.63 (online) lists 15 studies of polymorphisms in *NAT2*, of which 9 were included in a pooled analysis and 13 in a meta-analysis (Ambrosone *et al.*, 2008). [The study by Delfino *et al.* (2000) was excluded from these analyses because cases included women with benign breast disease; the study by Lilla *et al.* (2005) was not considered because it is based on the same population as that by Chang-Claude *et al.* (2002).] The meta-analysis found a statistically significant association between ever tobacco smoking and breast cancer risk among women with the *NAT2* slow acetylator genotype (meta-RR, 1.27; 95%CI: 1.16–1.40) but not in those with rapid acetylator genotype (meta-RR, 1.05; 95%CI: 0.95–1.17). Pack–years of tobacco smoking was significantly associated with increasing breast cancer risk among women with *NAT2* slow acetylator genotype (meta-RR for ever smokers, 1.44; 95%CI: 1.23–1.68, for > 20 pack–years versus never smokers), but not among rapid acetylators (Ambrosone *et al.*, 2008). No main effect was seen between *NAT2* status and breast cancer risk (meta-RR, 1.0; 95%CI: 0.93–1.07). In contrast to an earlier meta-analysis (Alberg *et al.*, 2004), this study observed no difference in risk for pre- or post-menopausal breast cancer. The pooled analysis of nine studies (Ambrosone *et al.*, 2008) reported pooled risk estimates for pre- and post-menopausal women of 1.49 (95%CI: 1.08–2.04) and 1.42 (95%CI: 1.16–1.74), respectively, among women with slow *NAT2* genotype and at least 20 pack–years of smoking compared to never-smokers. The corresponding values for women with rapid acetylator genotype were 1.29 (95%CI: 0.89–1.86) and 0.88 (95%CI: 0.69–1.13). A statistically significant interaction was observed between pack–years of smoking as a continuous variable and *NAT2* genotype (p interaction = 0.03).

A population-based case–control study published after the meta-analysis by Ambrosone *et al.* compared the prevalence of the *NAT2* genotypes and their joint effect with smoking on breast cancer risk in Hispanic and non-Hispanic white women (Baumgartner *et al.*, 2009). Non-Hispanic white women were more likely ($P < 0.001$) than Hispanics to have a slow (41.7% versus 33.5%) or very slow (19.0% versus 11.1%) *NAT2* acetylator status. Breast cancer risk was significantly increased in non-Hispanic smoking white women with a very slow acetylator genotype (RR, 2.46; 95%CI: 1.07–5.65 for current versus never).

[The Working Group noted that publication bias remains a concern in the studies of *NAT2* published to date. All of the studies included in the meta-analysis by Ambrosone *et al.* were published between 1996 and 2006; some among them (Morabia *et al.*, 2000; Sillanpää *et al.*, 2007) reported very strong associations that seem inconsistent with the rest of the data. Because genetic studies often examine multiple genes, it is plausible that studies that find no main effect with *NAT2* have not examined this association or that null results for smoking have not been published.]

Fewer studies with less consistent findings have been published on polymorphisms in other genes such as *NAT1*, *CYP1A1*, *GST*, *NOS3*, *MPO*, *MnSOD2* and various DNA repair genes (Table 2.63 online).

2.12.5 High penetrance genes & prognosis

At least seven studies have examined the hypothesis that tobacco smoking may modify breast cancer risk among women who carry *BRCA1* and *BRCA2* mutations (Brunet *et al.*, 1998; Ghadirian *et al.*, 2004; Colilla *et al.*, 2006; Gronwald *et al.*, 2006; Nkondjock *et al.*, 2006; Breast Cancer Family Registry, 2008; Ginsburg *et al.*, 2009). The results have been inconsistent. A recent case–control study of women under age 50 years who were carriers of mutations in *BRCA1* or *BRCA2* reported increased risk for breast cancer associated with as little as five pack–years of smoking. Compared to non-smokers, the risk associated with five or more pack–years of smoking was 2.3 (95%CI: 1.6–3.5) for *BRCA1* mutation carriers and 2.6 (95%CI: 1.8–3.9) for *BRCA2* mutation carriers (Breast Cancer Family Registry, 2008). In contrast, six other studies reported no increased risk among *BRCA1* or *BRCA2* carriers who smoke. The Canadian Panel review (Collishaw *et al.*, 2009) postulated that the five previous studies (Brunet *et al.*, 1998; Ghadirian *et al.*, 2004; Colilla *et al.*, 2006; Gronwald *et al.*, 2006; Nkondjock *et al.*, 2006) may have failed to observe a relationship because they included prevalent cases. However, a sixth study published since the Canadian panel review is also negative (Ginsburg *et al.*, 2009).

2.13 Cancer of the cervix

The association between smoking and cervical cancer has been examined in many epidemiological studies over the past few decades.

Since the previous *IARC Monograph* (IARC, 2004a), additional epidemiological studies have been published. Study design and results of the case–control studies restricted to HPV positive women or that adjusted for HPV status are presented in Table 2.64 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.64.pdf) and Table 2.65 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.65.pdf). Cohort studies and pooled analyses are presented in Table 2.66 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.66.pdf) and Table 2.67 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.67.pdf), respectively. Table 2.68 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.68.pdf) and Table 2.69 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.69.pdf) present additional cohort studies and pooled analyses on tobacco smoking and cervical, cervical intraepithelia neoplasia and carcinoma in situ, with our without controlling for HPV status, respectively.

2.13.1 Dose–response relationship

A positive association between smoking and incidence of cervical squamous-cell carcinoma, which account for approximately 90% of all cervical cancers, has been shown consistently over several decades in many epidemiological studies

of various designs conducted across different geographic regions. Dose–response associations with smoking intensity and duration were noted in many of the studies where such associations were examined (Berrington de González *et al.*, 2004; Appleby *et al.*, 2006). Conversely, no clear association was found among former smokers. For adenocarcinoma of the cervix, which usually account for less than 10% of the total of all types of cervical cancer, there appears to be no clear association with smoking (Berrington de González *et al.*, 2004).

2.13.2 Interaction with HPV positivity

Epidemiological studies of smoking and cervical cancer increasingly have considered the effects of HPV infection, which is recognized as the main etiological factor for invasive and pre-invasive cervical neoplasia worldwide (IARC, 1995, 2012b). HPV infection has been considered not only with respect to possible effect modification (Hellberg & Stendahl, 2005; Gunnell *et al.*, 2006), but also to confounding, as both HPV infection and smoking habits are directly associated with number of sexual partners and other indications of high-risk sexual behaviours (Sikström *et al.*, 1995; Wang *et al.* 2004; Hellberg & Stendahl, 2005; McIntyre-Seltman *et al.*, 2005; Syrjänen *et al.*, 2007). Although there have been exceptions (Syrjänen *et al.*, 2007), recent studies have generally continued to show that statistical adjustment for the potential confounding effects of HPV infection, or restricting studies to women with high risk HPV infection (Plummer *et al.*, 2003), does not appreciably alter the finding of a positive association or its magnitude (McIntyre-Seltman *et al.*, 2005; Appleby *et al.*, 2006; Tolstrup *et al.*, 2006; Tsai *et al.*, 2007; Nishino *et al.*, 2008; Kapeu *et al.*, 2009).

Statistical adjustment for the potentially confounding effect of HPV infection was usually based on the measured presence of HPV DNA in cervical cells or anti-HPV serum antibodies in multivariate analytical models; as noted above, studies have also restricted their analyses to HPV-positive cases and controls. As there is currently no reliable marker of persistent HPV infection, case–control studies based on a cross-sectional measurement of HPV cannot distinguish between transient and persistent infections (Franco *et al.*, 1999). Tobacco smoking is suspected to facilitate acquisition or persistence of an HPV infection through a reduced number of Langerhans cells and CD4 lymphocytes, which are markers of local immune response in the cervix (Vaccarella *et al.*, 2008). In addition, smoking may affect innate immunity (Ferson *et al.*, 1979). Current smokers have been shown to have a slightly higher HPV prevalence than non-smokers in a broad range of world populations after adjustment for life-time number of sexual partners (OR, 1.18; 95%CI: 1.01–1.39) (Vaccarella *et al.*, 2008). Studies have evaluated the effect of smoking on HPV persistence. One study shows lower probability of HPV clearance among ever smokers (Giuliano *et al.*, 2002) but a few others found no relationship (Molano *et al.*, 2003; Richardson *et al.*, 2005).

2.14 Cancer of the endometrium

2.14.1 Overview of studies

To date, at least 42 epidemiological studies have examined the association between smoking and endometrial cancer, 25 reviewed in the previous *IARC Monograph* (IARC, 2004a) and 17 published since then (Petridou *et al.*, 2002; Folsom *et al.*, 2003; Furberg & Thune, 2003; Newcomb & Trentham-Dietz, 2003; Beral *et al.*, 2005; Matthews *et al.*, 2005; Viswanathan *et al.*, 2005; Okamura *et al.*, 2006; Strom *et al.*, 2006; Trentham-Dietz *et al.*, 2006; Weiss *et al.*, 2006a; Al-Zoughool *et al.*, 2007; Bjørge *et al.*, 2007; Lacey *et al.*, 2007; Loerbroks *et al.*, 2007; Setiawan *et al.*, 2007; Lindemann *et al.*, 2008). Study design and results of the additional studies

are presented separately for the case–control studies (Table 2.70 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.70.pdf and Table 2.71 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.71.pdf, respectively) and for the cohort studies (Table 2.72 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.72.pdf and Table 2.73 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.73.pdf, respectively).

(a) Cohort studies

The majority of the 13 cohort studies (Engeland *et al.*, 1996; Terry *et al.*, 1999, 2002b; Folsom *et al.*, 2003; Furberg & Thune 2003; Beral *et al.*, 2005; Viswanathan *et al.*, 2005; Al-Zoughool *et al.*, 2007; Bjørge *et al.*, 2007; Lacey *et al.*, 2007; Loerbroks *et al.*, 2007; Setiawan *et al.*, 2007; Lindemann *et al.*, 2008) suggest a decreased risk among current smokers, including the largest study with over 9000 cases (Bjørge *et al.*, 2007). In five of these studies quantitative smoking measures have been examined in relation to endometrial cancer risk (Terry *et al.*, 1999, 2002b; Viswanathan *et al.*, 2005; Al-Zoughool *et al.*, 2007; Loerbroks *et al.*, 2007). Of these, one (Terry *et al.*, 1999) found a 50% reduced risk among current smokers in the highest level of intensity (11 cigarettes per day or more) compared with non-smokers, but the number of cases was low and the confidence intervals correspondingly wide. A more recent and larger cohort study (Terry *et al.*, 2002b) found a statistically significant 40% reduced risk among current smokers of more than 20 cigarettes per day, but showed somewhat weaker and statistically non-significant reductions in risk with smoking of long duration or high cumulative consumption (i.e. pack–years). In contrast, the risk among former smokers was similar to that among never smokers. The largest of these studies generally showed decreasing risk of endometrial cancer with increasing smoking intensity, duration, and pack–years of consumption (Viswanathan *et al.*, 2005). Three studies examined the association between time since smoking cessation and endometrial cancer risk. Two of these studies suggested a positive association with time since quitting (compared with non-smokers) (Viswanathan *et al.*, 2005; Loerbroks *et al.*, 2007), whereas one found no association (Terry *et al.*, 2002b).

(b) Case–control studies

The results of 17 population-based case–control studies (Smith *et al.*, 1984; Tyler *et al.*, 1985; Franks *et al.*, 1987; Elliott *et al.*, 1990; Rubin *et al.*, 1990; Brinton *et al.*, 1993; Goodman *et al.*, 1997; Shields *et al.*, 1999; Jain *et al.*, 2000; McCann *et al.*, 2000; Newcomer *et al.*, 2001; Weiderpass & Baron, 2001; Newcomb & Trentham-Dietz, 2003; Matthews *et al.*, 2005; Strom *et al.*, 2006; Trentham-Dietz *et al.*, 2006; Weiss *et al.*, 2006a), that have included between 46 and 1304 endometrial cancer cases, generally have shown reductions in risk among current smokers compared with never smokers (although the magnitude of the reduction in risk has varied somewhat); results among former smokers compared with never smokers were equally variable, albeit somewhat weaker overall. The results of eight hospital-based case–control studies (Kelsey *et al.*, 1982; Lesko *et al.*, 1985; Levi *et al.*, 1987; Stockwell & Lyman, 1987; Koumantaki *et al.*, 1989; Austin *et al.*, 1993; Petridou *et al.*, 2002; Okamura *et al.*, 2006), which included between 83 and 1374 endometrial cancer cases, are somewhat consistent with those of population-based studies. They showed moderate (e.g. 30–40%) reduction in risks among current compared with never smokers, and unaltered risks (or perhaps a small 10–20% reduction in risk) in former compared with never smokers. The largest of the hospital-based studies (Stockwell & Lyman, 1987), with 1374 cases and 3921 controls, found both former and current smokers to be at moderately (approximately 30%) reduced risk

of endometrial cancer. To date, six population-based case–control studies (Tyler *et al.*, 1985; Lawrence *et al.*, 1987, 1989; Brinton *et al.*, 1993; Newcomer *et al.*, 2001; Weiderpass & Baron, 2001) have examined quantitative measures of smoking in relation to endometrial cancer risk, generally showing inverse associations to be strongest among current smokers of high intensity or long duration.

2.14.2 Confounders

Whereas the majority of these studies adjusted their relative risk estimates for potentially confounding variables, such as BMI, HRT, parity, diabetes, and age at menopause, studies that did not adjust for these variables tended to show similar inverse associations. Within individual studies, statistical adjustment for the effects of BMI and other covariates often made little difference, although some attenuation of relative risk estimates has been noted (Weiderpass & Baron, 2001; Terry *et al.*, 2002c).

2.14.3 Effect modification

The association between smoking and endometrial cancer risk according to factors that are known determinants of endogenous hormone concentrations, and which may counteract or augment possible tobacco-related hormonal changes, have been examined in several studies. These factors include menopausal status, HRT and BMI. Effect modification can reflect true underlying differences in the association across strata (for example, if cigarette smoking acts to reduce or modify estrogen concentrations differently in one group compared with another), but can also reflect methodological factors, such as differences that occur by chance or through the varying prevalence of confounding variables.

(a) Menopausal status

Although endometrial cancer is rare among pre-menopausal women, several studies have examined the association between cigarette smoking and endometrial cancer risk according to menopausal status, because the effect of smoking (if any) might vary according to the underlying hormonal milieu. The studies have included two cohort studies (Terry *et al.*, 2002b; Al-Zoughool *et al.*, 2007), five population-based case–control studies (Smith *et al.*, 1984; Franks *et al.*, 1987; Lawrence *et al.*, 1987; Brinton *et al.*, 1993; Weiderpass & Baron, 2001), and four hospital-based case–control studies (Lesko *et al.*, 1985; Levi *et al.*, 1987; Stockwell & Lyman, 1987; Koumantaki *et al.*, 1989). In all but one of these studies, a study of early stage endometrial cancer (Lawrence *et al.*, 1987), the inverse association was (to varying degrees) stronger among post-menopausal than pre-menopausal women. Among pre-menopausal women, the relative risk estimates for cigarette smoking have been inconsistent, sometimes showing increased risks with certain measures of cigarette smoking (Smith *et al.*, 1984; Stockwell & Lyman, 1987; Koumantaki *et al.*, 1989; Brinton *et al.*, 1993; Al-Zoughool *et al.*, 2007), sometimes showing decreased risks (Lawrence *et al.*, 1987; Levi *et al.*, 1987; Brinton *et al.*, 1993; Terry *et al.*, 2002b), and sometimes showing practically no association (Lesko *et al.*, 1985; Weiderpass & Baron, 2001; Al-Zoughool *et al.*, 2007). In analyses limited to post-menopausal women, on the other hand, all showed between 10% and 80% reduced risks of endometrial cancer with the various smoking measures.

(b) Hormone replacement therapy

Given the possibility that cigarette smoking affects hormone concentrations mostly among women who are taking HRT (Jensen *et al.*, 1985; Jensen & Christiansen, 1988; Cassidenti *et al.*, 1990), the inverse association between tobacco

smoking and endometrial cancer risk might be stronger among HRT users than among non-users. However, the results of studies that have examined the association between smoking and endometrial cancer risk according to HRT use have been equivocal (Weiss *et al.*, 1980; Franks *et al.*, 1987; Lawrence *et al.*, 1987; Levi *et al.*, 1987; Terry *et al.*, 2002b; Beral *et al.*, 2005). Whereas in two studies (Franks *et al.*, 1987; Levi *et al.*, 1987) a larger reduction in risk among smokers taking HRT than among smokers not taking HRT was observed, in two other studies (Lawrence *et al.*, 1987; Terry *et al.*, 2002b) there was no difference in the association according to HRT status. A cohort study that examined associations only among women using HRT showed no clear association among users of continuous combined HRT and cyclic combined HRT, but some suggestion of increased risk among smokers who used tibolone (perhaps more clearly among former smokers) (Beral *et al.*, 2005). Thus, although effect modification by HRT status is biologically plausible, the available epidemiological evidence is equivocal.

(c) Relative body weight

Obesity is an established risk factor for endometrial cancer (IARC, 2002). Smokers tend to have a lower BMI than non-smokers, although former smokers tend to have a higher BMI than current or never smokers (Baron *et al.*, 1990). Two case–control studies have examined the association between cigarette smoking and endometrial cancer risk according to BMI, one population-based (Elliott *et al.*, 1990) and one hospital-based (Levi *et al.*, 1987). Neither of these studies found clear differences in the association between smoking and endometrial cancer risk according to BMI. In a population-based case–control study of early stage endometrial cancer (Lawrence *et al.*, 1987), the inverse association with cigarette smoking tended to become stronger with increasing absolute rather than relative body weight.

2.14.4 Gene polymorphisms

Cigarette smoking and estrogen are both thought to influence cancer risk through pathways that are under the control of specific genes, such as those involved in the formation of bulky DNA adducts by estrogen metabolites (Cavalieri *et al.*, 2000) and both bulky and non-bulky adducts formed by carcinogens in tobacco smoke (Terry & Rohan, 2002). Therefore, studies have been conducted to examine the association between smoking and endometrial cancer risk according to genes that repair these types of DNA damage. In a moderately-sized population-based case–control study no clear effect modification according to certain polymorphisms in the *XPA* and *XPC* genes, both of which are involved in the nucleotide excision repair of bulky DNA adducts and may influence endometrial cancer risk, were found (Weiss *et al.*, 2005, 2006b). A nested case–control study also showed no clear effect modification according to three polymorphisms in *CYP1A1* (McGrath *et al.*, 2007), a gene that encodes microsomal CYP1A1, which contributes to aryl hydrocarbon hydroxylase activity, catalysing the metabolism of PAHs and other carcinogens found in tobacco smoke (Masson *et al.*, 2005). In another nested case–control study some evidence was found that the association between smoking and endometrial cancer may vary according to a polymorphism (Ile^{143}Val) in O^6-methylguanine DNA methyltransferase (*MGMT*). Overall, studies that address the association between smoking and endometrial cancer risk according to genotype are scarce.

2.15 Cancer of the prostate

Many epidemiological studies have examined the association between cigarette smoking and prostate cancer risk, and most have shown no consistent association (Hickey *et al.*, 2001; Levi & La Vecchia, 2001; Batty *et al.*, 2008; Butler

et al., 2009; Huncharek *et al.*, 2010; Table 2.74 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.74.pdf; Table 2.75 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.75.pdf). However, questions remain regarding whether smoking may alter risk in various population subgroups, for example, those defined by certain genotypes, and whether any association with smoking may be stronger for, or limited to, advanced tumours or prostate cancer mortality. Regarding this latter issue, the majority of epidemiological studies, including several large, long-term cohort studies, have reported a positive association between smoking and prostate cancer mortality (Rohrmann *et al.*, 2007; Zu & Giovannucci, 2009). Several studies that examined smoking in relation to both prostate cancer incidence and mortality tend to show positive results only for the latter (Rohrmann *et al.*, 2007; Zu & Giovannucci, 2009). Given the largely null results with respect to prostate cancer incidence, the latter findings suggest that smoking is less likely to be a causal agent in prostate cancer initiation than an agent that acts on existing tumours to promote their progression (Zu & Giovannucci, 2009).

A recent review of smoking and prostate cancer that focused specifically on aggressive and fatal tumours, considered the findings from 14 cohort studies (Zu & Giovannucci, 2009). Nine of these studies showed statistically significant increased risk with at least one smoking measure, and five showed increased risks that were not statistically significant for any measure. Only one study showed no association with any measure of tobacco consumption. Seven studies of various designs examined smoking with respect to indicators of cancer aggressive behaviour at the time of diagnosis. In these studies smoking was associated positively with tumour grade, risk of regional, distant, extraprostatic or metastatic disease, Gleason score, and biochemical outcome (failure) after prostate brachytherapy and in several dose–response associations with the respective endpoint were demonstrated. In one study smoking cessation was associated with a decline in risk compared with that among current smokers.

The association between smoking and prostate cancer risk according to genotype and other potentially effect-modifying factors have been examined in several studies. For example, in a population-based case–control study tobacco use was a risk factor for prostate cancer primarily among men with high BMI (Sharpe & Siemiatycki, 2001). The results of a cohort study in Switzerland suggest that risk of prostate cancer mortality is increased in smokers, particularly those with low plasma vitamin E levels (Eichholzer *et al.*, 1999). These latter associations, as well as those regarding several genotypes that may modify the association (Mao *et al.*, 2004; Nock *et al.*, 2006; Quiñones *et al.*, 2006; Yang *et al.*, 2006; Iguchi *et al.*, 2009; Kesarwani *et al.*, 2009), have yet to be fully clarified.

[The Working Group noted that several of the studies of smoking and prostate cancer mortality did not demonstrate clear dose–response associations with risk, and noted the possibility of bias due to confounding by screening behaviour. However, in the Health Professionals Follow-up Study, screening behaviour was not found to differ appreciably between smokers and non-smokers. In an analysis limited to men with a negative digital rectal examination in the prior two years, stronger associations were found between smoking and metastatic prostate cancer risk among high intensity smokers (RR, 4.2; 95%CI: 1.6–10.9) (Zu & Giovannucci, 2009). This finding was evidence against bias from screening behaviour.]

2.16 Cancer of the ovary

2.16.1 Overview of studies

A total of over 30 epidemiological studies have investigated the association between tobacco smoking and ovarian cancer risk. Of these, 24 were case–control studies (IARC, 2004a; Table 2.76 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.76.pdf; Table 2.77 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.77.pdf) and six were cohort studies (IARC, 2004a; Table 2.78 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.78.pdf; Table 2.79 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.79.pdf). Most studies showed no statistically significant association between a measure of smoking and risk for ovarian cancer overall (Newhouse *et al.*, 1977; Smith *et al.*, 1984; Tzonou *et al.*, 1984; Baron *et al.*, 1986; Stockwell & Lyman, 1987; Whittemore *et al.*, 1988; Hartge *et al.*, 1989; Polychronopoulou *et al.*, 1993; Engeland *et al.*, 1996; Goodman *et al.*, 2001; Goodman & Tung, 2003; Pan *et al.*, 2004; Zhang *et al.*, 2004; Kurian *et al.*, 2005; Niwa *et al.*, 2005; Baker *et al.*, 2006; Huusom *et al.*, 2006; Fujita *et al.*, 2008; Lurie *et al.*, 2008; Nagle *et al.*, 2008; Tworoger *et al.*, 2008); some showed positive associations (Doll *et al.*, 1980; Tverdal *et al.*, 1993; Kuper *et al.*, 2000b; Marchbanks *et al.*, 2000; Green *et al.*, 2001; Modugno *et al.*, 2002; Gram *et al.*, 2008; Rossing *et al.*, 2008) and one (Riman *et al.*, 2004) showed an inverse association.

2.16.2 Histological subtypes

Differences in ovarian cancer risk factor profiles have been observed according to histological type, on the basis of which it has been suggested that mucinous and non-mucinous tumours are etiologically distinct diseases (Risch *et al.*, 1996). Epidemiological studies that have considered histological type tend to support a positive association primarily between cigarette smoking and mucinous ovarian tumours (Kuper *et al.*, 2000b; Marchbanks *et al.*, 2000; Green *et al.*, 2001; Modugno *et al.*, 2002; Pan *et al.*, 2004; Zhang *et al.*, 2004; Kurian *et al.*, 2005; Tworoger *et al.*, 2008). In contrast, two studies showed no clear association between smoking and risk of mucinous or non-mucinous ovarian tumours (Riman *et al.*, 2004; Baker *et al.*, 2006). In addition, one early case–control study (Newhouse *et al.*, 1977), with 300 ovarian cancer cases and with both population and hospital controls, found no clear association with "ever" compared with "never" smoking, and reported no differences according to histological type.

A pooled analysis of 10 case–control studies (Kurian *et al.*, 2005) with 254 cases of mucinous and 1580 non-mucinous tumours found an increased risk of mucinous tumours among current smokers (RR, 2.4; 95%CI: 1.5–3.8), a positive association that was not observed with other histological types. Former smokers in that analysis did not have an increased risk of any histological type of ovarian cancer. This type of dose–response, whereby current smokers have a higher risk than former smokers, was observed in most, but not all, studies of mucinous ovarian cancer (Tables 2.77 and 2.79 online). Overall, the positive association between cigarette smoking and risk of mucinous ovarian tumours is generally consistent across both case–control and cohort studies conducted among various populations. In contrast, associations with smoking have been mostly null with respect to non-mucinous ovarian tumours, suggesting that recall bias is unlikely to explain the association with mucinous tumours.

[The Working Group considered the possibility that women who smoke may come to medical attention more frequently. This raises the possibility of detection bias, because mucinous tumours, benign or malignant, tend to be quite large and could be more easily detected on routine physical exam or testing. However, the

Working Group felt that detection bias would not account for the association entirely.

2.17 Cancer of the thyroid

The previous *IARC Monograph* (IARC, 2004a) noted inconsistent associations between smoking and thyroid cancer risk. In 2003, a pooled analysis of 14 case–control studies showed that smoking was inversely associated with thyroid cancer risk (Mack *et al.*, 2003; Table 2.80 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.80.pdf; Table 2.81 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.81.pdf). The sample consisted of 2725 thyroid cancer cases (2247 women, 478 men) and 4776 controls (3699 women, 1077 men). The inverse association was stronger among current smokers (RR, 0.6; 9% CI: 0.6–0.7) than former smokers (RR, 0.9; 9% CI: 0.8–1.1) and were similar in both men and women, for both papillary and follicular thyroid cancers, as well as by age and region. An inverse association between smoking and thyroid cancer risk was also found in a subsequent case–control study (Nagano *et al.*, 2007). In contrast, two case–control studies (Zivaljevic *et al.*, 2004; Bufalo *et al.*, 2006) reported no clear association between smoking and thyroid cancer risk (no risk ratio estimates were reported; hence, data are not shown in the tables) and a cohort study with 169 incident cases of thyroid cancer, also found no clear association with any qualitative or quantitative smoking measure (Navarro Silvera *et al.*, 2005; Table 2.82 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.82.pdf; Table 2.83 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.83.pdf).

2.18 Other cancers

The cancers reviewed in this section generally have low incidence and mortality rates and are not considered to be strongly associated with cigarette smoking. This raises the possibility of preferential reporting of positive associations in epidemiological studies.

2.18.1 Cancer of the salivary gland

Studies of smoking and cancers of the salivary gland reviewed in the previous *IARC Monograph* (IARC, 2004a) were sparse and their results were inconsistent (Spitz *et al.*, 1990; Swanson & Burns, 1997; Hayes *et al.*, 1999). A few additional studies also show inconsistent results (Kotwall, 1992; Pinkston & Cole, 1996; Horn-Ross *et al.*, 1997; Vories & Ramirez, 1997; Muscat & Wynder, 1998). Studies that focused specifically on Warthin's tumour [papillary cystadenoma lymphomatosum or adenolymphoma, a benign tumour of the parotid gland] tend to show strong positive associations with smoking (Kotwall, 1992; Pinkston & Cole, 1996; Vories & Ramirez, 1997). One study (Pinkston & Cole, 1996) compared the risk for Warthin's tumour with that for other salivary gland tumours and found that smoking increased risk significantly only for Warthin's tumour.

2.18.2 Cancer of the small intestine

Epidemiological studies (all of case–control design) reviewd in the previous *IARC Monograph* (IARC, 2004a) have been inconsistent in showing a positive association between smoking and cancers of the small intestine (Chow *et al.*, 1993b; Chen *et al.*, 1994; Wu *et al.*, 1997; Negri *et al.*, 1999; Kaerlev *et al.*, 2002). A more recent study showed no clear association (Hassan *et al.*, 2008b).

2.18.3 Cancers of the gallbladder and extra-hepatic bile ducts

Epidemiological studies of smoking and risk of cancers of the gallbladder and extra-hepatic bile ducts reviewed in the previous *IARC Monograph* (IARC, 2004a) tended to show null, weak, or moderately strong positive associations. More recent studies also tend to show either no clear association with biliary tract carcinoma/extra-hepatic cholangiocarcinoma (Shaib *et al.*, 2007; Welzel *et al.*, 2007) or suggest positive associations with gallbladder/biliary cancers (Pandey & Shukla, 2003; Yagyu *et al.*, 2008; Grainge *et al.*, 2009). Attention should be paid to potential confounders, especially BMI, when considering the results of epidemiological studies of risk of cancers of the gallbladder and extra-hepatic bile ducts. Recent studies that statistically adjusted for BMI, on gallbladder disease risk (Grainge *et al.*, 2009) or on extrahepatic biliary tract carcinoma risk (Ahrens *et al.*, 2007), showed a positive and null association with smoking, respectively. To date, there are too few studies with adequate control for potentially confounding factors to determine any clear pattern.

2.18.4 Soft-tissue sarcoma

As reported in the previous *IARC Monograph* (IARC, 2004a), one cohort study found an association between cigarette smoking and mortality from soft-tissue sarcoma after 26 years of follow-up but no dose–response relationship with the number of cigarettes/day, duration of smoking or pack–years (Zahm *et al.*, 1992). No effect of cigarette smoking was detected in an Italian hospital-based case–control study (Franceschi & Serraino, 1992).

2.18.5 Cancer of the skin

(a) Melanoma

Several case–control studies found no difference in the prevalence of tobacco smoking between patients with malignant melanoma and controls, and one study found an inverse association (IARC, 2004a). An inverse association with smoking was also found in the US Radiologic Technologists cohort Study (Freedman *et al.*, 2003a). In that study, smoking for at least 30 years compared with never smoking was inversely related to melanoma risk (RR, 0.6; 95%CI: 0.3–1.3), though risk was not associated with number of cigarettes/day. An inverse association was also observed in a cohort of Swedish construction workers (Odenbro *et al.*, 2007). In this study, the risk for malignant melanoma was reduced in a dose-dependant manner for both cigarette and pipe smokers. The possibility that smoking may reduce the risk for melanoma should, therefore, be considered.

(b) Non-melanoma skin cancer

Four studies showed a positive association between smoking and non-melanoma skin cancer risk (De Stefani *et al.*, 1995; Wojno, 1999; Smith & Randle, 2001; Boyd *et al.*, 2002), and two found no clear association (van Dam *et al.*, 1999; Corona *et al.*, 2001). When distinguishing between histological subtypes, tobacco smoking was linked to the incidence of squamous-cell carcinoma of the skin in most studies, whereas the results for basal cell carcinoma remain inconsistent (Zak-Prelich *et al.*, 2004). No clear association between smoking and risk for basal cell carcinoma was found in a cohort study (Freedman *et al.*, 2003b).

2.18.6 Cancer of the penis

Case–control studies of smoking and penile cancer (Hellberg *et al.*, 1987; Daling *et al.*, 1992, 2005; Maden *et al.*, 1993; Harish & Ravi, 1995;

Table 2.84 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.84.pdf; Table 2.85 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.85.pdf) and reviews of studies of smoking and penile cancer and population surveys (Dillner *et al.*, 2000; Favorito *et al.*, 2008; Bleeker *et al.*, 2009; Table 2.86 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.86.pdf; Table 2.87 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.87.pdf) consistently showed a positive association. In most studies there was a dose–response relationship, with higher risks among those with increased smoking intensity and/or duration. A study in Brazil showed a positive correlation with penile tumour grade (Favorito *et al.*, 2008). Based on the two reviews (Dillner *et al.*, 2000; Bleeker *et al.*, 2009), relative risks were generally increased twofold to fivefold among smokers.

Most studies did not adjust for HPV infection. In one case–control study (Daling *et al.*, 2005), current smoking was associated with a 160% increased risk of HPV-positive penile cancer (n = 75), and a 180% increased risk of HPV-negative penile cancer (n = 19), suggesting no important effect modification.

2.18.7 Cancer of the testis

Studies reviewed in the previous *IARC Monograph* (IARC, 2004a) showed no association between cigarette smoking and risk for testicular cancer. More recently, two case–control studies showed positive associations with smoking, one in Canada (Srivastava & Kreiger, 2004) and one in the Czech Republic (Dusek *et al.*, 2008).

2.18.8 Cancer of the central nervous system

A recent meta-analysis was conducted on smoking in relation to glioma risk (Mandelzweig *et al.*, 2009), which included 17 epidemiological studies (6 cohort and 11 case–control). It was concluded that smoking is not associated with risk of glioma, despite a small significant increased risk seen in cohort studies. A recent cohort study found no association between smoking and carcinoma of the brain (Batty *et al.*, 2008). There have been no consistent associations of smoking with other CNS tumours (IARC, 2004a). In a population-based case–control study in the USA, smoking was associated with increased risk of intracranial meningioma in men (OR, 2.1; 95%CI: 1.1–4.2) but not in women (Phillips *et al.*, 2005).

2.18.9 Cancer of the adrenal gland

Data on risk factors for adrenal carcinoma are sparse. In the US Veterans' Study there was a fivefold increase in risk among current cigarette smokers during 26 years of follow-up, with risk being particularly high among those who smoked most intensely (Chow *et al.*, 1996). Other forms of tobacco use were associated with a statistically non-significant increase in risk. A case–control study in the USA found a twofold increase in risk for adrenal cancer among heavy smokers in men, but not in women (Hsing *et al.*, 1996).

2.19 Bidi smoking

2.19.1 Cancer of the oral cavity

(a) Overview of studies

The association between cancers of oral cavity and bidi smoking has been examined in 10 case–control studies conducted in India (Sankaranarayanan *et al.*, 1989a, b, 1990a; Rao *et al.*, 1994; Rao & Desai, 1998; Dikshit & Kanhere, 2000; Balaram *et al.*, 2002; Znaor *et al.*, 2003; Subapriya *et al.*, 2007; Muwonge *et al.*, 2008; Table 2.88 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.88.pdf). In these studies both cases and controls were interviewed and analyses were restricted

to men, except for the studies by Balaram *et al.* (2002) and Subapriya *et al.* (2007), because very few women smoked among study subjects.

Three hospital-based case–control studies considered cancers of subsites of the oral cavity (gingiva, tongue and floor of the mouth, buccal and labial mucosa) (Sankaranarayanan *et al.*, 1989a, b, 1990a). All three studies showed a higher oral cancer risk for bidi smoking. In one early study an unadjusted relative risk of 1.6 (95%CI: 1.3–2.0) for oral cancer in bidi smokers was reported (Rao *et al.*, 1994). [The Working Group noted that the study had several deficiencies, particularly in the selection of controls that resulted in cigarette smoking apparently being protective for oral cancer.] In another early study (Rao & Desai, 1998) relative risks were estimated after stratification by age and place of residence. Bidi smoking was a significant risk factor for cancer of the base of the tongue (RR, 5.9; 95%CI: 4.2–8.2) but not significant for cancer of the anterior tongue. Relative risk for bidi smoking adjusted for alcohol drinking, illiteracy, non-vegetarian diet and tobacco chewing showed significant risk for cancer of the base of the tongue (RR, 4.7; 95%CI: 3.5–6.3) but not for cancer of the anterior tongue. In a population-based case–control study a relative risk of 1.5 (95%CI: 0.9–2.4), adjusted for age and tobacco quid chewing for smokers (bidis and/or cigarettes), was found (Dikshit & Kanhere, 2000).

Two hospital-based multi centre case–control studies on cancer of the oral cavity were conducted in southern India. One included 309 cases and 292 controls (Balaram *et al.*, 2002). The risk for oral cavity cancer among those who smoked < 20 bidis per day was 2.0 (95%CI: 1.1–3.8) and 2.5 (95%CI: 1.4–4.4) for ≥ 20 per day. The second study included 1563 cases and 3638 controls and found a risk for bidi smoking only of 2.2 (95%CI: 1.75–2.63) compared to never smokers, adjusted for age, centre, level of education, alcohol consumption and chewing (Znaor *et al.*, 2003).

In a hospital-based case–control study with 388 oral squamous cell carcinoma cases (202 men and 186 women) and an equal number of age and sex-matched controls the effect of lifestyle factors (tobacco chewing, smoking and alcohol drinking, diet and dental care) on the risk of oral cancer was evaluated (Subapriya *et al.*, 2007). Both cases and controls were interviewed using a structured questionnaire. The risk estimate for bidi smoking based on 22 cases (84 cases included in the model) and 22 controls was 4.6 (95%CI not given).

Data from a randomized control trial conducted between 1996 and 2004 in Trivandrum, southern India were used in a nested case–control analysis with 282 (163 men and 119 women) incident oral cancer cases and 1410 matched population controls aged 35 years and over (Muwonge *et al.*, 2008). Oral cancer risk among men, adjusted for education and religion, was 1.9 (95%CI: 1.1–3.2) for bidi smokers only compared to never smokers. No association was found between mixed smoking of bidi and cigarette and risk of oral cancer.

Rahman *et al.* (2003) performed a meta-analysis to investigate the relationship between bidi smoking and oral cancer. They identified 12 case–control studies published in English during 1996–2002 with quantitative information on bidi smoking and oral cancer. Of these, ten studies were conducted in India, one in Sri Lanka and one in Pakistan. All cases were confirmed histologically and exposure data were collected by direct interview. In these studies ORs were not adjusted for tobacco chewing or alcohol drinking. The OR for bidi smokers compared to never smokers based on random effects model was 3.1 (95%CI: 2.0 –5.0). The ORs ranged from 2.0 to 3.6 in different regions of India: studies conducted in Mumbai had an OR of 3.6 (95%CI: 1.6 –7.9), in central India 2.7 (95%CI: 1.6–4.6), in Kerala 2.0 (95%CI: 1.5–2.9) and in Bangalore 2.0 (95%CI: 1.1–3.7).

(b) Dose–response evidence

The trends in relative risks by intensity and duration of bidi smoking were both statistically significant in two studies (Rao *et al.*, 1994; Rao & Desai, 1998). A meta-analysis based on three studies on duration of bidi smoking and on five studies on number of bidi sticks per day, showed a dose–response relationship for duration of bidi smoking but not for number of sticks used per day (Rahman *et al.*, 2003).

In a nested case–control analysis (Muwonge *et al.*, 2008) a dose–response relationship was observed for duration of bidi smoking ($P = 0.045$). [It is not clear if the analysis was restricted to bidi smokers only (n = 40 men) and if smokers with combined smoking habits (bidi and cigarette) were excluded. Moreover, ORs for the dose–response analysis were not reported.]

2.19.2 Cancer of the pharynx

Five case–control studies, two hospital-based (Wasnik *et al.*, 1998; Rao *et al.*, 1999), one population-based (Dikshit & Kanhere, 2000) and two multicentric studies (Znaor *et al.*, 2003; Sapkota *et al.*, 2007) were conducted on cancers of oropharynx and hypopharynx in India (Table 2.88 online). In all these studies, analyses were restricted to men because very few women smoked among study subjects.

Wasnik *et al.* (1998) conducted a case–control study on oropharyngeal cancers with cases and controls were matched on age and sex. Odds ratios for tobacco smoking, predominantly in the form of bidi and/or chillum, were 2.3 (95%CI: 1.2–3.7) after adjustment for tobacco chewing and outdoor occupation. [The Working Group noted some problems with the data analysis.]

Rao *et al.* (1999) reported a relative risk for bidi smoking adjusted for alcohol, illiteracy, diet and tobacco chewing of 4.7 (3.6–6.3) for oropharyngeal cancer and of 2.8 (2.1–3.7) for cancer of the hypopharynx. Dikshit & Kanhere (2000) found an odds ratio for oropharyngeal cancer among bidi smokers only of 7.9 (95%CI: 5.1–12.4).

Znaor *et al.* (2003) reported a risk for bidi smoking only for pharyngeal cancer of 4.7 (95%CI: 3.5–6.3) and for combined bidi and cigarette smoking of 3.6 (95%CI: 2.55–4.98). Sapkota *et al.* (2007) reported an odds ratio for hypopharyngeal cancer of 6.8 (95%CI: 4.6–10.0) for bidi smokers compared to never smokers.

A dose–response relationship was observed for intensity and duration of bidi smoking for both cancers of oropharynx and hypopharynx (Rao *et al.*, 1999; Dikshit & Kanhere, 2000; Sapkota *et al.*, 2007).

2.19.3 Cancer of the lung

One cohort study (Jayalekshmy *et al.*, 2008), one population-based case–control study (Dikshit & Kanhere, 2000) and two hospital-based case–control studies (Gupta *et al.*, 2001; Gajalakshmi *et al.*, 2003) in India (Table 2.88 online) have investigated the relationship between bidi smoking and lung cancer. In all these studies both cases and controls were interviewed and analyses were restricted to men because very few women smoked among study subjects. One hospital-based case–control study in Chiang Mai, Thailand, looked at the association between lung cancer and *khii yoo*, hand-rolled cigars. The risk for lung cancer for *khii yoo* smoking was 1.2 in men and 1.5 in women, $P > 0.05$ (Simarak *et al.*, 1977).

In the population based case–control study by Dikshit & Kanhere (2000) the age-adjusted relative risk for lung cancer among bidi smokers only was 11.6 (95%CI: 6.4–21.3).

Gupta *et al.* (2001) reported an odds ratio for bidi smoking of 5.8 (95%CI: 3.4–9.7) from a hospital-based case–control study of lung cancer conducted in Chandigarh. Gajalakshmi *et al.* (2003) conducted a case–control study in two centres in which all subjects were interviewed by trained social investigators with standard

questionnaires. Odds ratios were adjusted for age, educational level, centre, chewing and alcohol habit. The odds ratios of lung cancer for former and current bidi smokers were 3.4 (95%CI: 2.1–5.4) and 5.3 (95%CI: 3.8–7.3), respectively. Odds ratios for former and current smokers of cigarette and bidi combined were 4.0 (95%CI: 2.5–6.6) and 9.1 (95%CI: 6.2–13.2), respectively.

Baseline data of a cohort of 359 619 residents in Kerala, India was collected by direct interview using standardized questionnaires during 1990–97 (Jayalekshmy *et al.*, 2008). After excluding rare earth workers, those who died, were diagnosed with cancer before 1997 or died within three years of interview, there were 65 829 bidi-smoking men aged 30–84 years old. Two hundred and twelve lung cancer cases were identified by the Karunagappally Cancer Registry between 1997 and 2004. The relative risk for lung cancer for current compared to never bidi smokers calculated by Poisson regression analysis and adjusted for age, religion and education was 3.9 (95%CI: 2.6–6.0; $P < 0.001$). The risk was lower among former than among current smokers.

(a) Dose–response evidence

Lung cancer risks increased with increasing bidi smoking intensities. The highest odds ratio was found for 9 pack–years (3.9; 95%CI: 2.1–7.1) (Gupta *et al.*, 2001). In a cohort study Jayalekshmy *et al.* (2008) found increased lung cancer incidence with increasing number of bidi sticks smoked per day ($P < 0.001$) and with increasing duration of bidi smoking ($P < 0.001$). [The number of lung cancer cases was small in each category, resulting in wide confidence intervals.] Gajalakshmi *et al.* (2003) also reported increased risk with duration and intensity of bidi smoking.

(b) Cessation of smoking

In two case–control studies (Gupta *et al.*, 2001; Gajalakshmi *et al.*, 2003) there was a clear decreasing trend in risk for years since quitting. Gajalakshmi *et al.* (2003) reported that lung cancer risk of former bidi smokers fell to 0.4 (0.1–1.2) after quitting for more than 15 years. The cohort study conducted in Kerala did not have the power to assess the risk associated with stopping bidi smoking (Jayalekshmy *et al.*, 2008).

2.19.4 Cancer of the larynx

Two hospital based case–control studies (Sankaranarayanan *et al.*, 1990b; Rao *et al.*, 1999) showed a higher risk for bidi smokers (Table 2.88 online). The relative risk was adjusted for age and religion in Sankaranarayanan *et al.* (1990b) study and for alcohol use, illiteracy, vegetarian/non-vegetarian diet and tobacco chewing in Rao *et al.* (1999) study. A multicentre case–control study on laryngeal cancer was conducted in four Indian centres using standardized questionnaires adjusting risks for centre, age, socioeconomic status, alcohol consumption, tobacco snuffing and tobacco chewing (Sapkota *et al.*, 2007). Compared to never smokers bidi smokers had a higher risk for cancers of the supraglottis (OR, 7.5; 95%CI: 3.8–14.7), glottis (OR, 5.3; 95%CI: 3.2–8.9) and rest of larynx (OR, 9.6; 95%CI: 5.6–16.4).

All levels of intensity and duration of bidi smoking were associated with significant relative risk estimates and dose–response for laryngeal cancer (Sankaranarayanan *et al.*, 1990b; Rao *et al.*, 1999). A strong dose–response relationship was observed for duration and frequency of bidi smoking for cancers of supraglottis, glottis and rest of larynx (Sapkota *et al.*, 2007).

2.19.5 Cancer of the oesophagus

Three hospital-based case–control studies and one multicentre study (Sankaranarayanan *et al.*, 1991; Nandakumar *et al.*, 1996; Nayar *et al.*, 2000; Znaor *et al.* 2003) showed increased risk for oesophageal cancer among bidi smokers in India (Table 2.88 online). A significantly elevated

risk for all three segments of the oesophagus was reported (Nandakumar *et al.*, 1996). One study (Nayar *et al.*, 2000) adjusted for chewing of betel leaf with tobacco and low consumption of vegetables other than leafy vegetables. The multicentre case–control study conducted in two centres in South India found an increased risk for oesophageal cancer for bidi smoking only (OR, 3.3; 95%CI: 2.45–4.39) (Znaor *et al.*, 2003). Odds ratios were adjusted for age, centre, level of education, alcohol consumption and chewing. Only men were analysed in all the above studies.

Significant effects were noted in men for all levels of intensity and for duration of more than 20 years of bidi smoking (Sankaranarayanan *et al.*, 1991).

2.19.6 Cancer of the stomach

In a hospital-based case–control study the association between stomach cancer and bidi smoking was analysed as part of a multicentre study (Gajalakshmi & Shanta, 1996). Cases and controls were matched on age, sex, religion and mother tongue. The odds ratio for stomach cancer for current bidi smokers only was 3.2 (95%CI: 1.8–5.7) and for current smokers of any type of tobacco was 2.7 (95%CI: 1.8–4.1).

Table 2.88 (online) summarizes the studies published since the last *IARC Monograph* (IARC, 2004a). A hospital-based case–control study of stomach cancer included 170 stomach cancer cases (121 men and 49 women) and 2184 controls (1309 men and 875 women) aged 30–75 years (Rao *et al.*, 2002). The association between bidi smoking and stomach cancer was not significant (RR, 0.8; 95%CI: 0.5–1.2) in a univariate analysis. The risk increased with increase in lifetime exposure to bidi smoking and was highly significant ($P < 0.001$).

One study investigated stomach cancer risk in association with smoking of *meiziol*, a local cigarette in Mizoram, India (Phukan *et al.*, 2005). Statistically significant higher risks were seen for smokers of combined users of tobacco (cigarette and *meiziol*), with an odds ratio of 3.1 (95%CI: 2.0–11.1). Among users of a single type of tobacco, higher risks were seen for *meiziol* smokers (OR, 2.2; 95%CI: 1.3–9.3) in the multivariate model in comparison to cigarette smokers. Overall, the excess risk was limited to smokers of > 10 *meiziols* per day.

2.20 Synergistic effects of tobacco smoking and alcohol drinking

This section addresses the combined effects of smoking and alcohol consumption on cancers of oral cavity, pharynx, larynx and oesophagus, which have been examined extensively. For the purposes of this report interdependence of effects is termed *effect modification*, and *synergism* and *antagonism* are used to describe the consequences of the interdependence of disease risk when both risk factors are present (Rothman & Greenland, 1998). The studies varied in their methods and in the approaches used to assess effect modification, which ranged from descriptive to formal estimation of interaction terms in multivariate models. Study designs of the case–control and cohort studies are presented in Table 2.89 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.89.pdf) and Table 2.90 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.90.pdf), respectively; and the results for both study designs are presented in Table 2.91 (available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-01-Table2.91.pdf).

2.20.1 Cancers of the upper aerodigestive tract

It was noted in the previous *IARC Monograph* (IARC, 2004a) with relatively large numbers of cases and controls that the pattern of increasing cancer risk with increasing alcohol consumption is strong (Mashberg *et al.*, 1993; Kabat *et al.*, 1994).

For cancers of the oral cavity, recent evidence comes from seven case–control studies and one cohort study. The pattern of odds ratios for smoking, across categories of alcohol consumption, is consistent with synergism. In four case–control studies with relatively large numbers of cases and controls (more than 200 cases and equivalent number of controls), the pattern of increasing cancer risks with increasing alcohol consumption was strong (Schlecht *et al.*, 1999b; Znaor *et al.*, 2003; Castellsagué *et al.*, 2004; Hashibe *et al.*, 2009). In the cohort study from Taiwan, China (Yen *et al.*, 2008) similar strong risks were also observed. In all four case–control studies in which the estimate of formal statistical interaction was examined, the tests were statistically significant (Schlecht *et al.*, 1999b; Znaor *et al.*, 2003; Castellsagué *et al.*, 2004; Hashibe *et al.*, 2009). In two case–control studies from India (Znaor *et al.*, 2003; Muwonge *et al.*, 2008) and in the cohort study from Taiwan, China (Yen *et al.*, 2008) the interaction of tobacco smoking, alcohol and betel quid chewing was examined. In general, the results suggested increasing risks when betel quid chewing was included in the model.

Five case–control studies and one cohort study examined the effect of interaction between tobacco and alcohol in pharyngeal cancer. The results from case–control studies were similar to those observed for oral cancer (Olsen *et al.*, 1985b; Choi & Kahyo, 1991; Schlecht *et al.*, 1999b; Znaor *et al.*, 2003; Hashibe *et al.*, 2009). In a Singapore cohort study (Friborg *et al.*, 2007) the pattern of odds ratios for smoking across categories of alcohol consumption was consistent with synergism for oropharyngeal but not for nasopharyngeal cancer.

Two cohort and fourteen case–control studies reported on joint effects of tobacco smoking and alcohol drinking on the risk for oesophageal cancer. Since multiple logistic regression models were used for analysing most of these studies, some of them tested likelihood ratio test for departure from multiplicativity of the individual effects of tobacco and alcohol. Generally, the positive results were stronger for squamous cell carcinoma. However, these tests for interaction are inadequate to assess synergy. Four studies from India and Taiwan, China, included betel quid chewing to the joint effect analysis of tobacco smoking and alcohol consumption and the results suggested increasing risks of oesophageal cancer.

Most of the twenty case–control studies of laryngeal cancer provided strong evidence for synergism of tobacco smoking and alcohol consumption. Only Zheng *et al.* (1992) did not find consistent evidence with synergism. In several studies, tests for interaction were carried out and reported to be 'non significant.' These were tests for departure from the multiplicative models, typically multiple logistic regression models, used to analyse the case–control data, and not tests for departure from additive model.

Several studies (14 case–control, 3 cohort) reported on cancer of the 'mixed upper aerodigestive tract', comprising studies on squamous cell carcinomas, regardless of specific sites. These studies also provided strong evidence for synergism.

The Working Group considers that there is strong evidence of tobacco smoking and alcohol consumption interaction on the incidence of upper aerodigestive tract cancers, as well as with regard to cancer of specific subsites of this anatomical region.

2.21 Synthesis

2.21.1 Lung

Tobacco smoking is the major cause of lung cancer, primarily from cigarettes. Duration of smoking is the strongest determinant of lung cancer in smokers. Risk also increases in proportion to the number of cigarettes smoked. The strong dose– and duration–response

relationships between lung cancer and tobacco smoking have been confirmed more recently in both questionnaire-based and biomarker-based studies. Tobacco smoking increases the risk of all histological types of lung cancer.

Differences in the intensity and/or duration of tobacco smoking may explain, in part, the lower lung cancer risks in Asian populations relative to whites. However, several studies of genetic polymorphisms among African-American and Caucasian populations provide some preliminary evidence supporting the hypothesis of a racial/ethnic disparity in susceptibility.

The results from observational studies do not provide strong support that a higher intake or a greater circulating concentration of carotenoids reduce lung cancer risk, particular in light of the elevated risk of lung cancer observed in the randomized trials of β-carotene supplementation. Residual confounding from smoking and the possibility that carotenoid measurements are serving as markers for a diet rich in total fruit and vegetables mitigate the likelihood of any protective role for total carotenoids or β-cryptoxanthins.

The specific genes that are responsible for enhanced lung cancer risk remain poorly understood, in spite of hundreds of candidate gene studies. Single-gene studies conducted to date have several limitations which contribute to inconclusive results, including small sample size and associated low power to detect moderate risks when allele frequencies are low.

2.21.2 Upper areodigestive tract

(a) Oral cavity

Tobacco smoking is causally associated with cancer of the oral cavity in both men and women. Since the previous *Monograph*, additional evidence has accumulated that further confirms the association. Risk increases with duration and intensity of smoking, and decreases after quitting.

(b) Pharynx

Tobacco smoking is an important cause of oropharyngeal and hypopharyngeal cancers. The risk increases with increasing duration and intensity of smoking and decreases with increasing time since quitting.

(c) Nasal cavity and accessory sinuses

The evidence of an association between tobacco smoking and sinonasal cancer is based on the results from case–control studies, each of which may be subject to different sources of bias. However, presence of a dose–response relationship in most studies, the decrease in risk associated with time since quitting, the consistently higher risks for squamous-cell carcinoma than for adenocarcinoma and the lack of potential confounders support the existence of a causal association.

(d) Nasopharynx

Although the interpretation of the results is complicated by small sample sizes in several studies, by different criteria used for the selection of controls and by the control groups in some studies including smoking-related diseases, the combined evidence shows an association between tobacco smoking and nasopharyngeal carcinoma in both endemic and non-endemic areas. Most studies that adjusted for known and suspected causes of nasopharyngeal carcinoma such as intake of Chinese-style salted fish, other dietary factors, alcohol drinking and family history of nasopharyngeal carcinoma, suggested only a limited confounding effect of these factors. Adjustment for infection with Epstein–Barr virus (human herpes virus 4), a major cause of nasopharyngeal carcinoma worldwide, was possible in just one of the available studies. However, it is unlikely that confounding by infection with Epstein–Barr virus would explain the observed association between tobacco smoking and risk for nasopharyngeal carcinoma.

(e) Oesophagus

Several well conducted case–control studies found a statistically significant higher risk for adenocarcinoma of the oesophagus in smokers than in nonsmokers. Positive dose–response relationships obtained using various indicators of amount smoked support a causal association, which is further corroborated by the findings of decreasing risks after smoking cessation. Several of these studies reported relative risks adjusted for alcohol consumption and other potential confounders. Further risk factors, such as chewing betel quid with tobacco or use of other forms of smokeless tobacco, have not been considered in these populations, but are not likely to be strong confounders. Studies from Australia, China and Europe also found increased risks for smokers.

(f) Larynx

Laryngeal cancer is one of the cancers most strongly associated with cigarette smoking. Recent epidemiological evidence strengthens this conclusion.

2.21.3 Stomach

The additional epidemiologic data showing a consistent association of stomach cancer with tobacco smoking in both men and women greatly strengthens the previous conclusion of a causal association. There was insufficient evidence for differential risks between cardia and non-cardia stomach cancer. Confounding and effect modification by H. pylori has not been found.

2.21.4 Pancreas

The additional data supports the previous evaluation that cancer of the pancreas is causally associated with tobacco smoking. The risk increases with increasing daily consumption levels and duration of smoking and decreases with increasing time since cessation of smoking. The risk remains elevated after accounting for potential confounding factors.

2.21.5 Colorectum

At the previous evaluation, there was already some evidence from prospective cohort and case–control studies that the risk of colorectal cancer is increased among tobacco smokers. However, inadequate adjustment for various potential confounders was considered to possibly account for some of the small increase in risk that appears to be associated with smoking. Since then, an appreciable amount of data has accumulated to support a causal association with smoking. In virtually all the cohort studies published since elevated risk associated with smoking was found, although not always statistically significant. More than half of the cohort studies that assessed dose–response relationships found statistically significant increasing risks with increasing daily cigarette consumption, duration of smoking and/or pack–years of smoking. Risk of colorectal cancer decreased with increasing delay in smoking initiation and years since cessation of smoking. A meta-analysis based on 36 cohort studies with data from a total of 3 million subjects found a significantly 15% increased risk of colorectal cancer and 27% higher risk of colorectal cancer mortality in current smokers compared to never smokers. A stronger association with smoking for rectal cancer than for colon cancer was found in the meta-analysis of the subset of cohort studies that differentiated colorectal cancer by site. Risk for colorectal cancer increased significantly by 17% and by 38% with 20 cigarettes and 40 cigarettes/day, respectively, and was elevated by 9.4% and by 19.7% with a 20-year and a 40-year duration of smoking, respectively. While these results are persuasive, this meta-analysis could not correct for the potential confounders in the individual studies. Convincing evidence has been provided by three large cohort studies that adjusted for at

least four important potential confounders (i.e. physical activity, alcohol consumption, body mass index and dietary intake of fruits and vegetables and/or meat); two studies also adjusted for history of colonoscopy. Significant dose–response relationships were found with one or more of the smoking variables, for risk of colorectal cancer and/or colon cancer and/or rectal cancer. Earlier cohort studies may not have been able to establish the association because of insufficient follow-up time and a limited number of cases. Updated results of several large cohort studies, which now show clearly significant increased risk of colorectal cancer associated with smoking, provide support for the lag-time hypothesis for smoking and colorectal risk.

Recent evidence suggests that smoking may be associated with the subtype of colorectal cancer characterized by microsatellite instability, and by CIMP status and BRAF mutation. For this subtype, the magnitude of risk associated with smoking reaches the twofold risk elevation consistently observed for colorectal adenomas and supported by a recent meta-analysis. Smoking has been associated with a stronger risk for hyperplastic polyps than for adenomas. Also, CIMP positivity and BRAF mutations have been associated with hyperplastic polyps, particularly serrated polyps. These data suggest that smoking may be associated primarily with a subtype of colorectal cancer that develops through a hyperplastic (serrated) polyp progression. The association with smoking may therefore be diluted when considering colon cancers overall.

2.21.6 Liver

Recent studies on smoking and hepatocellular carcinoma supports the established causal relationship. Supporting evidence comes from the consistency of the findings across regions (with the best evidence coming from Asian studies), and the observations of an association among non-drinkers and after controlling for hepatitis B or C virus infection.

2.21.7 Kidney

Recent evidence supports a causal association between kidney cancer and smoking. After adjustment for body mass index and hypertension, current and former smokers still had a greater risk for renal-cell cancer. A dose–response relationship with the number of cigarettes smoked has been noted in most studies, and a few also noted a reduction in risk after cessation.

2.21.8 Urinary bladder

Tobacco smoking is causally associated to bladder cancer, based on a large number of case–control and cohort studies that showed statistically significant associations not explained by confounding or bias. Risk increased with the duration of smoking and the number of cigarettes smoked. Also, stopping smoking at any age avoids the further increase in risk incurred by continued smoking. The evidence supporting a modulating role by *NAT2* polymorphisms is convincing.

2.21.9 Myeloid leukaemia

There is evidence for a causal association of tobacco smoking with myeloid leukaemia.

2.21.10 Breast

New evidence from cohort and case–control studies and from meta-analyses of genetic polymorphisms has become available since the previous *IARC Monograph* (IARC, 2004a). Results from seven new cohort studies consistently show a small overall association between current smoking and breast cancer incidence, with relative risk estimates ranging from 1.1–1.3 in studies with at least 100 exposed cases. The overall association is weaker than that observed with other cancers that have been designated as causally related to smoking, and the dose–response relationships (with years of smoking,

cigarettes smoked per day, age at initiation) are correspondingly small.

Emerging evidence from case–control studies suggests that inherited polymorphisms in the *NAT2* gene, which encode the slow acetylator phenotype, may modify (increase) the association between smoking and breast cancer. The p-value for interaction with pack–years of smoking as a continuous variable is statistically significant (P = 0.03) and another small study published since this meta-analysis supports the conclusion. The potential for publication bias remains of concern.

It is biologically plausible that tobacco smoke could be causally related to breast cancer risk. There are multiple chemicals in tobacco smoke that are known to cause mammary cancer in rodents. These substances reach the breast in humans; some are stored in adipose tissue, and some can be detected in nipple aspirate and DNA adducts.

Hypotheses have been proposed to explain why numerous well conducted epidemiological studies have generally not observed strong or consistent associations between tobacco smoking and breast cancer. Underlying all of these is the theory that tobacco smoking may have both protective and detrimental effects on breast cancer risk, which cancel each other out and which could explain the atypical dose–response relationship that has been reported between tobacco smoke and breast cancer from some studies.

2.21.11 Cervix

The largely positive findings observed in studies of cohort design, the relatively high consistency of positive associations found for squamous-cell carcinoma of the cervix (but not adenocarcinomas) across all epidemiological studies, including those with adjustment for a wide range of potentially confounding variables, and the positive associations observed in studies restricted to HPV-positive individuals, all argue against the observed positive association being due to recall or selection bias or confounding.

2.21.12 Endometrium

The results of epidemiological studies to date, including recent studies, largely show inverse associations of smoking with risk of postmenopausal endometrial cancer. However, the Working Group noted the few studies of premenopausal cancer that were less consistent, as well as indications of an increased risk among smokers in a recent multicentre European study.

2.21.13 Prostate

Many epidemiological studies have examined the association between cigarette smoking and prostate cancer risk, and most have shown no consistent association. The question remains whether smoking may alter risk in various population subgroups.

2.21.14 Ovary

A causal association between cigarette smoking and risk for mucinous ovarian tumours is indicated by 1) the consistency of the positive association across the large majority of ten pooled case–control studies and ten additional independent epidemiological studies of both case–control and cohort design, 2) the relatively strong magnitude of the association (typically greater than a doubling of risk among current smokers), 3) the tendency to show dose–response associations with risk, such that current smokers generally have higher risk than former smokers and the dose–response observed with measures of smoking intensity in some (but not all) studies, and 4) the specificity of the positive association with the mucinous histological type, which argues against recall bias as an explanation of the findings.

2.21.15 Thyroid

A pooled analysis of 14 case–control studies showed that smoking was inversely associated with thyroid cancer risk. Similar inverse associations were also observed in two subsequent case–control studies.

2.21.16 Other sites

There is inconsistent or sparse evidence for an association between tobacco smoking and other cancer sites that were considered by the Working Group.

2.21.17 Bidi smoking

Overall, bidi smoking increases the risk for cancers of the oral cavity, oropharynx, hypopharynx, larynx, lung, oesophagus and stomach.

3. Cancer in Experimental Animals

3.1 Mainstream tobacco smoke

3.1.1 Mouse

There have been multiple studies of the carcinogenic potential of tobacco smoke in mice (Table 3.1). Lifetime exposure of several mouse strains to cigarette smoke failed to result in the production of lung tumours (Harris & Negroni, 1967; Otto & Elmenhorst, 1967; Henry & Kouri, 1986). However, studies involving lifetime exposure of C57BL mice to a mixture of flue-cured or air-cured cigarette smoke or to the gas phase of flue-cured cigarette smoke led to significant increases in the number of lung tumours (adenomas) (Harris *et al.*, 1974). Similarly, lifetime exposure of Snell's mice to the gas phase of cigarette smoke led to an increased incidence of lung adenocarcinomas (Leuchtenberger & Leuchtenberger, 1970). Exposure of $B6C3F_1$ female mice to smoke for lifetime led to increased incidence of lung adenomas, bronchiolar papillomas and lung adenocarcinomas in smoke-exposed mice. In addition, the occurrence of squamous cell carcinomas of the nasal cavity in smoke-exposed mice was increased (Hutt *et al.*, 2005). In a recent study, Swiss mice were exposed whole-body to cigarette smoke for 120 days, starting within 12 hours of the birth. Smoke-exposed mice developed microscopic lung tumours beginning only 75 days after birth and reaching an overall incidence of 78.3% after 181–230 days. The mean lung tumour multiplicity was 6.1 and 13.6 tumours per mouse in males and females, respectively. In addition, malignant tumours, some of which may have had a metastatic origin, were detected in the urinary tract of smoke-exposed mice (Balansky *et al.*, 2007).

3.1.2 Rat

Several studies have evaluated the carcinogenic potential of mainstream tobacco smoke in rats (Table 3.1). Exposure of Wistar rats to cigarette smoke for lifetime did not increase the lung tumour incidence (Davis *et al.*, 1975). In contrast, exposure of Fischer 344 rats to a mixture of non-filter cigarette smoke for 128 weeks resulted in an increased incidence of nasal and lung tumours. There was also an increase in subcutaneous sarcomas at forelimb ulceration sites (Dalbey *et al.*, 1980). CDF rats were exposed to low-dose cigarette smoke (LCS) or high-dose cigarette smoke (HCS) for 126 weeks. The incidence of lung tumours was significantly higher only in female rats that received HCS (Finch *et al.*, 1995). In a recent study, Fischer 344 rats received whole body exposure to smoke containing either 100 mg (LCS) or 250 mg (HCS) total particulate matter/m^3 for 30 months. This led to significant increases in the incidence of lung and nasal cavity tumours in male rats treated with HCS but not with LCS. In female rats, there were significant increases in the incidence of lung adenomas

in animals treated with HCS and of all lung tumours in animals treated with both LCS and HCS. There was also a significant increase in the occurrence of nasal cavity tumours in female rats treated with HCS (Mauderly *et al.*, 2004).

3.1.3 Hamster

Four studies have evaluated the ability of mainstream tobacco smoke to induce tumours in hamsters (Table 3.1). Syrian golden hamsters were exposed to either a mixture of German reference cigarette smoke or of dark air-cured cigarette smoke for lifetime. There were increases in the incidence of laryngeal carcinomas in hamsters exposed to both smoke preparations (Dontenwill *et al.*, 1973). In a subsequent study, hamsters were exposed to a mixture of German reference cigarette smoke containing 1.5 mg nicotine, 0.173 mg phenol and 12.7 mL carbon monoxide/cigarette for lifetime. The incidence of laryngeal tumours in smoke-exposed hamsters was higher than in controls (Dontenwill *et al.*, 1977). BIO male hamsters exposed to a mixture of US reference smoke for 100 weeks developed laryngeal and nasopharyngeal tumours (Bernfeld *et al.*, 1974). In a subsequent study, male BIO hamsters exposed to smoke from commercial British filter cigarettes developed higher incidence of laryngeal tumours than controls (Bernfeld *et al.*, 1979).

3.2 Co-administration of tobacco smoke with known carcinogens and other agents

Study design and results of the studies on co-administration of tobacco smoke with known carcinogens and other agents are summarized in Table 3.2.

3.2.1 Rat

(a) Benzo[a]pyrene

Wistar rats received a single intratracheal instillation of 2 mg benzo[*a*]pyrene followed by lifetime exposure to cigarette smoke. This treatment led to a low incidence of lung tumours that was not significantly higher than in controls (Davis *et al.*, 1975). In another study Wistar rats were given intratracheal instillations of benzo[*a*]pyrene mixed with ferric oxide and exposed to cigarette smoke either during initiation and post-initiation or only after treatment with benzo[*a*]pyrene/ferric oxide (post-initiation). Inhalation of cigarette smoke during the initiation and post-initiation phases of carcinogenesis resulted in a higher lung tumour (squamous-cell carcinoma) multiplicity than that seen in rats exposed during the post-initiation phase only (Gupta *et al.*, 1990).

(b) Radon progeny

Sprague-Dawley rats were exposed to radon progeny at cumulative doses of 4000, 500 or 100 work-level-months (WLM), with or without concurrent exposure to cigarette smoke by inhalation for one year. Rats exposed to 4000 WLM radon progeny, without exposure to smoke, developed lung carcinomas (17/50). Thirty four carcinomas were seen in 50 rats exposed to radon and cigarette smoke. The 500 WLM radon progeny group exposed to radon only had 2/28 lung carcinomas as compared with 8/30 rats exposed to radon and cigarette smoke. No tumours were observed in rats treated with 100 WLM radon and one carcinoma was seen among 30 rats exposed to 100 WLM radon and cigarette smoke. Seventy five percent of the lung tumours were squamous-cell carcinomas, 20% were adenocarcinomas, and the remainder were undifferentiated carcinomas (Chameaud *et al.*, 1982).

Table 3.1 Carcinogenicity in response to mainstream tobacco smoke in animals

Species, strain (sex) Reference	Animals/group at start Dosing regimen Duration	Lung burden	Results Target organ Incidence and/or multiplicity of tumours (%)	Significance	Comments

Syrian golden, (sex NR) Hoffmann *et al.* (1979)	20 or 40 animals/group Cigarette smoke/air (1/7); Cigarette smoke 2 × 10 min/d, 5 d/wk, 48 wk DMBA (0.24 mg); intralaryngeally	3/40 (7%, laryngeal C), 0/20 (smoke only), 0/20 (DMBA alone)	
Syrian golden (M) Takahashi *et al.* (1992)	10 or 30 animals/group Cigarette smoke/air (1/7); Smoke of 30 cigarettes for 9 min; twice/d, 5 d/wk, 12 wk NDEA (100 mg/kg bw); subcutaneously	Non-filter cigarettes (2.10 ± 1.74 P+H/animal) and filter cigarettes (1.93 ± 1.55 P + H/animal) versus sham-exposed (0.97 ± 1.03 P + H/animal)	$P < 0.01$ $P < 0.01$
Syrian golden (M) Harada *et al.* (1985)	30 animals/group Non-filter cigarette smoke/air (1/7); Smoke of 30 cigarettes for 6 min: twice/d, 5 d/wk, 58 wk NDEA (10 mg/hamster); subcutaneously (12 weekly doses)	Nasal cavity tumours 14/30 (47%, smoke + NDEA), 5/30 (17%, NDEA alone)	$P < 0.05$

A, adenoma; bw, body weight; C, carcinoma; d, day or days; DMBA, 7,12-dimethylbenz[*a*]anthracene; F, female; h, hour or hours; HCS, high cigarette smoke; LCS, low cigarette smoke; M, male; min, minute or minutes; mo, month or months; NDEA, *N*-nitrosodiethylamine; NR, not reported; NS, not significant; P + H, epithelial hyperplasias and papillomas; sec, second or seconds; wk, week or weeks; WLM, work-level-months; yr, year or years

(c) Plutonium oxide

CDF®/CrlBR rats were exposed to either filtered air or mainstream cigarette smoke at concentrations of either 100 or 250 mg total particulate matter/m^3 (LCS and HCS groups, respectively). At 12 weeks, rats were removed from smoke chambers and exposed nose-only to plutonium oxide ($^{239}PuO_2$) then returned to the smoke chambers one week later for 30 months of continuous exposure to either filtered air or cigarette smoke. The incidence and multiplicity of lung tumours (adenocarcinomas, squamous-cell carcinomas, adenosquamous carcinomas) in animals exposed to both concentrations of cigarette smoke and $^{239}PuO_2$ were higher than those in animals exposed to $^{239}PuO_2$, LCS or HCS alone (Finch *et al.*, 1995).

3.2.2 Hamster

(a) 7,12-Dimethylbenz[a]anthracene

Groups of 160 Syrian golden hamsters received 7,12-dimethylbenz[*a*]anthracene (DMBA) intratracheally, followed by cigarette smoke for life, or treated with cigarette smoke or DMBA only. A total of 32 squamous-cell carcinomas of the larynx were observed in animals treated with both DMBA and cigarette smoke, in comparison with 17 in hamsters exposed to cigarette smoke only and none in hamsters treated with DMBA alone (Dontenwill *et al.*, 1973). Similar results were reported from other experiments in which Syrian golden hamsters were exposed to DMBA and cigarette smoke (Hoffmann *et al.*, 1979).

(b) N-Nitrosodiethylamine

Groups of hamsters received a single subcutaneous injection of *N*-nitrosodiethylamine (NDEA) and then were exposed to smoke from unfiltered cigarettes, filtered cigarettes and sham smoke. Controls were exposed to either unfiltered cigarette smoke, filtered cigarette smoke or sham smoke. In the NDEA-smoke-treated groups, epithelial hyperplasias and/or papillomas of the larynx were induced at higher frequency than in controls (Takahashi *et al.*, 1992). Hamsters exposed to cigarette smoke in air also received 12 weekly subcutaneous injections of NDEA (total dose, 10 mg/hamster). Treatment with NDEA only resulted in both benign and malignant tumours of the respiratory tract, and co-exposure to cigarette smoke potentiated the development of tumours in the nasal cavity (Harada *et al.*, 1985).

3.3 Smoke condensates

Study design and results of the studies on administration of tobacco smoke condensates are summarized in Table 3.3.

3.3.1 Skin application

(a) Mouse

Cigarette-smoke condensate produces both benign and malignant tumours on mouse skin. The carcinogenic potency of the cigarette-smoke condensate depends upon tobacco variety, composition of cigarette paper and the presence of additives (Wynder *et al.*, 1957; Gargus *et al.*, 1976; Gori, 1976).

(b) Rabbit

Cigarette-smoke condensate induced skin papillomas and carcinomas when applied to the ears of rabbits for lifetime (Graham *et al.*, 1957).

3.3.2 Intrapulmonary administration

Injection of 24 mg cigarette-smoke condensate into the lungs of female Osborne Mendel rats led to the development of squamous cell carcinomas (Stanton *et al.*, 1972). These observations were confirmed by Dagle *et al.* (1978) who observed a dose-dependent incidence of lung carcinomas when cigarette-smoke condensate prepared from two types of cigarettes were given.

Table 3.3 Carcinogenicity in response to exposure to cigarette-smoke condensate in animals

Species, strain (sex) Reference	Animals/group at start Dosing regimen Duration	Results Target organ Incidence and/or multiplicity of tumours (%)	Significance
Mice CAF1 (M, F) Wynder *et al.* (1953)	112, 44 controls Skin painting (dorsal) of CSC, CSC/acetone solution (40 mg CSC/ application), 3 × /wk, lifetime	36/81 (44%, skin epidermoid C), 0/30 (acetone controls)	
Mice ICR Swiss (F) Gargus *et al.* (1976)	5200 Skin painting (dorsal) of CSC, CSC/acetone solution (150 mg or 300 mg CSC/wk), 6 × /wk, 78 wk	482/5200 (9%, skin C), 3/800 (0.4%, acetone controls)[a]	
Mice ICR Swiss (F) Gori (1976)	4900 Skin painting (dorsal) of CSC, CSC/acetone solution (25 mg or 50 mg CSC/application), 6 × /wk, 78 wk	1157/4900 (24%, skin C), 0/800 (acetone controls)	
Mice, ICR/Ha Swiss (F) Hoffmann & Wynder (1971)	30 animals/group Skin painting (dorsal) with CSC active fraction with or without subsequent painting of the skin with croton oil, CSC active fraction/acetone (2.5 mg of 0.6% CSC/application), 10 times on alternate d Croton oil (2.5%), 3 × /wk, up to 12 mo, 10 d after last CSC active fraction application; 15 mo	After 12 and 15 mo: 4/30 (13%, skin C), 0/65 (croton oil controls)	
Mice, Swiss (F) Wynder & Hoffmann (1961)	30–50 animals/group Skin painting (dorsal) of CSC with or without initiation by DMBA application; DMBA (75 µg); CSC/acetone (75 mg CSC/application, start: 1 wk after DMBA application), 2–3 × /wk, 12 mo; 15 mo	DMBA: 2/30 (7%, skin C) 2 × CSC: 1/40 (3%, skin C) DMBA + 2 × CSC: 8/30 (27%, skin C) 3 × CSC: 11/50 (22%, skin C) DMBA + 3 × CSC: 11/30 (37%, skin C)	
Mice, SENCAR (F) Meckley *et al.* (2004a)	40 animals/group Skin painting (dorsal) of CSC from Kentucky 1R4F reference cigarettes, with or without initiation by DMBA application; DMBA (75 µg) or acetone, 1x. Then starting 1 wk after DMBA or acetone: CSC in acetone, 0, 10, 20 or 40 mg/application, 3 × /wk, 29 wk; 31 wk	Mean mice with tumours/mice per group at 31 wk[e]: No DMBA: 0/40 acetone-acetone, 9/40 (22%) acetone-CSC 40 mg/treatment DMBA/CSC: 0/40, 3/40 (1.0), 16/40 (75 tumours/16 mice = 4.7), 32/40 (200 tumours/32 mice = 6.3)	
Mice, SENCAR (F) Meckley *et al.* (2004b)	40 animals/group Skin painting (dorsal) of CSC from Kentucky 1R4F reference cigarettes or ECLIPSE (non-burned) cigarettes, with or without initiation by DMBA application; DMBA (75 µg) or acetone, 1 × . Then starting 1 wk after DMBA or acetone: CSC in acetone, 0, 10, 20 or 40 mg/application, 3 × /wk, 29 wk; 31 wk	No DMBA: acetone/acetone 0/40 (0); acetone/1R4F CSC 40 mg, 9/40 (1.8); acetone/ECLIPSE CSC 40 mg, 0/40 (0) DMBA/CSC: acetone, 0/40 (0); 1R4F CSC 10 mg, 6/40 (1.8); 1R4F CSC 12 mg, 28/40 (6.6); 1R4F CSC 40 mg, 36/40 (6.8); ECLIPSE CSC, 0/40 (0); ECLIPSE CSC 10 mg, 1/40 (1); ECLIPSE CSC 20 mg, 2/40 (5.5); ECLIPSE CSC 40 mg, 12/40 (2.6)	

Table 3.3 (continued)

Species, strain (sex) Reference	Animals/group at start Dosing regimen Duration	Results Target organ Incidence and/or multiplicity of tumours (%)	Significance
Mice, SENCAR (F) Hayes *et al.* (2007)	40 or 50 animals/group Skin painting (dorsal) of CSC from heat-exchanged flue cured tobacco (HE; low TSNA) or direct-fire (DF) cured tobacco, with or without initiation by DMBA application; DMBA (75 µg) or acetone, 1 × . Then starting 1 wk after DMBA or acetone: CSC/acetone, 0, 9, 18, or 36 mg/application, 3 × /wk, 29 wk; 31 wk	No DMBA: acetone/acetone 0/40; acetone/DF CSC 36 mg, 5/50 (1.4); acetone/HE CSC 36 mg, 8/50 (1.3) DMBA/CSC: DF CSC, 0/40, DF CSC 9 mg, 15/40 (5.5); DF CSC 18 mg, 30/40 (10.0); DF CSC 36 mg, 43/50 (8.2); HE CSC, 0/40, HE CSC 9 mg, 17/40 (4.8); HE CSC 18 mg, 32/40 (7.3); HE CSC 36 mg, 42/50 (8.5)	$P < 0.05$ $P < 0.05$ $P < 0.05$
Mice, Swiss albino (M) Pakhale *et al.* (1988)	20 animals/group Oral gavage of Indian bidi smoke condensate; 1 mg bidi smoke condensate/0.1 mg DMSO, 5 d/wk, 55 wk; 90 wk	4/15 (27%, hepatic haemangiomas); 1/15 (7%, stomach papilloma); 1/15 (7%, stomach carcinoma); 1/15 (7%, oesophageal carcinoma); 0/15 (untreated or DMSO-treated controls)	
Rats, Osborne Mendel (F) Stanton *et al.* (1972)	Number/group at start (NR) Intrapulmonary administration of CSC pellet; CSC/beeswax:tricaprylin (24 mg CSC/injection), up to 107 wk after implantation	14/40[c] (35%, lung squamous-cell C), 0/63[c] (beeswax:tricaprylin controls)	
Rats, OM/NCR (F) Dagle *et al.* (1978)	120[d] Intrapulmonary administration of CSC pellet; CSC/beeswax:tricaprylin (5, 10, 20 or 67 mg CSC/injection), 120 wk after implantation	4, 10, 20 and 42% pulmonary C prevalence; 0% C prevalence for 3 control groups of about 190 rats each	
Rabbits, Albino New Zealand (M, F) Graham *et al.* (1957)	38, 7 controls Skin painting of CSC (both ears); CSC/acetone solution (100 mg CSC/application/ear), 5 × /wk, lifetime (4–6 yr)	4/38 (11%, 2 skin C + 1 skin liposarcoma + 1 skin fibrosarcoma), 0/7 (acetone controls)	

[a] Skin papillomas
[b] Mostly adenomas
[c] Incidence in animals that died 43–107 weeks after injection
[d] 4 × 10 rats/group terminated before 120 weeks
[e] Total visually identified and histologically confirmed skin tumours included mostly squamous papillomas and carcinomas [Tumour incidences and multiplicities estimated from graphs]
C, carcinoma; CSC, cigarette-smoke condensate; d, day or days; DMBA, 7,12-dimethylbenz[*a*]anthracene; DMSO, dimethyl sulfoxide; F, female; M, male; NR, not reported; TSNA, tobacco-specific *N*-nitrosamines; wk, week or weeks

3.3.3 Initiation-promotion skin painting studies

Cigarette-smoke condensate and its fractions can act as skin co-carcinogens in Swiss and SENCAR mice when tested in conjunction with croton oil (Hoffmann & Wynder, 1971) or DMBA (Wynder & Hoffmann, 1961; Meckley *et al.*, 2004a, b; Hayes *et al.*, 2007).

3.3.4 Bidi smoke

Swiss albino mice administered 1 mg bidi smoke condensate in dimethyl sulfoxide (DMSO) by oral gavage developed haemangiomas (4/15), stomach carcinoma (1/15), and esophageal carcinoma (1/15), whereas no tumours were observed in controls (Pakhale *et al.*, 1988).

3.4 Synthesis

Mainstream tobacco smoke induced lung tumours in mice, lung and nasal cavity tumours in rats and laryngeal carcinomas in hamsters.

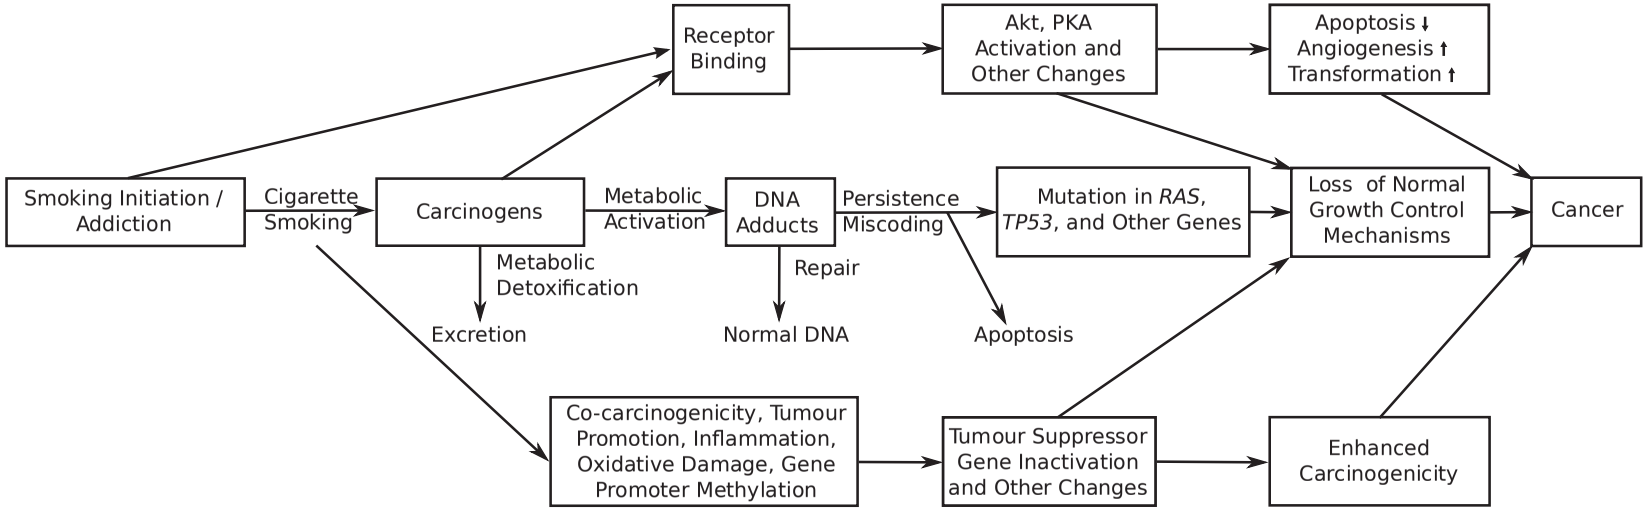
Co-administration of tobacco smoke with benzo[*a*]pyrene, radon progeny and plutonium resulted in higher lung tumour responses in rats than administration of either agent alone. Hamsters exposed to cigarette smoke and either DMBA or NDEA had higher lung tumour responses compared to cigarette smoke, DMBA or NDEA alone.

Topical application of cigarette-smoke condensate led to the development of skin tumours in mice and rabbits; intrapulmonary administration of cigarette-smoke condensate induced squamous cell carcinomas in rat lung.

4. Other Relevant Data

4.1 Overview of the mechanistic evidence for the carcinogenicity of tobacco

4.1.1 Conceptual model of the carcinogenesis of tobacco and tobacco smoke



A conceptual model for understanding mechanisms by which tobacco smoke causes cancer is shown in Fig. 4.1 (Hecht, 1999, 2003). This model also applies to smokeless tobacco and other forms of smoked tobacco and, in theory, to second-hand tobacco smoke since it contains all of the same carcinogens and toxicants as mainstream cigarette smoke, although at lower doses.

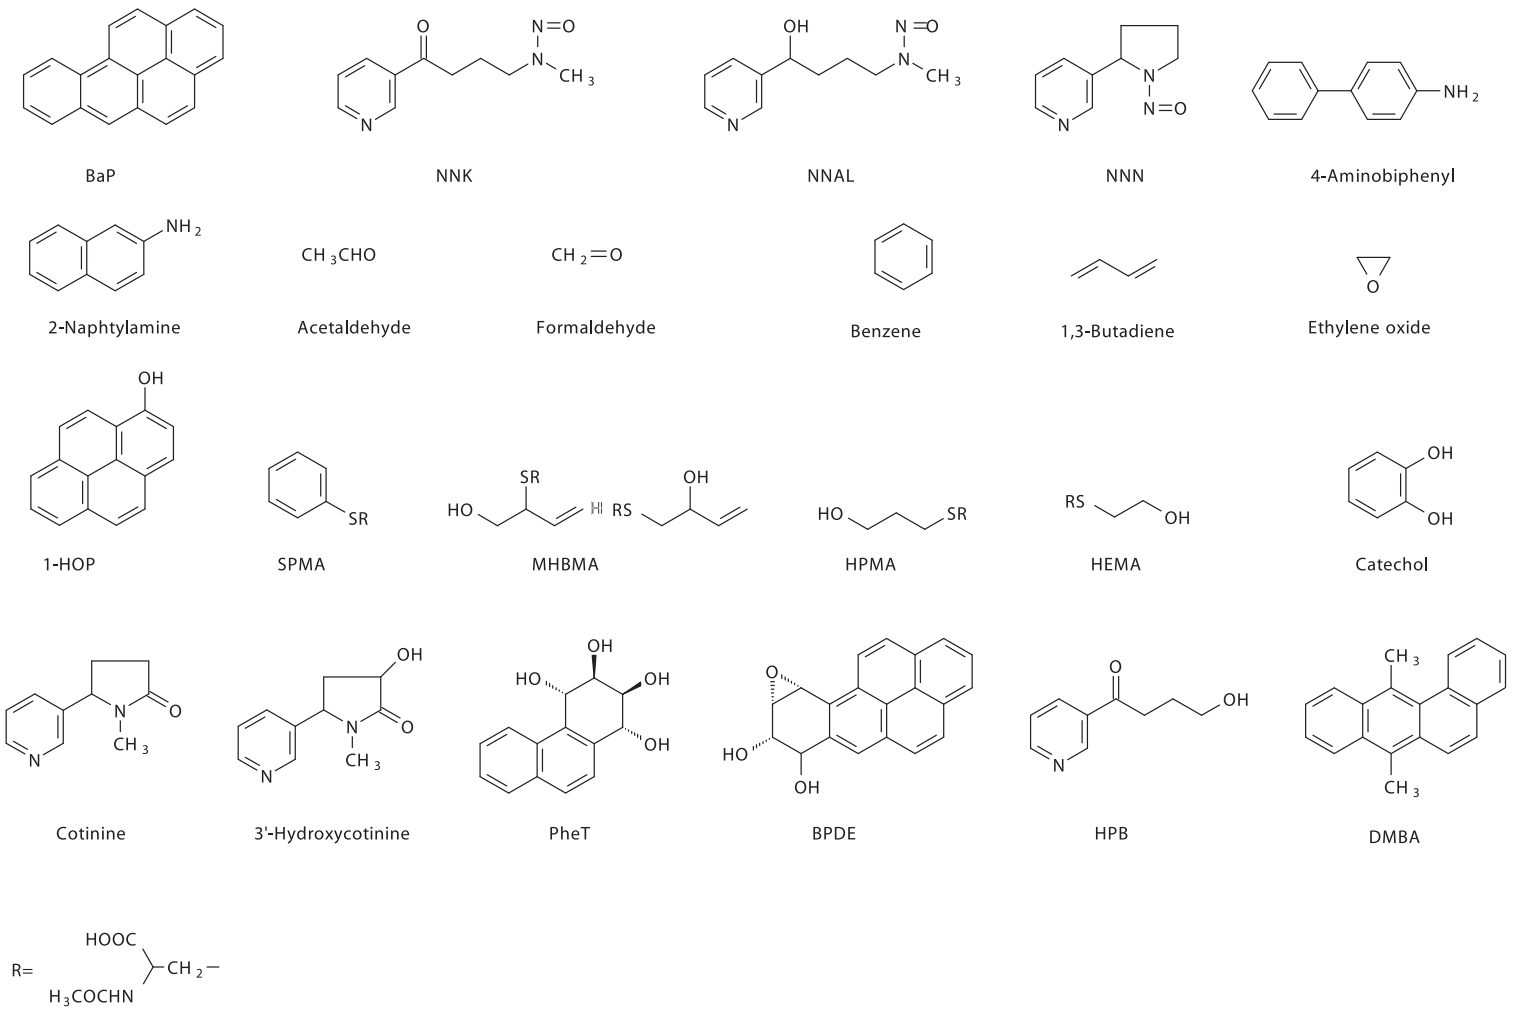
The major accepted mechanistic pathway is summarized in the central track of Fig. 4.1. Smokers inhale carcinogens which, either directly or after metabolism, covalently bind to DNA, forming DNA adducts. DNA adducts are central to chemical carcinogenesis because they can cause miscoding and permanent mutations. If these mutations occur in critical regions of oncogenes and tumour suppressor genes, which are essential in growth control, the result can be loss of normal cellular proliferation mechanisms, genomic instability, and cancer. A study that sequenced 623 cancer-related genes in 188 human lung adenocarcinomas validated this premise by finding multiple somatic mutations in critical growth control genes, consistent with the chronic bombardment of cellular DNA by tobacco smoke carcinogens and their metabolically activated forms (Ding *et al.*, 2008).

Each step of this conceptual model is considered in detail below.

Most people begin smoking cigarettes when they are teenagers, and become addicted to nicotine. Nicotine is not generally considered to be a carcinogen (Schuller, 2009), but it is accompanied in each puff of each cigarette by a complex

Fig. 4.1 Conceptual model for understanding mechanisms of tobacco carcinogenesis

There may be overlap between these three tracks: e.g. mutation in *TP53* leading to tumour suppressor gene inactivation.



mixture of carcinogens and toxicants. There are over 60 carcinogens in cigarette smoke that have been evaluated in the previous *IARC Monograph* as having *sufficient evidence* for carcinogenicity in laboratory animals (IARC, 2004a), sixteen of which are considered to be *carcinogenic to humans (Group 1)*. There are also many other carcinogens and potential carcinogens in cigarette smoke that have not been evaluated (Rodgman & Perfetti, 2006; see Section 1.1). Structures of tobacco smoke constituents and biomarkers discussed here are presented in Fig. 4.2.

Numerous studies demonstrate the uptake of tobacco smoke carcinogens and toxicants by smokers, and showed higher levels of their metabolites in urine and blood of smokers than non-smokers (Sections 4.1.1 and 4.1.2). There are substantial differences in carcinogen exposure among people because of the number and types of cigarettes they smoke and the ways in which they smoke them. These differences can be monitored in part by biomarkers of exposure such as urinary metabolites or haemoglobin adducts (Section 4.1.2). Haemoglobin adducts of multiple aromatic amines and volatile carcinogens have been demonstrably related to tobacco (Hatsukami *et al.*, 2006a). There may also be differences in carcinogen exposure due to genetic variations (Section 4.2).

The body's response to cigarette smoke constituents is similar to its response to pharmaceutical agents and other foreign compounds. Drug metabolizing enzymes, most frequently CYPs, convert these compounds to more water soluble forms, facilitating excretion. During this natural protective attempt, some reactive intermediates are formed. These intermediates are frequently electrophilic (electron seeking, or bearing a partial or full positive charge). Electrophilic intermediates may react with water, generally resulting in detoxification, or may covalently bind to nucleophilic (electron rich) sites in DNA, forming DNA adducts (Guengerich, 2001; Jalas *et al.*, 2005), which are critical in the carcinogenic process (see Section 4.1.3c). CYP1A1 and CYP1B1, repeatedly shown to be inducible by cigarette smoke via interactions of smoke compounds with the aryl hydrocarbon receptor (AhR), are particularly important in the metabolic activation of PAHs, while CYP2A13 is critical for the metabolism of NNK (Nebert *et al.*, 2004; Jalas *et al.*, 2005). The inducibility of certain CYPs may be a critical aspect of cancer susceptibility in smokers (Nebert *et al.*, 2004). CYP1A2, CYP2A6, CYP2E1 and CYP3A4 are also important in the metabolism of cigarette smoke carcinogens to DNA binding intermediates (Jalas *et al.*, 2005), and aldo-keto reductase enzymes, also induced by tobacco smoke (Quinn *et al.*, 2008), are involved in the metabolism of NNK, BaP and other tobacco smoke carcinogens. Competing with this process of "metabolic activation" resulting in DNA binding is the intended metabolic detoxification, which leads to harmless excretion of carcinogen metabolites, and is also catalysed by CYPs and a variety of other enzymes including GSTs, uridine diphosphate-glucuronosyl transferases (UGTs), and arylsulfatases. The relative amounts of carcinogen metabolic activation and detoxification differ among individuals. It is widely hypothesized that this balance will affect cancer risk with those having higher activation and lower detoxification capacity being the most susceptible. This premise is supported in part by molecular epidemiologic studies of polymorphisms, or variants in more than 1% of the population, in certain genes coding for these enzymes (Vineis *et al.*, 2003; Carlsten *et al.*, 2008).

DNA adducts are thought to be a critical lesion in carcinogenesis. Many investigations demonstrate the presence of DNA adducts in human tissues, and some of these are summarized in Section 4.1.2c. There is massive evidence, particularly from studies which use relatively non-specific DNA adduct measurement methods, that DNA adduct levels in the lung and other tissues of smokers are higher than in non-smokers, and some epidemiologic data link

Fig. 4.2 Structures of compounds discussed in the text

BaP, Benzo[*a*]pyrene; BPDE, Benzo[*a*]pyrene diol epoxyde; DMBA, dimethylbenz[*a*]anthracene; 1-HOP, 1-hydroxypyrene; HEMA, 2-hydroxyethyl-mercapturic acid; HPMA, 3-hydroxypropyl-mercapturic acid; HPB, 4-hydroxy-1-(3-pyridyl)-1-butanone; HPMA, 3-hydroxypropyl-mercapturic acid; MHBMA, monohydroxybutyl-mercapturic acid; NNAL, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol; NNK, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone; NNN, *N*'-nitrosonornicotine; PheT, phenanthrenetetrol; SPMA, S-phenyl-mercapturic acid

these higher adduct levels to increased cancer risk (IARC, 2004b; Veglia *et al.*, 2008). However, there is much more limited evidence from studies using specific carcinogen-derived DNA adducts as biomarkers (Pfeifer *et al.*, 2002). Oxidative DNA damage has also been observed, and this may result partially from exposure to metals in cigarette smoke (Stavrides, 2006).

Cellular DNA repair systems can excise DNA adducts and restore normal DNA structure (Christmann *et al.*, 2003). These complex multiple systems include direct base repair by alkyltransferases, removal of DNA damage by base and nucleotide excision repair, mismatch repair, and double strand repair. If these DNA repair systems are unsuccessful in fixing the damage, then the DNA adducts can persist, increasing the probability of a permanent mutation. There are polymorphisms in genes coding for some DNA repair enzymes. If these variants lead to deficient DNA repair, the probability of cancer development can increase (Vineis *et al.*, 2009).

DNA adducts can cause miscoding during replication when DNA polymerase enzymes misread the DNA adduct and consequently insert the wrong base opposite to it. There is some specificity in the relationship between specific DNA adducts formed from cigarette smoke carcinogens and the types of mutations which they cause. G to T and G to A mutations have often been observed (Section 4.1.3) (Hecht, 1999). Extensive studies have characterized the mutations which occur because of specific carcinogen-DNA adducts (Delaney & Essigmann, 2008). Mutations have been reported in the *KRAS* oncogene in lung cancer and in the *TP53* tumour suppressor gene in a variety of cigarette smoke-induced cancers (Ahrendt *et al.*, 2001; Pfeifer *et al.*, 2002; Ding *et al.*, 2008). The cancer causing role of these genes has been firmly established in animal studies (Lubet *et al.*, 2000; Johnson *et al.*, 2001). A selection and promotion process may also play a role in the final mutation spectrum seen in genes in smoking-associated tumours (Rodin & Rodin, 2005; Sudo *et al.*, 2008).

Urinary mutagenicity, sister chromatid exchanges, micronuclei in buccal cells, and other genetic effects have been consistently observed in smokers at higher levels than in non-smokers (IARC, 2004a; Proia *et al.*, 2006). In addition to mutations, numerous cytogenetic changes are observed in lung cancer, and chromosome damage throughout the field of the aerodigestive tract is strongly associated with cigarette smoke exposure. Mutations resulting from DNA adducts can cause loss of normal cellular growth control functions, via a complex process of signal transduction pathways, ultimately resulting in genomic instability, cellular proliferation and cancer (Ding *et al.*, 2008). Apoptosis, or programmed cell death, is a protective process, and can remove cells which have DNA damage, thus serving as a counterbalance to these mutational events. The balance between apoptotic mechanisms and those suppressing apoptosis will have a major impact on tumour growth.

While the central track of Fig. 4.1 is the major pathway by which tobacco smoke carcinogens cause cancer, other mechanisms also contribute, as indicated in the top and bottom tracks (Hecht, 2003). Nicotine, NNK, and NNN bind to nicotinic and other cellular receptors, resulting in activation of serine/threonine kinase Akt (also known as protein kinase B), protein kinase A, and other changes. Nicotine and NNK increase expression of survivin, an inhibitor of apoptosis in normal human bronchial epithelial cells, and survivin mRNA is detected in bronchial brush samples from heavy smokers (Jin *et al.*, 2008). This can cause decreased apoptosis, increased angiogenesis, and increased transformation (Heeschen *et al.*, 2001; West *et al.*, 2003). Thus, although nicotine is not carcinogenic, it may enhance carcinogenicity in various ways (Schuller, 2009). Cigarette smoke also contains well established oxidants, co-carcinogens, tumour promoting fractions, and inflammatory agents, as well as

cilia-toxic compounds such as acrolein, which impede clearance. Many studies demonstrate the co-carcinogenic and cytotoxic effects of catechol, an important constituent of cigarette smoke. An epigenetic pathway frequently observed in tobacco-induced cancers is enzymatic methylation of promoter regions of genes such as *p16* and *FHIT* [fragile histidine triad gene, a gene coding for a dinucleoside 5′, 5‴- P^1, P^3-triphosphate hydrolase, a putative tumour suppressor protein] resulting in gene silencing, which are also strongly implicated in tobacco-induced lung cancer (D'Agostini *et al.*, 2006; Bhutani *et al.*, 2008). When this occurs in tumour suppressor genes, the result can be unregulated proliferation (Belinsky, 2005). Inflammation due to smoking is associated with tumour promotion and activation of factors such as NFκB. Inflammation also plays a role in chronic obstructive pulmonary disease (COPD), which in turn is an independent risk factor for lung cancer (Smith *et al.*, 2006; Turner *et al.*, 2007; Lee *et al.*, 2008a).

This conceptual model can be applied to smokeless tobacco products. Smokeless tobacco products have much lower levels of carcinogens and toxicants that result from combustion, so the effects of these agents are not seen to a significant extent. The most prevalent strong carcinogens in smokeless tobacco are the tobacco-specific nitrosamines; other nitrosamines, PAHs, aldehydes and metals are also present, and there are large amounts of some inorganic salts that may contribute to inflammation (IARC, 2007a; Stepanov *et al.*, 2008). An additional factor in carcinogenesis by betel quid with tobacco is the basic pH resulting from addition of slaked lime to the quid, leading to oxidative damage and inflammation (IARC, 2004b).

Multiple studies demonstrate that tobacco-specific nitrosamines are absorbed and metabolised in smokeless tobacco users (IARC, 2007a).

There is evidence for DNA adduct formation in oral tissues of smokeless tobacco users, and sister chromatid exchanges, chromosomal aberrations, and micronuclei – consequences of DNA adduct formation – have been reported (Proia *et al.*, 2006; Warnakulasuriya & Ralhan, 2007). Many studies have demonstrated *RAS* and *TP53* mutations in smokeless tobacco users (Warnakulasuriya & Ralhan, 2007) consistent with the conceptual framework.

Oxidative stress and reactive oxygen species could play a significant role in cancer induction in smokeless tobacco users, particularly at high pH (Boffetta *et al.*, 2008). Chronic local inflammation and irritation induced by smokeless tobacco and its constituents could have a tumour promoting or co-carcinogenic effect (Boffetta *et al.*, 2008). Upregulation of cyclooxygenase-2, involved in prostaglandin synthesis and inflammation, has been observed in animal studies upon exposure to smokeless tobacco (Boffetta *et al.*, 2008). Smokeless tobacco products have relatively high levels of sodium chloride (NaCl), which could contribute to inflammation, tumour promotion, and co-carcinogenesis. Cancer of the oral cavity is strongly associated with tobacco smoking (IARC, 2004a) or chewing (IARC, 2007a) and alcoholic beverage drinking (IARC, 2010a) However only a fraction of exposed subjects develop tumours, which suggests that other exposures such as HPV may be independently involved or act as cofactors. HPV is known to infect the oral cavity of healthy individuals and several HPV-related lesions have been characterized (IARC, 2007b). Herpes simplex virus has also been shown to enhance the carcinogenicity of smokeless tobacco products in animal studies (Park *et al.*, 1986). These factors may contribute significantly to the local carcinogenic effects characteristic of smokeless tobacco use.

4.1.2 *Absorption, distribution, metabolism and excretion*

There are examples of toxicant and carcinogen metabolism and excretion for representatives of virtually every major class of compounds;

some of these are summarized in Table 4.1. Nicotine and five of its urinary metabolites – cotinine, 3′-hydroxycotinine and their glucuronides, and nicotine glucuronide – comprise about 73–96% of the nicotine dose (Hukkanen *et al.*, 2005), and are found in blood, sweat, hair and toenails (Al Delaimy, 2002; Hukkanen *et al.*, 2005; Stepanov *et al.*, 2007; Al Delaimy & Willett, 2008). Metabolites of various polycyclic aromatic hydrocarbons including pyrene, phenanthrene, fluorene, and benzo[*a*]pyrene have been quantified in human urine and are higher in smokers than in non-smokers (Hecht, 2002; Hecht *et al.*, 2005a; Jacob *et al.*, 2007; Hansen *et al.*, 2008). Metabolites of tobacco-specific nitrosamines – NNAL and its glucuronides (total NNAL) from NNK; and NNN and its glucuronides (total NNN) from NNN – are present in human urine (Hecht, 2002; Stepanov & Hecht, 2005; Hecht *et al.*, 2008a; Stepanov *et al.*, 2008). Total NNAL has also been quantified in blood and toenails (Hecht *et al.*, 2002; Stepanov *et al.*, 2007). Aromatic amine-haemoglobin adducts have been frequently measured in human blood, and their levels increase with smoking (Hecht, 2002; Hatsukami *et al.*, 2006a). Mercapturic acids of several tobacco smoke compounds such as benzene, 1,3-butadiene, acrolein, and ethylene oxide are present in human urine and are related to smoking (Carmella *et al.*, 2009). Haemoglobin adducts of acrylonitrile and related compounds are elevated in smokers' blood, and levels of metals such as Cd are increased in smokers' urine (Carmella *et al.*, 2002; IARC, 2004b).

All of the metabolites listed in Table 4.1 are elevated in cigarette smokers; in studies of second-hand smoke exposure, only nicotine metabolites and urinary total NNAL are consistently increased in exposed versus non-exposed subjects, although one very large study also observed an increase in PAH metabolites (Pirkle *et al.*, 2006; Hecht, 2008; Suwan-ampai *et al.*, 2009). Smokeless tobacco users have significantly raised levels of nicotine metabolites and tobacco-specific nitrosamine metabolites compared to non-tobacco users (Hecht *et al.*, 2007).

4.1.3 Biomarkers

Tobacco carcinogen biomarkers are quantifiable entities that can be *specifically* related to tobacco carcinogens. Specificity to a given carcinogen is critical because tobacco carcinogens vary widely in their potency and target organs.

Considering the mechanistic framework outlined in Fig. 4.1, one could visualize various types of biomarkers. Currently, biomarkers of carcinogen/toxicant dose, reflecting the second box of the central track of Fig. 4.1, are by far the most extensively used and validated. The second most common are measurements of DNA adducts (or protein adducts as their surrogates), but fewer of these have both practical utility and validation with respect to tobacco carcinogen specificity.

The use of tobacco carcinogen biomarkers bypasses many uncertainties in estimation of dose. The most commonly used estimation of dose is self-reported number of cigarettes/day, but this is not a very good marker. It may not be reported accurately and it provides no information on the way in which the cigarettes were smoked, which is critical when one considers the common phenomenon of smoker's compensation. Brand information together with machine smoking measurements of specific components is another way of obtaining a measure of dose. However, machine smoking measurements are known to have limitations and the application of a given machine smoking protocol to a given smoker requires smoking topography measurements for that smoker. A disadvantage of tobacco carcinogen biomarkers is that they are affected to some extent by individual differences in metabolism, which may complicate interpretation of dose.

Table 4.1 Examples of toxicant or carcinogen metabolites in tobacco users

Toxicant or carcinogen	Examples of metabolites in tobacco users	References
Nicotine	Cotinine, 3′-hydroxycotinine and their glucuronides in urine, blood or saliva; nicotine and cotinine in toenails	Al Delaimy (2002), Hukkanen *et al.* (2005), Al Delaimy & Willett (2008), Stepanov *et al.* (2007)
Polycyclic Aromatic Hydrocarbons (PAHs)	1-hydroxypyrene, phenanthrols, phenanthrene tetraols, fluorenols, benzo[*a*]pyrenols, benzo[*a*]pyrene tetraols in urine	Hecht (2002), Hecht *et al.* (2005a), Hansen *et al.* (2008), Jacob *et al.* (2007)
Tobacco-specific nitrosamines	NNAL and its glucuronides (total NNAL) in urine or blood, total NNN in urine; NNAL and NNN in toenails	Hecht (2002), Hecht *et al.* (2002, 2008a), Stepanov & Hecht (2005), Stepanov *et al.*, (2007, 2008)
Aromatic amines	Parent amines in urine and haemoglobin adducts in blood	Hecht (2002), Hatsukami *et al.* (2006a)
Volatile hydrocarbons		
Benzene 1,3-Butadiene	Muconic acid and S-phenyl-mercapturic acid (SPMA) in urine; Monohydroxybutyl-mercapturic acid (MHBMA) in urine	Hecht (2002), Carmella *et al.* (2009)
Acrolein	3-hydroxypropyl-mercapturic acid (HPMA) in urine	Carmella *et al.* (2009)
Ethylene oxide	2-hydroxyethyl-mercapturic acid (HEMA) in urine, haemoglobin adducts in blood	Bono *et al.* (2002), Carmella *et al.* (2009)
Acrylonitrile	Haemoglobin adducts in blood	Carmella *et al.* (2002)
Metals	Cadmium in urine	IARC (2004a)

(a) Urinary biomarkers

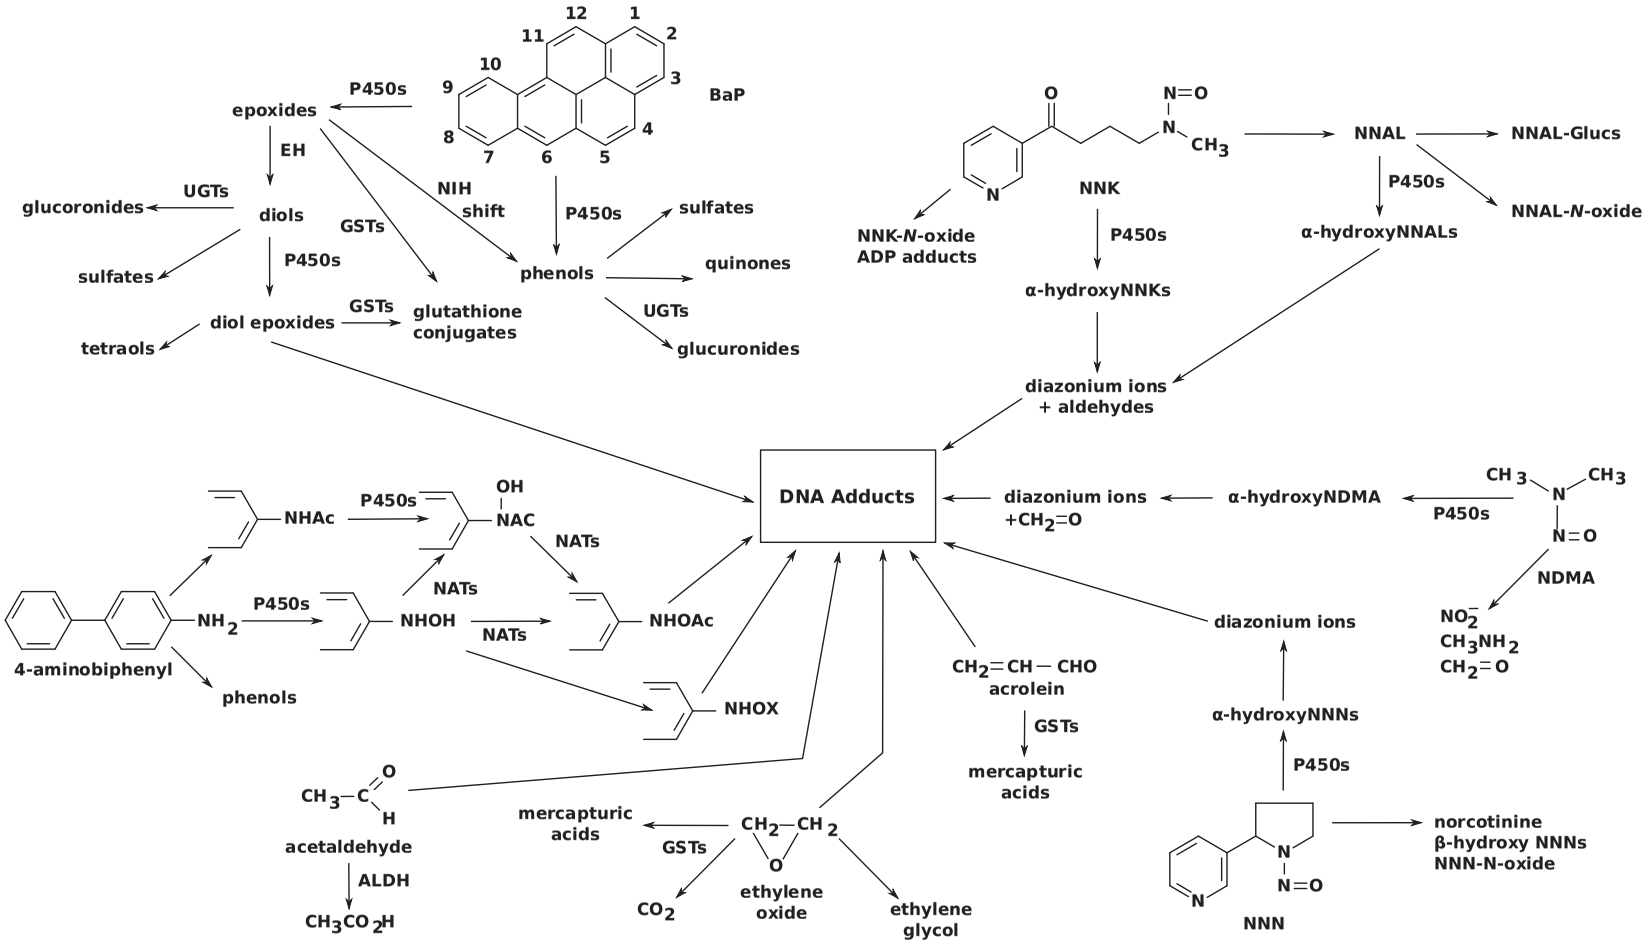
Probably the most practical and, to date, the most extensively applied tobacco carcinogen biomarkers are urinary metabolites of tobacco carcinogens, and these have been comprehensively reviewed (Hecht, 2002; IARC, 2004a). Advantages include the ready availability of samples, and concentrations in urine that are easily quantifiable using modern analytical chemistry methods, most frequently liquid chromatography-tandem mass spectrometry (LC-MS/MS). The urinary metabolites listed in Table 4.1 have all been used as biomarkers and all are validated with respect to exposure in cigarette smokers (Carmella *et al.*, 2009). Total nicotine equivalents (the sum of nicotine and the five metabolites in Table 4.1) is a particularly effective way of estimating nicotine dose from tobacco products.

Total NNAL, the sum of NNAL and its glucuronides, is a highly useful biomarker of NNK exposure (Hecht, 2002, 2003; Hatsukami *et al.*, 2006a). The tobacco-specificity of NNK, and therefore total NNAL, is a key feature of this biomarker because studies in which it is applied are not confounded by other environmental or dietary exposures. It also has a considerably longer half-life than cotinine and several other urinary biomarkers. Total NNAL has been used in numerous studies that estimated uptake of NNK in smokers under varying circumstances. In one example, smokers reduced their number of cigarettes smoked per day, but there was not a corresponding decrease in NNK uptake due to compensation (Hecht *et al.*, 2004). In another study, NNK and PAH uptake, estimated by total NNAL and 1-hydroxypyrene, respectively, were compared in smokers of regular, light, and ultra-light cigarettes, and found to be similar, consistent with epidemiologic studies that

demonstrate no protection against lung cancer in smokers of light compared to regular cigarettes (Hecht *et al.*, 2005b). Other studies evaluated NNK uptake in smokers who switched from their current cigarette brand to products advertised as being less hazardous, but the results generally did not support these claims (Hatsukami *et al.*, 2004). One of the most useful applications of total NNAL has been in studies of non-smokers exposed to second-hand tobacco smoke (Hecht, 2003). The sensitivity and specificity of this biomarker are ideal for such studies, and it is the most commonly elevated tobacco carcinogen biomarker in non-smokers exposed to second-hand smoke. Total NNAL has also found utility in establishing NNK uptake in smokeless tobacco users (Hecht *et al.*, 2002, 2007, 2008a, b; Hecht, 2008)

The relationship of urinary total NNAL to lung cancer was demonstrated in a study of stored urine samples collected years before diagnosis of lung cancer from smokers in Shanghai, China and Singapore (Yuan *et al.*, 2009). There was a significant relationship between total NNAL and lung cancer incidence, after correction for numbers of cigarettes smoked per day and duration of smoking. An 8.5 fold increased risk for lung cancer was observed for those smokers in the highest tertile of total NNAL and cotinine, relative to smokers with the same smoking history but in the lowest tertiles of total NNAL and cotinine. Urinary biomarkers were also used to demonstrate higher uptake of nicotine and NNK per cigarette in smokers with polymorphisms in the nicotinic acetylcholine genes associated with lung cancer in genome-wide association studies (see Section 4.2; Le Marchand *et al.*, 2008). Collectively, these results indicate that urinary total NNAL is not only a biomarker of exposure, but also a biomarker of risk for lung cancer.

(b) Serum and saliva metabolites



Serum and saliva metabolites have been used as biomarkers much less often than urine metabolites. The most frequently measured tobacco smoke toxicant in serum and saliva is cotinine, documented as a useful biomarker of cigarette smoking in many studies (Lee, 1999; Hukkanen *et al.*, 2005). Total NNAL can be readily quantified in serum and its levels remain relatively constant in a given smoker sampled at bimonthly intervals over a one year period. Consistent with the results described above, one study showed a significant relationship between total NNAL in prospectively collected serum samples from smokers and lung cancer risk (Church *et al.*, 2009). Other biomarkers that have been measured in serum include cadmium, benzene, styrene and *r*-1,*t*-2,3,*c*-4-tetrahydroxy-1,2,3,4-tetrahydrophenanthrene (PheT) (IARC, 2004a; Church *et al.*, 2009).

(c) DNA adducts

Fig. 4.3 presents an overview of metabolism and DNA adduct formation from eight tobacco smoke compounds (clockwise from top left): BaP, NNK, *N*-nitrosodimethylamine (NDMA), NNN, acrolein, ethylene oxide, acetaldehyde and 4-aminobiphenyl. Evidence exists for DNA adduct formation from each of these carcinogens in smokers, based on studies carried out with tissues or blood cells. DNA adduct biomarkers have been applied mainly in studies of smokers, and there is far less evidence from studies of second-hand tobacco smoke or smokeless tobacco use.

The structures of DNA adducts of tobacco smoke carcinogens have been characterized in detail, but a complete description of these structures is beyond the scope of this section. Selected DNA adduct structures are shown in Fig. 4.4. A major DNA adduct of BaP results from *trans*- addition of the benzo[*a*]pyrene diol epoxide (BPDE) to the N^2-position of dG (Szeliga

& Dipple, 1998). Pyridyloxobutyl (POB)-DNA adducts of NNK and NNN are formed at the 7- and O^6-positions of deoxyguanosine dG, the O^2-position of thymidine, and the O^2-position of deoxycytidine (Hecht, 2008). They can be measured in part as 4-hydroxy-1-(3-pyridyl)-1-butanone (HPB) released upon hydrolysis. Metabolic activation of NNK also leads to 7-methyl-dG and O^6-methyl-dG, identical to the DNA adducts formed from NDMA and other DNA methylating agents (Hecht, 2008). Ethylating agents and ethylene oxide in cigarette smoke also alkylate dG (Zhao *et al.*, 1999; Singh *et al.*, 2005). Acrolein and crotonaldehyde react with DNA to produce exocyclic 1,N^2-dG adducts, while acetaldehyde forms a Schiff base adduct with the exocyclic N^2 amino group of dG. There is evidence for the presence of all these DNA adducts in tissues or blood cells of smokers, but there are also many studies in which these specific adducts have been sought but not found (Boysen & Hecht, 2003).

Measurement of these DNA adducts as biomarkers potentially can provide the most direct link between cellular exposure and cancer, because DNA adducts are so critical in carcinogenesis. However, it is challenging because their levels are extremely low, frequently ranging from 1 per 10^6 to 1 per 10^8 normal bases, and the tissue or blood samples containing them are usually available in only small quantities. Fortunately, the routine detection of amol levels [attomole, equivalent to 10 moles] of DNA adducts by conventional LC-MS/MS techniques is now feasible (Singh & Farmer, 2006). There are still relatively few examples of quantitation of *specific* DNA adducts of tobacco carcinogens in tissues of smokers using mass spectrometry, high pressure liquid chromatography (HPLC)-fluorescence, HPLC with electrochemical detection, or postlabelling techniques (Pfeifer *et al.*, 2002). A much larger body of work has used the highly sensitive, but relatively non-specific ^{32}P-postlabelling and immunoassay methods of DNA adduct detection. Although the adducts detected using ^{32}P-postlabelling are often referred to as "aromatic DNA adducts," there is strong evidence that they are not related to PAHs (Arif *et al.*, 2006). Adduct levels are generally higher in lung tissues of smokers than non-smokers while studies using blood DNA have produced varied results. Adducts have also been detected in the larynx, oral and nasal mucosa, bladder, cervix, breast, pancreas, stomach, placenta, foetal tissue, cardiovascular tissues, sputum, and sperm of smokers (IARC, 2004a). A meta-analysis of the relationship of DNA adduct levels in smokers to cancer, as determined by ^{32}P-postlabelling in the majority of studies or enzyme linked immunosorbent assay (ELISA), demonstrated a positive relationship in current smokers (Veglia *et al.*, 2003; 2008).

(d) Protein adducts

Carcinogen-haemoglobin (Hb) and serum albumin adducts are regarded as surrogates for DNA adduct measurements. Although these proteins are not targets for carcinogenesis, virtually all carcinogens that react with DNA will also react with protein. Advantages of haemoglobin adducts include the ready availability of haemoglobin from blood and the relatively long lifetime of the erythrocyte in humans – 120 days –,which provides an opportunity for adducts to accumulate. Studies on protein adducts in smokers have been comprehensively reviewed (IARC, 2004a).

Haemoglobin adducts of aromatic amines are a highly informative type of carcinogen biomarker, with levels that are consistently higher in smokers than non-smokers, particularly for 3-aminobiphenyl and 4-aminobiphenyl-Hb adducts. Haemoglobin binds aromatic amines efficiently because heme accelerates the rate of nitrosoarene formation from the hydroxylamine, which is produced metabolically from the aromatic amine by CYP1A2 (Fig. 4.3; Skipper & Tannenbaum, 1990). Binding of the nitrosoarene occurs at the β-93 cysteine residue of human

haemoglobin; the adduct is hydrolysed releasing the free amine, which is quantified by GC-MS (Skipper & Tannenbaum, 1990). Adduct levels are clearly related to cigarette smoking (Skipper & Tannenbaum, 1990). Adducts that form at the terminal valine of haemoglobin are also useful biomarkers: examples include those derived from ethylene oxide, acrylonitrile and acrylamide (Bergmark, 1997; Fennell *et al.*, 2000). Ethylated N-terminal valine of haemoglobin is also higher in smokers than in non-smokers (Carmella *et al.*, 2002).

HPB-releasing Hb adducts of NNK and NNN have been quantified in studies of smokers and smokeless tobacco users (IARC, 2004a, 2007a). These adducts are thought to be tobacco-specific, but some studies report their presence in non-smokers (Falter *et al.*, 1994; Schlöbe *et al.*, 2008).

4.1.4 Genetic and related effects

(a) Mutagenicity and cytogenetic effects

Tobacco smoke and its condensates are mutagenic in a wide variety of test systems from bacteria to mammalian cells in culture to rodents and humans (DeMarini, 2004; IARC, 2004a; Husgafvel-Pursiainen, 2004). In bacterial systems, the heterocyclic amines and aromatic amines in condensates account for much of the frameshift mutagenicity, whereas the PAHs and nitrosamines may account for some of the base-substitution mutagenicity (DeMarini *et al.*, 1995). G to T is the predominant class of base-substitution mutation induced by condensates in experimental systems and found in oncogenes and tumour-suppressor genes in smoking-associated lung tumours (IARC, 2004a). The genotoxic potencies of a variety of condensates in several genotoxicity assays likely have only qualitative value with regard to health risk assessment (DeMarini *et al.*, 2008). This is consistent with findings that smokers of low- or high-tar cigarettes have similar urinary levels of lung carcinogens (Hecht *et al.*, 2005b; Hatsukami *et al.*, 2006b) and similar risks for lung cancer (Harris *et al.*, 2004).

In rodents, cigarette smoke induces sister chromatid exchange and micronuclei in bone marrow and lung cells. Human newborns of smoking mothers have increased frequencies of *HPRT* mutations, chromosomal translocations, and DNA strand breaks. Sperm of smokers has increased frequencies of aneuploidy, DNA adducts, strand breaks, and oxidative damage. Cigarette smoke also causes germ-cell mutations in mice (Yauk *et al.*, 2007). Collectively, these data suggest that smoking is likely a germ-cell mutagen in humans. Smoking produces mutagenic urine and somatic-cell mutations in humans, including *HPRT* mutations, sister chromatid exchange, microsatellite instability and DNA damage in a variety of tissues. Genotoxic effects have been found in eight organ sites at which tobacco smoke causes cancer in humans (DeMarini, 2004; IARC, 2004a).

(b) Mutations in TP53, KRAS and related genes

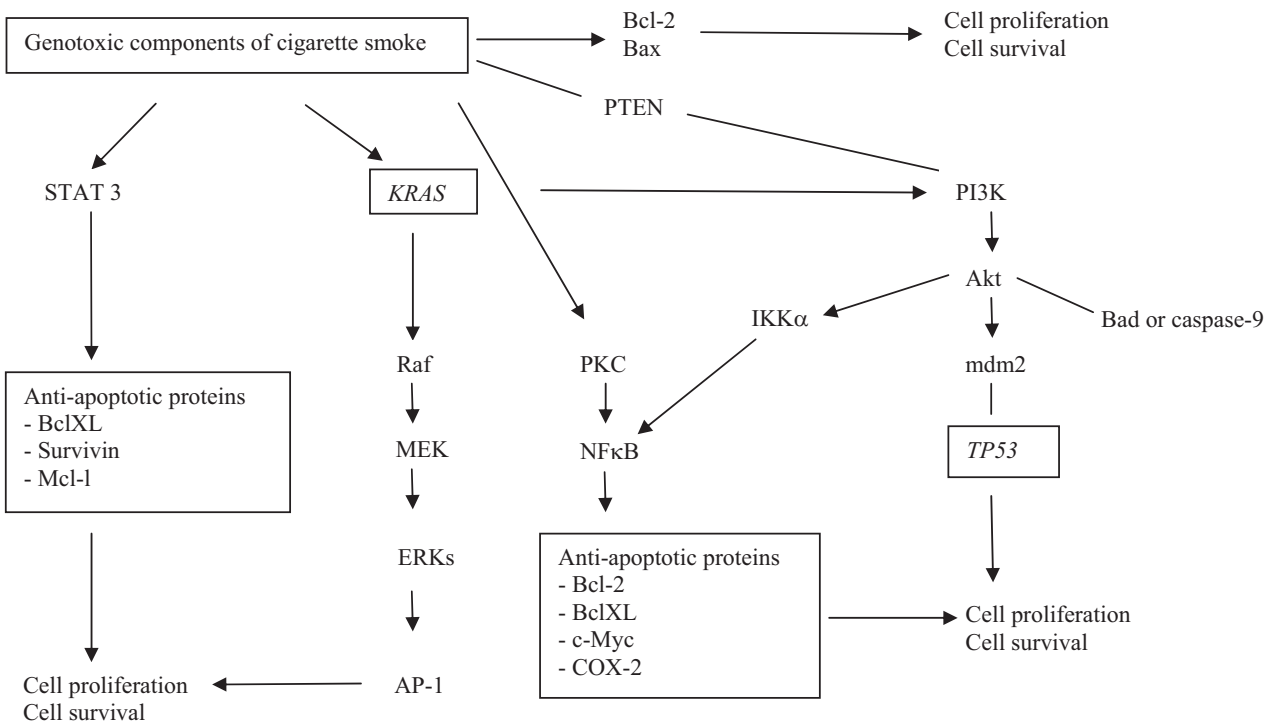
Gene mutation data from a variety of databases, including the IARC Cancer *TP53* Mutation Database (http://www-p53.iarc.fr/), have been collated in the Genetic Alterations in Cancer (GAC) database (http://dir-apps.niehs.nih.gov/gac/) so that mutations in a variety of genes in various cancerous tissues can be compared. An assessment of the Gene Alterations in Cancer database showed that at least three genes were mutated more frequently in lung tumours from smokers than non-smokers (Lea *et al.*, 2007): *TP53* (39 versus 26%), *K-RAS* (20 versus 3%), and loss of heterozygosity at *FHIT* (57 versus 27%). Thus, genes in the cell cycle (*TP53*), cell signalling (*KRAS*) and apoptotic (*FHIT*) pathways are mutated more frequently in smoking- rather than in nonsmoking-associated lung tumours. Genomic sequencing of lung tumours has identified other mutated genes that are associated with smoking; ten times more genes are mutated in

lung tumours from smokers compared to non-smokers (Ding *et al.*, 2008).

GC to TA transversions were the predominant class of base-substitution mutation found in *TP53* and *KRAS* genes in lung tumours from smokers, with the frequency of this mutation in *TP53* being 30% in smokers versus 22% in non-smokers. In smoking-associated oral cancers, the percentage of GC to TA mutations in *TP53* was 15% versus 2%, respectively. This mutation spectrum is consistent with that produced by a variety of known carcinogens present in tobacco smoke (IARC, 2004a). At the codon level, the most frequently mutated codons in *TP53* in lung tumours of smokers were 157, 175, 245, 248, and 273, all of which occur in the DNA-binding domain of the protein; among these codons, only 273 was mutated in lung tumours from non-smokers. Only three of these codons (157, 245 and 273) were mutated in smoking-associated larynx tumours, and only codon 157 was mutated in smoking-associated oral tumours. Thus, the mutational specificity at *TP53* is different among smoking- and nonsmoking-associated tumours and among smoking-associated tumours at various organs (Lea *et al.*, 2007). Thus, different pathways are involved in the development of different types of tumours (Le Calvez *et al.*, 2005; Mounawar *et al.*, 2007; Subramanian & Govindan, 2008).

4.1.5 Effects on gene expression profile

As indicated in a review by Sen *et al.* (2007) involving microarray analysis of 18 studies in human smokers, 7 in smoke-exposed rodents, and 3 in condensate-exposed mammalian cells, smoking generally upregulated a wide variety of genes, especially those involved in the stress response, phase I metabolism, and immune response. Genes that were consistently expressed differentially in smokers (as assessed in alveolar macrophages, lung cells or peripheral lymphocytes) included metallothioneins, heat-shock proteins, superoxide dismutase, glutathione transferase, heme oxygenase, *CYP* genes (*1A2*, *1A1* and *1B1*), interleukins and chemokines.



Spira *et al.* (2004) analysed global gene expression in bronchial epithelial cells and found that the expression levels of metabolizing and antioxidant genes had reverted to control levels after two years of smoking cessation. However, expression of potential oncogenes and tumour-suppressor genes never reverted to never-smoker levels even after years of smoking cessation. Consistently, expression of microRNAs is generally downregulated by cigarette smoke (Izzotti *et al.*, 2009). As discussed below, smoking also altered methylation patterns and gene expression in smoking-associated tumours.

4.1.6 Other effects associated with carcinogenesis

(a) Proliferation, differentiation, apoptosis, and inflammation

As noted above, the signal-transduction pathways in lung tumours from smokers are distinctly different from those of non-smokers (Mountzios *et al.*, 2008). Fig 4.5 shows details of signalling pathways that are deregulated by tobacco smoke. The involvement of high frequencies of mutated *K-RAS* and *TP53* genes in smoking-associated lung tumours results in altered regulation of cell proliferation, differentiation, cytoskeletal organization and protein trafficking. Cigarette smoking activates *NF-κB*, which induces pro-inflammatory cytokine expression and induces growth factors and proliferative signals (Mountzios *et al.*, 2008). This gene also influences the expression of the anti-apoptotic gene *BCL2* and pro-apoptotic gene *BAX*. Smoking produces chronic inflammation, which promotes cancer (Walser *et al.*, 2008). Smoking results in high levels of reactive oxygen species, which damage epithelial and endothelial cells and impair their function. In smoking-associated lung cancer, elevated levels of cyclooxygenase-2 (COX-2) and

Fig. 4.5 General scheme of some cell-signalling pathways that are deregulated by tobacco smoke in lung carcinogenesis

Akt, serine/threonine protein kinase; ERKs, extracellular regulated kinases; MEK, mitogen-activated protein kinase; Bad, Bcl2-associated agonist of cell death; PI3K, phosphatidylinositol 3-kinase; PKC, protein kinase C; NF-κB, nuclear factor κB; IKKα, inhibitor of nuclear factor κ-B kinase; PTEN, phosphatase and tensin homologue; STAT3, signal transducer and activator of transcription, COX-2, cyclooxygenase-2

prostaglandin (PGE_2) indicate apoptosis resistance, proliferation, immunosuppression, angiogenesis, invasion, and epithelial-mesenchymal transition (Walser *et al.*, 2008).

(b) Endogenous nitrosation

Intragastric formation of *N*-nitroso compounds, measured using urinary nitrosamino acids excreted in urine, was increased in smokers compared to non-smokers (Hoffmann & Brunnemann, 1983). Two recent studies demonstrated that NNN forms endogenously in some users of nicotine replacement therapy products (Stepanov *et al.*, 2009a, b).

(c) Hormonal changes

These are described in Section 4.3.2a.

4.2 Polymorphisms in carcinogen-metabolizing genes

4.2.1 Introduction

It has been long proposed that the known variation among individuals in their capacity to activate and detoxify carcinogens may be associated with increased susceptibility to cancer, and that polymorphisms of carcinogen-metabolising genes may play a significant role. The most intensively studied genes involved in the metabolism of carcinogens include the various *CYP* genes, the *GST* genes and the *NAT* genes. Other relevant xenobiotic-metabolising genes, such as *EPHX*, sulfotransferase (*SULT*), *UGT*, myeloperoxidase (*MPO*), and NAD(P)H quinone oxidoreductase-1 (*NQO1*) genes, have also been studied. Recently, extensive pooled studies and

reviews have been published on polymorphisms of carcinogen-metabolising genes and their role in cancer susceptibility, especially in tobacco-related lung cancer and cancers at other sites. Similarly, various biomarkers of exposure and genotoxicity that are presumed to provide a mechanistic basis for such associations have been comprehensively investigated in relation to these polymorphisms. A brief overview based largely on reviews and the meta- and pooled analyses is presented here.

4.2.2 Genetic polymorphisms of carcinogen metabolism: some central genes

(a) CYP genes

CYPs comprise the principal enzyme system catalysing various phase I oxidation reactions, including metabolic activation and detoxification of many carcinogenic substances in tobacco smoke such as PAHs. Of the various CYP enzymes expressed in humans, many of those belonging to CYP1 to CYP3 families play a role in carcinogen metabolism, producing highly reactive DNA-damaging metabolites as well as detoxified metabolites (Guengerich & Shimada, 1998; Lang & Pelkonen, 1999; Ingelman-Sundberg, 2004). CYPs have evolved into a wide superfamily with close to 60 different active genes currently identified; most of these genes exhibit polymorphism (www.cypalleles.ki.se).

(i) *CYP1A1*

Several allelic variants of the human *CYP1A1* gene are currently known (www.cypalleles.ki.se). The major variant forms of the *CYP1A1* gene (wildtype allele *CYP1A1*1*) mostly frequently studied for association to cancer susceptibility include the following two alleles: (i) *CYP1A1*2A* allele (m1 allele; *Msp* I) and (ii) *CYP1A1*2B* (Cascorbi *et al.*, 1996) or *CYP1A1*2C* (www.cypalleles.ki.se) allele (m2 allele; Ile^{462}Val). Importantly, the *CYP1A1* m1 allele and m2 allele are in complete linkage disequilibrium in Caucasians (Kawajiri, 1999; Bartsch *et al.*, 2000). In addition, *CYP1A1*4* allele (m4; Thr^{461}Asn) (Cascorbi *et al.*, 1996), and *CYP1A1*3* (m3) allele found in African-Americans but not in Caucasians or Asians (Crofts *et al.*, 1993) are included in some studies (Bartsch *et al.*, 2000).

In smoking-related lung cancer, the various *CYP1A1* polymorphisms as well as the differences in the frequencies of the rare variant alleles between ethnicities contribute to the differences in findings. There are collective analyses of data predominantly indicating an overall mild to moderate effect of *CYP1A1* polymorphisms on lung cancer risk (Kawajiri, 1999; Bartsch *et al.*, 2000; Houlston, 2000; Le Marchand *et al.*, 2003; Vineis *et al.*, 2003; Vineis *et al.*, 2004; Lee *et al.*, 2008a; Shi *et al.*, 2008). In many reviews and meta- or pooled analyses the increased risk associated with *CYP1A1* polymorphism has most clearly been seen in Asian populations (Kawajiri, 1999; Le Marchand *et al.*, 2003; Vineis *et al.*, 2003; Lee *et al.*, 2008a; Shi *et al.*, 2008).

Multiple studies have also analysed the gene-gene interactions between *CYP1A1*, *GSTM1* and *GSTT1* polymorphisms and lung cancer (d'Errico *et al.*, 1999; Houlston, 1999; Benhamou *et al.*, 2002; Bolt & Thier, 2006; Raimondi *et al.*, 2006; Ye *et al.*, 2006; Carlsten *et al.*, 2008). Some of the analyses have indicated that the elevated risk for lung cancer may be more pronounced for some *CYP1A1/GSTM1* null genotype combinations (Le Marchand *et al.*, 1998; Bartsch *et al.*, 2000; Vineis *et al.*, 2004, 2007; Lee *et al.*, 2008a; Shi *et al.*, 2008).

(ii) *CYP1A2*

CYP1A2 is highly inducible and metabolises, including deacetylation reactions, many tobacco smoke carcinogens such as aromatic and heterocyclic amines and nitro-aromatic compounds, and tobacco-specific nitrosamines such as NNK (Nebert *et al.*, 2004; Jalas *et al.*, 2005; IARC, 2007a). A few major variant alleles have been described (www.cypalleles.ki.se), some of which

may have been reported to influence inducibility (Nakajima *et al.*, 1999; Ingelman-Sundberg *et al.*, 2007). Overall, the phenotype-genotype relations have not been well established for *CYP1A2*, although current evidence points towards contribution of genetic variation (Murayama *et al.*, 2004; Ingelman-Sundberg *et al.*, 2007); data on possible associations with tobacco related cancer are sparse (Agundez, 2004; Nebert & Dalton, 2006).

(iii) CYP2A6

Several aspects of smoking behaviour are likely to be influenced by *CYP2A6* genetic variation, which influences nicotine metabolism (Malaiyandi *et al.*, 2005; Mwenifumbo & Tyndale, 2007). The most important functionally altered allele is *CYP2A6*4* (gene deletion), which confers a poor-metabolizer phenotype in homozygous individuals (Malaiyandi *et al.*, 2005; Ingelman-Sundberg *et al.*, 2007; Mwenifumbo & Tyndale, 2007). In some studies, polymorphic variants of *CYP2A6* gene have been implicated in susceptibility to smoking-related cancers (Gambier *et al.*, 2005; Malaiyandi *et al.*, 2005; Nakajima, 2007). In line with this, the accumulated data have suggested that *CYP2A6* polymorphism may affect cancer risk in smokers but not in non-smokers (Tan *et al.*, 2001; Kamataki *et al.*, 2005; Malaiyandi *et al.*, 2005; Canova *et al.*, 2009).

(iv) CYP2A13

From human CYPs, CYP2A13 is the primary form involved in the metabolic activation of the tobacco-specific nitrosamines NNK and NNN (Jalas *et al.*, 2005; IARC, 2007a). The *CYP2A13* gene exhibits polymorphism in humans (Zhang *et al.*, 2002; Jalas *et al.*, 2005), and experimental studies suggest that some of the polymorphisms may affect the hydroxylation of NNN and NNK (Jalas *et al.*, 2005; Schlicht *et al.*, 2007). However, the data on possible effects of these polymorphisms on the risk of tobacco-related cancers in humans are still limited (Wang *et al.*, 2003; Song *et al.*, 2009; Timofeeva *et al.*, 2009).

(v) CYP2D6

The *CYP2D6* gene shows high variability in expression. The enzyme is not inducible, and therefore genetic variation largely contributes to the interindividual variation in enzyme activity. Currently, more than 100 different functional CYP2D6 gene variants have been described, and these are divided into alleles causing abolished, decreased, normal, and ultrarapid enzyme activity (Ingelman-Sundberg, 2005; Ingelman-Sundberg *et al.*, 2007). The most important null alleles leading to poor-metabolizer phenotype are *CYP2D6*4* (splice defect) and *CYP2D6*5* (gene deletion) (Ingelman-Sundberg, 2005; Ingelman-Sundberg *et al.*, 2007).

A large series of studies have been carried out over the past 20 years on the association between *CYP2D6* polymorphism and susceptibility to lung cancer and to some other tobacco-related cancers (Wolf & Smith, 1999). Despite some indication of an association between CYP2D6 poor-metabolizer and decreased risk for lung cancer, no major role for CYP2D6 in carcinogen metabolism or a molecular basis for such an association have been discovered (Wolf & Smith, 1999; Ingelman-Sundberg, 2005).

(vi) Other CYP genes

CYP1B1 allelic variants that affect the catalytic activity have been described but they have been studied to a lesser extent for the association with susceptibility to smoking-related cancers (Thier *et al.*, 2003). Some positive findings have been reported on head and neck cancer (Ko *et al.*, 2001), and lung cancer (Zienolddiny *et al.*, 2008).

Several polymorphisms have been characterized in the *CYP2E1* gene and several positive associations with the risk of different cancers have been reported, in particular for cancers of the upper aerodigestive tract, lung and gastrointestinal tract (Section 2.19). *CYP2E1* may also

play an important role in the interaction of the carcinogenic effects of alcohol and tobacco (Section 4.4).

From the human *CYP3A* locus (*CYP3A4*, *CYP3A5* and *CYP3A7*), the *CYP3A4*1B* allele has been associated with lung cancer and prostate cancer in some studies but not in all (Dally *et al.*, 2003; Rodriguez-Antona & Ingelman-Sundberg, 2006). However, the role of these variants in relation to tobacco smoking is unknown.

(b) GSTM1 and other GST genes

Polymorphic *GST* genes have long been proposed to modify susceptibility to lung cancer (Seidegård *et al.*, 1986; Ketterer *et al.*, 1992). The polymorphic genes encoding the various classes of cytosolic GST enzymes include the *GSTM1* and *GSTM3* genes (mu class), the *GSTP1* gene (pi class), and the *GSTT1* gene (theta class). The gene deletion (null) allele of the *GSTM1* gene (*GSTM1*0*) and of the *GSTT1* gene (*GSTT1*0*) have been the most intensively studied polymorphisms in relation to increased susceptibility to cancer (Strange *et al.*, 2001; Bolt & Thier, 2006; McIlwain *et al.*, 2006). For the *GSTP1* gene, the form most abundantly present in lung tissue, genetic variation in exon 5 (*GSTP1*2*; $Ile^{105}Val$), in exon 6 ($Ala^{114}Val$), as well as a combination of these, are the variations most frequently studied for cancer susceptibility (Watson *et al.*, 1998; Cote *et al.*, 2009).

Numerous reviews, meta- and pooled analyses have been published over the past 15 years or so for the *GST* genes with systematic assessments covering altogether tens of thousands of cases and controls. For the *GSTM1* null genotype, such analyses have largely provided negative, suggestive or at most moderately positive results for an association with an increased risk for lung cancer (d'Errico *et al.*, 1999; Houlston, 1999; Benhamou *et al.*, 2002; Ye *et al.*, 2006; Carlsten *et al.*, 2008). The larger the studies, the less significant the estimates for the role of *GSTM1* emerge in systematic analysis (Ye *et al.*, 2006; Carlsten *et al.*, 2008). Also the varying allele frequencies related to ethnic background affect the findings for *GSTM1* as well as for many other genes (Garte *et al.*, 2001; Ye *et al.*, 2006; Carlsten *et al.*, 2008; Lee *et al.*, 2008a).

In a meta-analysis of the association between the *GSTT1* gene polymorphism and lung cancer no association between *GSTT1* null genotype and risk for lung cancer in Caucasians was observed, but a positive association was found for Asians (Raimondi *et al.*, 2006). A significant association for either Caucasians or Asians was also not found in a pooled analysis (Raimondi *et al.*, 2006). A meta-analysis found no significant association between lung cancer risk and the *GSTP1* $Ile^{105}Val$ polymorphism; but the pooled analysis suggested an overall statistically significant mild association between lung cancer and homozygosity or heterozygosity for the Val^{105} allele (Cote *et al.*, 2009).

A recent body of epidemiologic data suggests an inverse association between cruciferous vegetables/isothiocyanates intake and cancers of the colorectum, lung and breast; the studies also provide evidence that this protective effect is greater among individuals who possess the *GSTM1* or *T1* null genotype, who would be expected to accumulate higher levels of isothiocyanates at the target tissue level, a pre-requisite for their enzyme-inducing effects (Seow *et al.*, 2005). The association between isothiocyanates and cancer, and its modification by *GSTM1* and *GSTT1* status, is most consistent for lung cancer and appears to be strongest among current smokers who possess the combined *GSTM1* and *GSTT1* null genotypes (London *et al.*, 2000a; Spitz *et al.*, 2000; Zhao *et al.*, 2001; Brennan *et al.*, 2005; Seow *et al.*, 2005).

(c) NAT1 and NAT2 genes

The pooled and meta-analyses carried out on *NAT1* and *NAT2* polymorphisms and bladder cancer risk have consistently reported significantly increased risk for *NAT2* slow acetylators

(Dong *et al.*, 2008; Malats, 2008; see also Section 2.9). Data on *NAT1* fast acetylators are inconsistent, as are the studies suggesting an increased risk for *NAT2* rapid acetylator status. Additionally, genotypes for other genes, specially *GSTM1*, have also been implicated (Vineis *et al.* 2001; García-Closas *et al.*, 2005; Hein, 2006; Sanderson *et al.*, 2007; Dong *et al.*, 2008; Malats, 2008).

In a recent large study on tobacco-related lung cancer and upper aerodigestive cancers, the *NAT* genes, in particular *NAT*10* haplotype, emerged from a set of 16 genes as involved in the risk (McKay *et al.*, 2008). When more than one hundred single nucleotide polymorphisms for 31 genes involved in phase I or phase II metabolism or in antioxidant defence were investigated, only four of the previously reported polymorphisms of the *GSTP1*, *EPHX1* and superoxide dismutase *SOD2* genes and the *NAT1* fast acetylator phenotype remained significantly associated with risk of non-small cell lung cancer after correction for multiple testing (Zienolddiny *et al.*, 2008).

In breast cancer, several recent meta-analyses of epidemiological studies have suggested increased risk among smokers with the *NAT2* slow acetylator genotype; such an association has been observed especially among long-term smokers and post-menopausal women (Terry & Goodman, 2006; Ambrosone *et al.*, 2008; Ochs-Balcom *et al.*, 2007; Baumgartner *et al.*, 2009).

In all, the role of the *NAT* gene polymorphisms in tobacco-related cancers, with the exceptions of increased risk of bladder cancer and possibly breast cancer in *NAT2* slow acetylators, remains largely open due to the incomplete understanding of phenotype-genotype relationships, and the interplay between these two genes and their polymorphisms (Hein, 2002, 2006).

(d) Others

Genes coding for EPHX, UGT and SULT enzymes, mainly but not exclusively involved in detoxification reactions, exhibit polymophisms with numerous gene variants discovered (Mackenzie *et al.*, 1997; London *et al.*, 2000b; Glatt *et al.*, 2001; Burchell, 2003). Additional polymorphic genes studied for their significance in cancer susceptibility are the *NQO1* and *MPO* genes, with NQO1 playing a dual role in the detoxification and activation of procarcinogens, and MPO converting lipophilic carcinogens into hydrophilic forms (Nebert *et al.*, 2002). All these genes have been studied for their possible association with tobacco-related cancer risk to a varying extent and with variable outcomes (London *et al.*, 2000b; Bamber *et al.*, 2001; Garte, 2001; To-Figueras *et al.*, 2001; Tiemersma *et al.*, 2002b; Guillemette, 2003; Wells *et al.*, 2004; Kiyohara *et al.*, 2005; Moreno *et al.*, 2005; Nagar & Remmel, 2006; Gallagher *et al.*, 2007).

4.2.3 Biomarkers of tobacco carcinogenesis and polymorphic genes of carcinogen metabolism

A myriad of studies have investigated association between various biomarkers of tobacco-related carcinogenesis and genetic variation of genes involved in carcinogen metabolism. For involvement in increased cancer susceptibility, a large variety of intermediate biomarker have been studied, including PAH metabolites in urine, urinary mutagenicity, DNA and protein adducts, cytogenetic alterations, *HPRT* mutant lymphocytes, as well as somatic mutations of the tumour suppressor gene *TP53* and *KRAS* oncogene occurring in cancer tissue.

(a) PAH metabolites and mutagenicity in urine

(i) PAH metabolites in urine

Increased excretion of 1-hydroxypyrene in urine in association with the *GSTM1* null genotype has been reported in many studies on individuals with occupational or environmental exposure to PAHs (Yang *et al.*, 1999; Alexandrie *et al.*, 2000; Lee *et al.*, 2001; Kuljukka-Rabb *et al.*, 2002; Kato *et al.*, 2004). The associations seen between *GSTT1* polymorphism and the

PAH metabolites are somewhat more variable. Similarly, the joint effect of *GSTM1* and *GSTT1* null genotypes, as well as the effects of some other genes of xenobiotic metabolism, such as *EPHX*, *CYP1A1*, *CYP1A2* and the aryl hydrocarbon receptor (*AhR*) gene have been either positive or negative (Yang *et al.*, 1999; Alexandrie *et al.*, 2000; Lee *et al.*, 2001; Zhang *et al.*, 2001; Kuljukka-Rabb *et al.*, 2002; Yang *et al.*, 2003; Chen *et al.*, 2007; Cocco *et al.*, 2007; Bin *et al.*, 2008).

Another PAH metabolite studied in this context is phenanthrene, the simplest PAHs with a bay region, a feature closely associated with carcinogenicity. A study quantified ratios of urinary products of metabolic activation (such as PheT) and detoxification (such as phenanthrols, HOPhe) of phenanthrene in 346 smokers, who were also genotyped for 11 polymorphisms in genes involved in PAHs metabolism, including the *CYP1A1* and *GSTM1* genes. A significant association between the presence of the *CYP1A1* $Ile^{462}Val$ polymorphism and high PheT/3-HOPhe ratios was found, particularly in combination with the *GSTM1* null polymorphism (Hecht *et al.*, 2006).

Overall, the data on the influence of genetic variation in PAHs metabolism on the levels of the urinary metabolite biomarkers are variable, and currently inconclusive.

(ii) Urinary mutagenicity

One relatively early line of research investigated the relationship between urinary mutagenicity and genetic variation in activation or detoxification genes. These studies, however, have seldom been focused on smokers only but rather on other sources of exposure (Pavanello & Clonfero, 2000).

In some studies, *NAT2* slow acetylator genotype either alone or in combination with *GSTM1* null genotype has been associated with increased urinary mutagenicity in the *Salmonella* test in individuals with occupational, environmental or medicinal PAH-related exposure, or in smokers (Vineis & Malats, 1999; Pavanello & Clonfero, 2000). In another study, CYP1A2 activity, but not *NAT2*, *GSTM1* or *GSTT1* genotypes influenced urinary mutagen excretion in smokers (Pavanello *et al.*, 2002). A further study also suggested contribution of the *CYP1A2* gene variation to increased urinary mutagenicity in heavy smokers (Pavanello *et al.*, 2005). Associations with variants of other xenobiotic-metabolising genes (such as *EPHX1*) have also been reported, with somewhat complex results (Kuljukka-Rabb *et al.*, 2002).

(b) DNA adducts

The relationship between the variants of polymorphic genes of carcinogen metabolism and tobacco smoke-related DNA adduct formation has been addressed in an abundant number of studies among smokers, occupationally exposed groups, and patients with smoking-related cancer. In addition, multiple *in vitro* studies on this relationship have been carried out (Bartsch *et al.*, 2000; Pavanello & Clonfero, 2000; Alexandrov *et al.*, 2002; Wiencke, 2002).

The intensive efforts to study the relationship between *CYP1A1* and *GSTM1* gene polymorphism and the level of aromatic-hydrophobic/bulky PAH-DNA adducts in human lungs have so far provided little evidence for a role of a single metabolic genotype or their combinations on DNA adduct formation, with largely weak, non-significant or contradictory results. However, a trend of increasing adduct levels in subjects with the *CYP1A1*2-GSTM1*0* genotype combination has been observed, which was reinforced when BPDE-DNA adducts were specifically assessed. These results suggest a gene-gene interaction, supported by biological data from other studies (Bartsch *et al.*, 2000; Alexandrov *et al.*, 2002; Wiencke, 2002). Such gene-gene interaction lends support to the increased risk for lung cancer found in carriers of these genotypes in Japanese, among whom the frequency of the

variant *CYP1A1* allele is much higher (Bartsch *et al.*, 2000; Alexandrov *et al.*, 2002).

A wide selection of genes and genotypes included in the various studies have made it difficult to assess the overall role of the polymorphisms of *GSTM1* and other genes alone or in combination. Differences between the studies in the types of adducts determined, the various tissues, cell types and cancers studied, detection methods, variation in sources and types of exposure, sample size, gender differences, and sometimes poor knowledge regarding the alleles, genotypes and haplotypes under study also contribute to the large variability seen in these studies (d'Errico *et al.*, 1999; Hemminki *et al.*, 2001; Alexandrov *et al.*, 2002; Wiencke, 2002).

(c) Cytogenetic biomarkers of genotoxicity

(i) Chromosome aberrations and sister chromatid exchanges

Early studies investigating whether homozygosity for the *GSTM1* null allele affects prevalence of cytogenetic changes in lymphocytes of smokers reported positive results (Seidegård *et al.*, 1990; van Poppel *et al.*, 1992; Cheng *et al.*, 1995). Since then, studies have investigated the association between genetic polymorphisms of xenobiotic-metabolising genes and cytogenetic biomarkers in smokers and in some occupational groups (Rebbeck, 1997; Autrup, 2000; Pavanello & Clonfero, 2000; Norppa, 2003, 2004).

Collectively, the reported findings are in support of increased susceptibility of smokers to chromosomal effects in association with *GSTM1* and *GSTT1* null variants deficient in detoxification of tobacco smoke carcinogens. Exposure to genotoxicants generated from other environmental sources (e.g. polluted air, diet, endogenous sources such as reactive oxygen species) may contribute to the observed associations, and it is likely that other polymorphic metabolic genes such as *NAT2* may be involved (Pavanello & Clonfero, 2000; Norppa, 2001, 2003).

(ii) Micronucleus induction

The relationship between formation of micronuclei and genetic polymorphisms of carcinogen metabolism has been addressed in a wide range of human population studies (Norppa, 2003, 2004). Induction of micronuclei in smokers may be little, if at all, affected by *GSTM1*, *GSTT1* or *NAT2* genotypes. In contrast, the *NAT1* rapid genotype appears to show an association with increased susceptibility to smoking-related micronuclei (Norppa, 2004).

A recent review evaluated more than seventy human studies on genetic polymorphisms and micronucleus frequency detected either in peripheral blood lymphocytes or exfoliated cells in populations exposed to various genotoxic agents. There were no significant genotype effects involved in micronucleus induction in smokers (Iarmarcovai *et al.*, 2008). The relationship between genetic polymorphisms and micronucleus formation is complex, and is influenced to a variable extent by several genes of xenobiotic metabolism and DNA repair, as well as the variety of chromosomal alterations known to contribute to micronucleus formation (Iarmarcovai *et al.*, 2008).

(iii) Chromosomal damage induced in vitro

The effects of genotypes or genotype combinations *in vitro* on the induction of various cytogenetic endpoints by tobacco-smoke carcinogens and their metabolites have been studied, initially focused on the *GSTM1* and *GSTT1* null genotypes (Norppa, 2001, 2004). In a study investigating NNK *in vitro*, lymphocytes from *GSTM1* null donors were more sensitive to induction of chromosomal aberrations and sister chromatid exchanges by NNK than lymphocytes from *GSTM1* positive donors (Salama *et al.*, 1999).

(d) Gene mutations

(i) HPRT mutant lymphocytes

Associations between the frequencies of *HPRT* mutant T-lymphocytes in populations exposed to genotoxic agents, such as smokers, and the polymorphism of xenobiotic-metabolising genes have been studied. In the early studies, positive, weak, or negative associations were reported for *GSTM1* null genotype, and negative findings were published for *NAT2* slow acetylator genotype in occupationally exposed or non-exposed subjects (Rebbeck, 1997; Vineis & Malats, 1999). When healthy, non-smoking and occupationally non-exposed young adults were studied for HPRT mutant frequency and polymorphisms in *CYP1A1*, *GSTM1* and *NAT2* genes, none of these polymorphisms, analysed individually, were found to influence the *HPRT* mutant frequency (Davies *et al.*, 1999). A significant interaction between the *GSTM1* null genotype and *NAT2* slow acetylator was associated with higher mutant frequency, but no other genotype combinations (Davies *et al.*, 1999). Some later studies have reported variable associations between *HPRT* mutant frequency and polymorphisms for either individual genes (*GSTM1*, *GSTT1* or *EPHX1*) or some of the genotypes in combination among exposed (Viezzer *et al.*, 1999; Abdel-Rahman *et al.*, 2001, 2003).

(ii) Mutations of the TP53 gene and other cancer-related genes

Whether the frequency of somatic mutations detected in tumour tissue in cancer-related genes, primarily the *TP53* tumour suppressor gene and *KRAS* oncogene, may be modified by polymorphisms in carcinogen metabolizing genes was first investigated assessing the effects of the *GSTM1* genotype, alone or in combination with other genetic polymorphisms. Several, but not all, such studies showed significant association between *GSTM1* null genotype and either the frequency or type of *TP53* mutations in smoking-induced lung cancer or other cancer type (Rebbeck, 1997; Vineis & Malats, 1999; Autrup, 2000). Fewer studies examined the association between *TP53* mutations and *GSTT1* polymorphism, and some results suggested the involvement of both null genotypes (Vineis & Malats, 1999; Autrup, 2000).

In smokers with non-small cell lung cancer, the risk of mutation was found to be the highest among the homozygous carriers of the *CYP1A1* rare allele *CYP1A1 MspI* (*Ile*^{462}*Val*) who also exhibited the *GSTM1* null genotype (Kawajiri *et al.*, 1996). Similarly, positive associations between *K-RAS* mutations and homozygosity for the *CYP1A1* rare allele were observed; the risk of mutation was enhanced when the *CYP1A1* susceptible genotype was combined with *GSTM1* null genotype (Kawajiri *et al.*, 1996). In another study, also carried out in a Japanese study population, *K-RAS* mutations occurred with greater frequency in lung adenocarcinoma smoking patients and of the *GSTM1* null genotype as compared with the *GSTM1* positive genotype (Noda *et al.*, 2004).

Many of the studies that assessed *NAT2* acetylator genotypes have found non-significant associations with the frequency or type of *TP53* mutation in bladder, lung, or other cancers (Vineis & Malats, 1999; Autrup, 2000). A study on bladder cancer did not find an overall association between *TP53* mutation frequency and *GSTM1*, *GSTT1*, *GSTP1* or *NAT2* genotypes. However, among patients with *TP53* mutations, transversion mutations were more frequent in those with *GSTM1* null genotype as compared to those with GSTM1 positive genotype; no significant associations were found for the *NAT2* gene (Ryk *et al.*, 2005).

In rectal cancer, overall negative results for an association between *TP53* or *KRAS* mutations and *GSTM1* and *NAT2* polymorphisms among smokers and non-smokers exposed to tobacco smoke were found (Curtin *et al.*, 2009). An interaction of second-hand tobacco smoke and *NAT2*

was found in *TP53* mutation positive tumours but not in smokers (Curtin *et al.*, 2009). Earlier, an increased risk of *TP53* transversion mutations among *GSTM1* positive individuals who smoked cigarettes was found in colon cancer (Slattery *et al.*, 2002).

A statistically significant association was observed between the *GSTT1* null genotype and *TP53* mutation status of breast tumour in one study (Gudmundsdottir *et al.*, 2001), while in another larger study none of the genotypes for *CYP1B1*, *GSTM1*, *GSTT1* and *GSTP1* genes alone were associated with somatic *TP53* mutations (Van Emburgh *et al.*, 2008).

In summary, data from various cancer types on the association between genetic polymorphisms of carcinogen-metabolizing genes and somatic mutations of the *TP53* and *K-RAS* genes vary widely and do not permit to conclude (Rebbeck, 1997; Vineis & Malats, 1999; Autrup, 2000).

4.3 Site-specific mechanisms of carcinogenicity of tobacco smoke

4.3.1 Sites with sufficient evidence of carcinogenicity of tobacco smoking

(a) Lung

The conceptual model presented in Section 4.1 (Fig. 4.1) depicts the main mechanistic steps by which cigarette smoke causes cancer. Smokers inhale into their lungs carcinogens which, either directly or after metabolism, covalently bind to DNA, forming DNA adducts (see Section 4.1, Fig. 4.3). Tobacco smoke contains multiple strong lung carcinogens such as NNN, NNK, PAHs, 1,3-butadiene and cadmium. Levels of tobacco smoke-related DNA adducts, mainly ^{32}P-postlabelled aromatic-hydrophobic/PAH-related bulky DNA adducts, in the lung are higher in smokers than in non-smokers (Phillips, 2002; IARC, 2004a; Hecht, 2008). Higher levels of DNA adducts have further been linked to increased risk for cancer in pooled and meta-analyses (IARC, 2004a; Veglia *et al.*, 2008).

Mutations in *TP53* and *K-RAS* genes, two central genes of human carcinogenesis, are more frequently mutated in smokers' lung cancer as compared to lung cancer from non-smokers (DeMarini, 2004; IARC, 2004a; Lea *et al.*, 2007; Ding *et al.*, 2008; see Section 4.1.3). In particular, *TP53* but also to some extent *K-RAS* mutations found in smoking-associated lung tumours exhibit mutational specificity that is consistent with the pattern produced by PAH diol epoxides in experimental studies and different from that observed in non-smokers' lung cancer (Pfeifer *et al.*, 2002; DeMarini, 2004; IARC, 2004a; Le Calvez *et al.*, 2005; Section 4.1.3). Keeping with such exposure-specific mutation profile, lung cancer in non-smokers exposed to second-hand tobacco smoke shows mutational similarity to smokers' lung cancer, although less data are available (Husgafvel-Pursiainen, 2004; IARC, 2004a; Le Calvez *et al.*, 2005; Subramanian & Govindan, 2008). The different pathways of lung carcinogenesis for smokers and non-smokers are likely to involve somatic mutations and other genetic alterations in a larger set of genes that are critical in controlling normal cellular growth via signal transduction (Bode & Dong, 2005; Lea *et al.*, 2007; Ding *et al.*, 2008).

Smoking-related lung carcinogenesis also involves a multitude of other alterations influencing the complex pathogenic pathways involved in lung cancer development, such as increased inflammation, aberrant apoptosis, increased angiogenesis, tumour progression and tumour metastasis (Wolff *et al.*, 1998; Heeschen *et al.*, 2001; Schuller, 2002; West *et al.*, 2003; Smith *et al.*, 2006; Lee *et al.*, 2008b; Section 4.1.5). Continued exposure to toxicants, genotoxicants, carcinogens, co-carcinogens and tumour promoters present in tobacco smoke has major effects on biological processes at all steps of multistep tumourigenesis of human lung (Hecht,

2003, 2008; Section 4.1). For example, nicotine in tobacco smoke is currently not described as a full carcinogen, but it exerts its biological effects via binding to nicotinic and other cellular receptors and likely enhances cell transformation and carcinogenicity through mechanisms not yet defined (Heeschen *et al.*, 2001; West *et al.*, 2003).

Numerous studies have provided evidence that the human genome may contain one or several loci that confer susceptibility to lung cancer. There are low-penetrance genes involved in the metabolism of tobacco smoke carcinogens, DNA repair and cell cycle control that may influence individual susceptibility to lung cancer (Spitz *et al.*, 2006). The role of the polymorphisms of these various classes of genes in lung carcinogenesis requires a systematic evaluation of the genetic evidence with stringent criteria (Ioannidis, 2008; Risch & Plass, 2008; Vineis *et al.*, 2009; Sections 4.1 and 4.2). Recently, genome-wide association studies have identified a susceptibility locus at chromosome 15q25.1 (Amos *et al.*, 2008; Hung *et al.*, 2008; Thorgeirsson *et al.*, 2008). The identity or function of the gene is not yet known, nor is the mechanism through which it may predispose to lung cancer. It is however likely that lung cancer susceptibility is related to the nicotine receptor gene residing at 15q25.1, and there is some evidence suggesting that it may be related to increased uptake of nicotine and NNK per cigarette (Le Marchand *et al.*, 2008).

In addition to genetic alterations, a growing body of evidence shows that epigenetic mechanisms, such as aberrant DNA methylation, histone modifications and RNA-mediated gene silencing are involved in cancer development (Jones & Baylin, 2007; Cortez & Jones, 2008). In lung carcinogenesis, gene promoter-associated (CpG island-specific) hypermethylation is an early and frequent event causing transcriptional inactivation of genes involved in regulation of cellular growth and differentiation (Belinsky, 2004). For example, several studies have indicated that the tumour suppressor gene *p16* ($p16^{INK4a/CDKN2A}$), a cell cycle regulator, is among the genes most frequently inactivated by aberrant methylation in lung cancer from smokers (Belinsky, 2004), with differences seen between smokers and never-smokers (Toyooka *et al.*, 2006). Significant associations have been established between smoking and promoter hypermethylation of tumour suppressor genes in lung tumours from smokers, and in plasma, serum or sputum DNA from cancer-free smokers (Belinsky, 2004; Belinsky *et al.*, 2005, 2006; Toyooka *et al.*, 2006).

(b) Oral cavity

PAHs can be carcinogenic at the site of application, which could include the human oral cavity. DMBA, a highly carcinogenic PAH not present in tobacco or tobacco smoke, is a standard model compound for induction of oral tumours in the hamster cheek pouch; less is known about the effects on the oral cavity of PAHs that do occur in tobacco products (Shklar, 1972; Rao, 1984; Vairaktaris *et al.*, 2008). A mixture of NNN and NNK induced oral tumours in rats when applied locally (Hecht *et al.*, 1986), and DNA adduct formation from NNN, NNK and NNAL has been observed in the rat oral cavity (Zhang *et al.*, 2009a, b). HPB-releasing DNA adducts from NNK and/or NNN have been reported in exfoliated oral cells from smokers and smokeless tobacco users (Heling *et al.*, 2008) and HPB-releasing heamoglobin adducts are elevated in smokeless tobacco users (IARC, 2007a). Unidentified DNA adduct levels are consistently elevated in oral cells and tissues from smokers compared to non-smokers (IARC, 2004a). Mutations in the *TP53* gene have been observed in oral tumours from smokers and smokeless tobacco users (IARC, 2006b, 2007a; Warnakulasuriya & Ralhan, 2007). Tobacco-associated genetic mutations including micronuclei, gene mutations, DNA polymorphisms, and chromosomal abnormalities have been reported in studies of buccal cells from smokers and smokeless tobacco users (Proia *et al.*, 2006). The use of lime by betel quid chewers is associated

with enhanced oxidative damage that could play a role in inflammation or tumour promotion (IARC, 2004b).

(c) Larynx and nasopharynx

Hamsters exposed to cigarette smoke by inhalation consistently developed benign and malignant tumours of the larynx; tumours were produced by inhalation of the particulate phase, but not the gas phase of cigarette smoke (IARC, 1986). In related studies in which hamsters were treated with DMBA by intratracheal instillation followed by exposure to cigarette smoke, a significantly higher incidence of laryngeal tumours was observed than in hamsters exposed only to cigarette smoke or to DMBA (IARC, 1986). Collectively, these results indicate an initiation-promotion mechanism for the production of laryngeal tumours, and are consistent with the results of experiments in which tobacco smoke condensate is applied to mouse skin (IARC, 1986). The combined data implicate PAHs and tumour promoters in tobacco smoke as potential etiologic agents for cancer of the larynx in hamsters. Levels of DNA adducts measured by non-specific methods were higher in larynx tissue from smokers than from non-smokers (IARC, 2004a). Analyses of mutations in the *TP53* gene from tumours of the larynx in smokers show a pattern similar to that observed in lung tumours, and both are consistent with the pattern produced by PAH diol epoxides (IARC, 2006b). The available data are consistent with the conceptual framework illustrated in Fig. 4.1 (Szyfter *et al.*, 1999).

Formaldehyde, a constituent of cigarette smoke, causes nasopharyngeal cancer in humans (IARC, 2006a). A recent study demonstrates a 10-fold higher level of the formaldehyde-DNA adduct N^6-hydroxymethyldeoxyadenosine in leukocytes of smokers compared to non-smokers, suggesting its possible involvement in nasopharyngeal cancer in smokers (Wang *et al.*, 2009). Acetaldehyde, another carcinogenic constituent of tobacco smoke, which also forms genotoxic adducts (Section 4.1), may also contribute to the development of these forms of head and neck cancer.

(d) Oesophagus

Nitrosamines are probably the most effective oesophageal carcinogens known, with particularly strong activity in the rat (Lijinsky, 1992). NNN and NDEA are both present in cigarette smoke, and levels of NNN greatly exceed those of NDEA (IARC, 2004a). NNN is also present in considerable quantities in smokeless tobacco and betel quid containing tobacco (IARC, 2004a, 2007a). Thus, NNN is a likely candidate as a causative agent for esophageal cancer in smokers, smokeless tobacco users, and chewers of betel-quid with tobacco. While considerable mechanistic data are available from studies of NNN in laboratory animals (Hecht, 1998; Wong *et al.*, 2005; Lao *et al.*, 2007; Zhang *et al.*, 2009a), there are little comparable data in humans.

Increased acetaldehyde production derived both from tobacco smoke and from microbial alcohol oxidation may play a role in the synergistic carcinogenic action of alcohol and smoking on oesophagus, as well as on other upper aerodigestive locations (Homann *et al.*, 2000; Salaspuro & Salaspuro, 2004; Lee *et al.*, 2007a).

(e) Stomach

Hypermethylation of the E-cadherin 1 gene (*CDH1*) was observed preferentially in gastric tumours from smokers rather than non-smokers (Poplawski *et al.*, 2008). *CDH1* can act as a tumour-suppressor gene, preventing cells from growing and dividing in an uncontrolled way to form a cancerous tumour. Because the protein encoded by this gene helps cells stick together, altered regulation may lead to metastasis.

Boccia *et al.* (2007) found an increased risk for stomach cancer among smokers who had the *SULT1A1 His* genotype, and Lee *et al.* (2006) found an increased risk for those who had the *m2* allelic variant of *CYP1A1*. A nested case–control

study found that smokers had an increased risk of gastric cancer if they carried at least one variant allele A in Ex7+129 C > A (*Thr*^{461}*Asn*, *m4*) of *CYP1A1* (Agudo *et al.*, 2006). Stomach cancer tissue from smokers had higher levels of stable DNA adducts than did those from non-smokers; however, the number of non-smokers was quite small (Dyke *et al.*, 1992).

(f) Pancreas

NNK and its metabolite NNAL are the only pancreatic carcinogens known to be present in tobacco and tobacco smoke. NNK was detected in the pancreatic juice of 15 of 18 samples from smokers, at levels significantly higher than in non-smokers; NNAL and NNN were also detected in some samples (Prokopczyk *et al.*, 2002). DNA adducts of NNK and NNAL were present in pancreatic tissue of rats treated with these nitrosamines (Zhang *et al.*, 2009b), but were not detected in most human pancreatic tissue samples (Prokopczyk *et al.*, 2005).

(g) Colorectum

Tobacco smoke contains heterocyclic amines, such as 2-amino-1-methyl-6-phenylimidazo[4,5,6]pyridine (PhIP), which are intestinal carcinogens in rats and mutate the adenomatous polyposis coli (*Apc*) gene in mice (Møllersen *et al.*, 2004). The *APC* gene is frequently mutated and has altered expression in human colon cancer (Samowitz *et al.*, 2007; Samowitz, 2008). A recent model of colon cancer by Sweeney *et al.* (2009) suggests that this disease can develop via at least three independent mechanistic pathways. One pathway is initiated by methylation of *MINT* (methylation in tumour) markers that proceeds down a pathway predisposing to microsatellite instability, followed by methylation of the mismatch repair gene mutL homologue 1 (*MHL1*) and the tumour-suppressor gene *TP16,* followed by mutation in *BRAF* (a homologue of a viral raf oncogen). A second independent pathway is initiated with a mutation in the *APC* gene, followed by a mutation in the *TP53* gene. A third independent pathway involves only *KRAS2* mutations. One study found BPDE-DNA adducts at a higher frequency in colon DNA from smokers than from non-smokers (Alexandrov *et al.*, 1996). Mutations or epigenetic changes in some or all of these genes have been found in smoking-associated colon or colorectal tumours.

Microsatellite instability, which is the expansion or contraction of short nucleotide repeats, occurs in approximately 10–15% of sporadic colorectal cancer, and is usually associated with smoking and hypermethylation of the promoter of the mismatch repair gene *MLH1* (Samowitz, 2008). Smoking-associated colorectal tumours also have high frequencies of methylation at CpG islands (Samowitz, 2008).

In a case–control study of colorectal cancer, Kasahara *et al.* (2008) found that the genetic polymorphism *APEX1/APE1* (apurinic/apyrimidinic endonuclease-1) Asp^{148}Glu, which is a gene involved in DNA repair, was associated with risk for colorectal cancer among smokers but not non-smokers. Other studies have also found associations between polymorphisms in the DNA repair genes *XRCC1* and smoking and risk for colorectal cancer (Stern *et al.*, 2007; Campbell *et al.*, 2009).

(h) Liver

Tobacco smoke contains liver carcinogens such as furan and certain nitrosamines. Liver tumours exhibit increased expression of *C-MYC, P16*^{INK4A}, epidermal growth factor receptor (*EGFR*), telomerase, transforming growth factor-*α* (*TGF-α*), insulin-like growth factor-2 (*IGF-2*) and *RAF* oncogene (Abou-Alfa, 2006). Smokers show altered expression of some of these genes or of genes in the same or similar pathways (Sen *et al.*, 2007). A genome-wide association study found that SNP rs1447295 in the 8q24 chromosome was positively associated with liver cancer among ever-smokers (Park *et al.*, 2008). Thus, tobacco smoke appears to have epigenetic

effects on the liver that may contribute to hepatocellular carcinoma.

(i) Urinary bladder

Tobacco smoke contains aromatic amines such as 4-aminobiphenyl and 2-naphthylamine, which are human bladder carcinogens (see IARC, 2012a). In bladder tumours, smoking was associated with a more than twofold increase risk of methylation of the promoter region of the *P16*^{INK4A} gene and of the soluble Frizzled receptor protein (*SFRP*) gene (Marsit *et al.*, 2006). In addition, Tang *et al.* (2009) suggested that epigenetic silencing of *Wnt* antagonists through hypermethylation may play a role in smoking-related invasive bladder cancer (Tang *et al.*, 2009). SNP rs6983267 of the 8q24 chromosome was inversely associated with bladder cancer among ever-smokers (Park *et al.*, 2008). Smokers generally have mutagenic urine and smoking is associated with specific cytogenetic changes and DNA breaks in bladder tumours (DeMarini, 2004). Smoking-associated stable DNA adducts have been found in bladder tissue or exfoliated urothelial cells, supporting a role for DNA damage in smoking-associated bladder cancer (Phillips, 2002).

(j) Cervix

The cervical mucus of smokers is more mutagenic than that of non-smokers, and cervical epithelia of smokers have higher frequencies of micronuclei than those of non-smokers (DeMarini, 2004). Several studies have found increased levels of DNA adducts in cervical tissue from smokers relative to non-smokers, suggesting a role for smoking-associated DNA damage in cervical cancer (Phillips, 2002).

(k) Ovary

It has been observed that the inverse associations reported for serous and endometrioid tumours with respect to parity and oral contraceptives did not hold for the mucinous tumours. Based on these observations, Risch *et al.* (1996) suggested that mucinous ovarian tumours may be etiologically unrelated to the other types of epithelial tumours. Whereas mucinous elements such as gastric or intestinal type glands may be seen in mature teratomas, a form of germ cell neoplasia, overall mucinous tumours are classified as surface epithelial tumours because transitions among the subtypes may be observed. The major difference between mucinous and serous tumours is their biologic behaviour. Mucinous carcinomas of the ovary are slow growing tumours that appear to develop from their benign counterparts. The fact that the transitions between the benign, borderline, and malignant form of the disease can be seen in the same tumour suggests that over time, there is a progression from benign to malignant (Riopel *et al.*, 1999). *K-ras* mutational analysis, for example, demonstrates a heterogeneous distribution of the mutation within different parts of the same neoplasm, suggesting that acquisition of the *K-ras* mutation occurs in malignant transformation (Mandai *et al.*, 1998). Serous carcinomas seem to develop de novo rather than from a benign pre-existing lesion; alternatively, the rate of progression is rapid and the precursor lesion is obliterated before the detection of the tumour. In some data, current smoking is associated with a shorter interval to detection of mucinous than non-mucinous tumours. Because the mucinous tumour is slow growing, smoking could contribute to the malignant progression of the adenoma-carcinoma sequence, as the benign form of the tumour may have been present for some time.

(l) Leukaemia

Tobacco smoke contains known leukaemogens such as benzene, 1,3-butadiene and formaldehyde (IARC, 2012a). The mechanisms of leukaemogenesis are currently not well understood. Data indicate that leukaemogenic agents, such as benzene, cause toxicity to the

haemotopoietic system, as well as genotoxicity at low levels, and that genetic polymorphisms may be involved in these processes (Aksoy, 1989; Lan *et al.*, 2004; Garte *et al.*, 2008; Hosgood *et al.*, 2009; Lau *et al.*, 2009; Rappaport *et al.*, 2009). Recent studies suggest the importance in carcinogen-related leukaemogenesis of damage to haematopoietic stem/progenitor cells circulating in the peripheral blood, or, alternatively, damage to primitive pluripotent progenitor cells present in other tissues (Zhang *et al.*, 2009c). In these two models, damaged stem/progenitor cells would then travel to the bone marrow and become initiated leukaemic stem cells. Mechanisms considered central in these models are: disruption of bone marrow DNA, through e.g. formation of DNA adducts, DNA–protein crosslinks, the action of free radicals or active states of oxygen; intercalation of metals within the DNA structure; or inhibition of enzymes involved in cell division (Zhang *et al.*, 2007, 2009c).

4.3.2 Sites with limited evidence of carcinogenicity or evidence suggesting lack of carcinogenicity

(a) Breast

(i) Carcinogenic pathway

Carcinogens found in tobacco smoke pass through the alveolar membrane and into the blood stream, by means of which they can be transported to the breast via plasma lipoproteins (Yamasaki & Ames, 1977; Shu & Bymun, 1983; Plant *et al.*, 1985). Tobacco smoke contains known rodent mammary carcinogens, including PAHs and aromatic amines (IARC, 1986, 2004a; el-Bayoumy, 1992; Ambrosone & Shields, 1999; Ambrosone, 2001; Hoffmann *et al.*, 2001) which, due to their lipophilicity, can be stored in breast adipose tissue (Obana *et al.*, 1981; Morris & Seifter, 1992) and then metabolized and activated by human mammary epithelial cells (MacNicoll *et al.*, 1980). Tobacco smoke constituents reach the breast as demonstrated by the detection of cotinine in breast fluid (Petrakis *et al.*, 1978). There is evidence suggesting the presence of mutagenic arylamines (Thompson *et al.*, 2002) and PAHs (Zanieri *et al.*, 2007) in human breast milk. Cigarette smoke condensate has been shown to transform normal human breast epithelial cells *in vitro* (Narayan *et al.*, 2004), perhaps by blocking long-patch base excision repair (Kundu *et al.*, 2007). Transformation and cytogenetic effects have been observed in human mammary epithelial cells after exposure to chemical carcinogens such as PAHs or arylamine (Mane *et al.*, 1990; Eldridge *et al.*, 1992; Calaf & Russo, 1993).

The formation of specific adducts from PAHs and aromatic amines has been observed in human breast epithelial cells *in vitro*, and unspecified-DNA adducts have been found in exfoliated ductal epithelial cells in human breast milk (Gorlewska-Roberts *et al.*, 2002; Thompson *et al.*, 2002).

Mutations in the *TP53* tumour suppressor gene have been found in 15–30% of breast cancers (Goldman & Shields, 1998; Olivier & Hainaut, 2001). An increased prevalence and altered spectrum of *TP53* mutations in breast tumours have been observed among current smokers compared with never smokers (Conway *et al.*, 2002). The breast tumours with the most pronounced smoking-related mutational pattern (for example, a greater number of G:C→T:A transversions) were from women who had smoked for more than 20 years, although total *TP53* mutations were not associated with smoking duration (Conway *et al.*, 2002). This increased frequency of G to T transversions in smokers versus non-smokers is also observed in the IARC TP53 database (IARC, 2006b; Van Emburgh *et al.*, 2008).

Recent meta-analyses of epidemiological studies tend to show positive associations of breast cancer with long-term smoking among *NAT2* slow acetylators, especially among post-menopausal women (who are more likely than pre-menopausal women to be very long-term

smokers). Firozi *et al.* (2002) showed that breast tissue from *NAT2* slow acetylators had significantly higher levels of the diagonal radioactive zone (smoking-related) DNA adduct pattern than that from fast acetylators.

High rates of breast cancer in women exposed to ionizing radiation during adolescence (aged 10–19 years at exposure) (Tokunaga *et al.*, 1987) suggested that the adolescent breast may also be sensitive to the DNA-damaging effects of other exposures. This might also be true for the genotoxic compounds contained in tobacco smoke. Although some studies have supported such association, the results have been sparse and mixed. In addition, it is difficult to separate the effects of early life exposure to tobacco and smoking duration (Terry & Rohan, 2002).

Early age at first full-term pregnancy has been associated with reduced breast cancer risk (Kelsey *et al.*, 1993), hypothetically due to terminal differentiation of the breast epithelium that occurs late in the first trimester. It has been suggested that in the early stages of pregnancy, when growth-promoting hormone levels are high, but before terminal differentiation (Montelongo *et al.*, 1992), the breast may be particularly susceptible to the cancer-promoting chemicals in tobacco smoke. Several epidemiological studies compared measures of smoking before and after a first full-term pregnancy. Although suggestive, the data did not consistently show an increased risk for breast cancer among women who smoked before a first full-term pregnancy (Adami *et al.*, 1988; Hunter *et al.*, 1997; Band *et al.*, 2002; Egan *et al.*, 2003; Gram *et al.*, 2005; Li *et al.*, 2005; Olson *et al.*, 2005; Cui *et al.*, 2006). Smoking was associated with a 50% increased risk among women with slow *NAT2* acetylation genotype (Egan *et al.*, 2003). Overall, studies of risk in association with the timing of smoking relative to a first pregnancy are inconclusive; nevertheless, the breast tissue appears to have a greater susceptibility to the carcinogenic chemicals in tobacco smoke before compared to after terminal differentiation of breast epithelium.

(ii) Estrogenic pathway

The "anti-estrogenic" mechanism through which tobacco smoking may inhibit breast cancer progression is unclear. Estrogen is a known risk factor for breast cancer and several hypotheses have been proposed: earlier age at menopause among smokers, a reduction in the gastrointestinal absorption or distribution of estrogen, enhanced metabolism of estradiol to inactive catechol estrogens, increased binding of estrogens by serum sex hormone-binding globulin, lowered levels of estrogen derived from adipose tissue (Baron, 1984; Baron *et al.*, 1990; Terry & Rohan, 2002). Several studies of cigarette smoking and mammographically-defined breast density showed lower measures of breast density in current smokers than in non-smokers (Sala *et al.*, 2000; Vachon *et al.*, 2000; Warwick *et al.*, 2003; Jeffreys *et al.*, 2004; Modugno *et al.*, 2006; Bremnes *et al.*, 2007; Butler *et al.*, 2008). Since exposure to estrogen has been associated positively with breast density, a strong risk factor for breast cancer (McCormack & dos Santos Silva, 2006), the results of these studies are consistent with an anti-estrogenic effect of cigarette smoking. Although smokers and non-smokers may have the same concentrations of estrogens overall, it may be the type rather than the absolute levels of circulating estrogens that is important. Smokers might have a lower concentration of more biologically active estrogens, primarily 16-α-hydroxyestrone (16α-OHE1) (Michnovicz *et al.*, 1986, 1988; Berta *et al.*, 1992; Berstein *et al.*, 2000; Terry *et al.*, 2002b). Estrogen can be metabolized along three pathways, to 16α-OHE1 or to 2-OHE1 or to 4-OHE1. 16α-OHE1 and 4-OHE1 have been observed to increase mammary epithelial cell proliferation rates in experimental studies (Schütze *et al.*, 1993, 1994; IARC, 2007c). In contrast, 2-OHE1 might decrease epithelial cell proliferation rates (Bradlow *et al.*, 1996;

Muti *et al.*, 2000). If cigarette smoking increases estradiol 2-hydroxylation, as has been suggested (Michnovicz *et al.*, 1986), thereby increasing the ratio of 2-OHE1:16-α-OHE1, an inverse association between smoking and breast cancer risk might be observed. However, only one study has directly examined 2-hydroxylation in relation to cigarette smoking (Michnovicz *et al.*, 1986). Using injected radiolabelled estradiol, a 50% increased estradiol 2-hydroxylation was found in premenopausal women who smoked at least 15 cigarettes/day compared with non-smokers. Two studies of urinary estrogens found increased excretion of 2-OHE1 and decreased excretion of estriol among smokers (Michnovicz *et al.*, 1988; Berstein *et al.*, 2000), which may also support the hypothesis that smoking decreases the formation of active estrogen metabolites along the 16α-hydroxylation pathway. However, the ratio of urinary 2-OHE1:16α-OHE1 was not related to breast cancer risk in the one case–control study that examined the association (Ursin *et al.*, 1999). The 4-hydroxylation of estrogens is catalysed by CYP1B1, which is induced by tobacco smoke (Nebert *et al.*, 2004). This has been postulated as an additional pathway that could lead to formation of DNA adducts via catechol estrogen-quinones (Gaikwad *et al.*, 2008) and oxidative/DNA damage via redox-cycling (Zhu & Conney, 1998). The ratio of 2-OHE1:4-OHE1 has been studied in relation to breast cancer risk and smoking in one study (Berstein *et al.*, 2000). Smokers carrying the *CYP1B1 Val* allele [associated with high hydroxylation activity] had a significantly higher risk for breast cancer compared to never smokers with the *Leu/Leu* [wildtype] genotype (Saintot *et al.*, 2003).

(b) Endometrium

Exogenous estrogens unopposed by progesterone have been shown to increase the risk for endometrial cancer through increased mitotic activity of endometrial cells, increased number of DNA replication errors, and somatic mutations resulting in the malignant phenotype (IARC, 2007c, 2012c). Hence, factors associated with estrogen absorption or metabolism may alter the risk of this malignancy. Several investigators have hypothesized that cigarette smoking might be have anti-estrogenic effects, and through this mechanism reduce the risk of endometrial cancer (Baron, 1984; Baron *et al.*, 1990; Terry *et al.*, 2002b, 2004a).

Whether mediated through changes in the amount of adipose tissue, altered age at menopause, or anti-estrogenic effects, blood hormone concentrations might be an important link between smoking and the reduced risk of endometrial cancer observed in most epidemiological studies. The estrogens that have typically been studied in relation to cigarette smoking include estrone, sex hormone binding globulin (SHBG)-bound estradiol, and estriol. Blood concentrations of androgens, typically androstenedione and dehydroepiandrosterone sulfate (DHEAS), have also been studied, because these are biological precursors of estrone. Studies that have examined blood concentrations of SHBG are less common, and studies of unbound (free) estradiol are scarce.

Studies of cigarette smoking and blood hormone concentrations have been conducted mostly among post-menopausal women who were not taking HRT. Of these studies, nine examined serum (Friedman *et al.*, 1987; Cauley *et al.*, 1989; Slemenda *et al.*, 1989; Schlemmer *et al.*, 1990; Cassidenti *et al.*, 1992; Austin *et al.*, 1993; Law *et al.*, 1997) or plasma (Khaw *et al.*, 1988; Longcope & Johnston, 1988) estrone, ten examined serum (Friedman *et al.*, 1987; Cauley *et al.*, 1989; Slemenda *et al.*, 1989; Schlemmer *et al.*, 1990; Key *et al.*, 1991; Cassidenti *et al.*, 1992; Austin *et al.*, 1993; Law *et al.*, 1997) or plasma (Khaw *et al.*, 1988; Longcope & Johnston, 1988) estradiol, and two examined serum (Cassidenti *et al.*, 1992) or plasma (Longcope & Johnston, 1988) free estradiol. These studies consistently showed little or no association between smoking

and blood estrogen concentrations among post-menopausal women who were not taking hormone replacement therapy. Among pre-menopausal women, three studies (Longcope & Johnston, 1988; Key *et al.*, 1991; Berta *et al.*, 1992) found no clear association between cigarette smoking and estrogen concentrations. Studies that adjusted hormone measurements for the effects of BMI (and other covariates) showed similar results to those that did not, suggesting that BMI is not a strong confounder of this association.

In two studies the association between cigarette smoking and blood estrogen concentrations after randomization of women to groups receiving either estradiol or placebo were examined (Jensen & Christiansen, 1988; Cassidenti *et al.*, 1990). In a small study of 25 post-menopausal women, unbound estradiol was significantly lower among smokers than non-smokers both at baseline and shortly after taking micronized estradiol orally (Cassidenti *et al.*, 1990). No important differences were observed between smokers and non-smokers in serum concentrations of either estrone or bound estradiol. In contrast, in a study in which 110 post-menopausal women were randomized to take hormones (either orally or percutaneously) or a placebo (Jensen & Christiansen, 1988), smokers had lower concentrations of both estrone and bound estradiol than non-smokers after oral (but not percutaneous) hormone treatment for at least one year (concentrations of free estrogens were not examined). These results indicate that smoking might affect the absorption or metabolism of hormones used in replacement therapy.

Of the five studies that have examined the association between cigarette smoking and serum (Lapidus *et al.*, 1986; Cassidenti *et al.*, 1992; Law *et al.*, 1997) or plasma (Khaw *et al.*, 1988; Longcope & Johnston, 1988) SHBG, none found any clear association. However, one of these studies (Khaw *et al.*, 1988) found an inverse association between smoking and the ratio of bound estradiol to SHBG, a measure of estrogen activity. In this context, Cassidenti *et al.* (1990) found unbound (but not SHBG-bound) estradiol was significantly lower among smokers than non-smokers both at baseline and after taking oral estradiol, suggesting an increased SHBG-binding capacity in the women who smoked.

In post-menopausal women, androgens are the major source of estrone, converted through aromatization in fat deposits. Thus, adiposity is positively correlated with estrogen concentrations in post-menopausal women. Of the nine studies in which blood concentrations of androstenedione were examined in smokers (Friedman *et al.*, 1987; Khaw *et al.*, 1988; Longcope & Johnston, 1988; Cauley *et al.*, 1989; Slemenda *et al.*, 1989; Schlemmer *et al.*, 1990; Cassidenti *et al.*, 1992; Austin *et al.*, 1993; Law *et al.*, 1997), higher circulating concentrations were found among current than among never or former smokers in all studies. However, there was no clear variation in blood estrone concentrations by smoking status, suggesting a reduced conversion of androstenedione to estrone among smokers. Of the five studies where cigarette smoking and DHEAS concentrations were examined, three (Khaw *et al.*, 1988; Cassidenti *et al.*, 1992; Law *et al.*, 1997) found increased blood concentrations among current smokers, one (Friedman *et al.*, 1987) found also an increase that was not statistically significant, whereas another (Key *et al.*, 1991) found no clear differences according to smoking status.

Cigarette smoking and urinary estrogen concentrations have been examined in seven studies (MacMahon *et al.*, 1982; Michnovicz *et al.*, 1986; Trichopoulos *et al.*, 1987; Michnovicz *et al.*, 1988; Berta *et al.*, 1992; Key *et al.*, 1996; Berstein *et al.*, 2000). Of these, three found no major differences according to smoking status (Trichopoulos *et al.*, 1987; Michnovicz *et al.*, 1988; Berta *et al.*, 1992). The remaining four studies all showed lower urinary estriol concentrations among smokers than among non-smokers, but mixed results for urinary estrone and estradiol.

Two of these studies (Michnovicz *et al.*, 1988; Berstein *et al.*, 2000) showed higher concentrations of 2-hydroxyestrone among smokers, than non-smokers but only after estrogen treatment in Berstein *et al.* (2000).

Age at natural menopause varies substantially under the influence of genetic and environmental factors (McKinlay, 1996). A relatively early age at menopause has been associated with reduced risk of endometrial cancer (Kelsey *et al.*, 1982; Baron, 1984; Baron *et al.*, 1990; Akhmedkhanov *et al.*, 2001). A one year decrease in age at menopause has been associated approximately with a 7% decrease in risk (Kelsey *et al.*, 1982). It has been proposed that cigarette smoking decreases the age at natural menopause (Baron *et al.*, 1990), more clearly with qualitative than quantitative smoking measures (Parente *et al.*, 2008), and thus might reduce endometrial cancer risk through reduced exposure to endogenous estrogens. On average, smokers have menopause approximately 1 to 1.5 years earlier than non-smokers (Terry *et al.*, 2002b, 2004a). Adjustment for obesity and other covariates did not alter the results (Terry *et al.*, 2002b).

4.4 Mechanistic considerations of the interaction of ethanol and tobacco carcinogens

The combined effects of alcoholic beverages and tobacco on the risk for cancer incidence and mortality have been widely studied in human populations. When tested for multiplicative and additive interactions, synergistic effects of alcoholic beverages and tobacco have been found, especially for oropharyngeal and oesophageal cancers (Homann *et al.*, 2000; Castellsagué *et al.*, 2004; Salaspuro & Salaspuro, 2004; Lee *et al.*, 2005a; Lee *et al.*, 2007b).

Data support at least four possible mechanisms for the modifying effects of alcoholic beverages on cancer risk due to tobacco.

1. Alcohol may have a local permeabilizing effect on penetration of the oral mucosa by tobacco carcinogens (Du *et al.*, 2000), particularly important in the case of oropharyngeal and oesophageal cancer.
2. CYP2E1 and other CYPs may both activate and detoxify carcinogens present in tobacco smoke, including NDMA, NDEA, NNK, benzene and other tobacco-derived carcinogens in two ways: CYP induction increases metabolic activation of tobacco carcinogens leading to enhanced formation of proximate reactive chemical species at target sites; and alteration of phase II conjugation/detoxification enzymes by ethanol may also occur, changing the effective dose at the target site.
3. Competitive inhibition of CYP metabolism leads to reduced central hepatic and gastrointestinal clearance thus increasing dose delivery of carcinogens to peripheral target tissues (reviewed in Meskar *et al.*, 2001).
4. Effects of acetaldehyde derived by microbial alcohol oxidation and from the tobacco smoke (Homann *et al.*, 2000; Salaspuro & Salaspuro, 2004).

Supportive evidence for ii) and iii) is briefly presented below.

4.4.1 Effects of induction of CYPs by ethanol

(a) CYP2E1

Ethanol induces CYP2E1 in the human liver and in all species tested. Over 70 substrates of CYP2E1 have been compiled (Raucy & Carpenter, 1993; Guengerich *et al.*, 1994; Djordjević *et al.*, 1998; Klotz & Ammon, 1998; Cederbaum, 2006). Among those are tobacco carcinogens such as benzene, vinyl chloride, NDMA, NDEA and *N*-nitrosopyrrolidine, as well as many low-molecular-weight compounds. Induction of CYP2E1 by ethanol generated increased levels of toxic metabolites from the metabolism of many of these chemicals (Novak & Woodcroft, 2000). Pyridine, a constituent of tobacco smoke and

substrate of CYP2E1, generates DNA damaging products by redox-cycling (Kim & Novak, 1990).

In humans, in addition to the prominent CYP2E1 expression in the centrilobular regions of the liver, the enzyme is also detectable in the kidney cortex and, at lower levels, in organs such as the oropharynx, nasal mucosa, ovary, testis, small intestine, colon and pancreas (Ingelman-Sundberg *et al.*, 1994; Lieber, 1999, 2004).

In rats, ethanol induced CYP2E1 in epithelia of the cheek, tongue and oesophagus (Shimizu *et al.*, 1990). As a result of CYP2E1 induction by ethanol in the upper respiratory tract and possibly of inhibition of carcinogen clearance, hamsters had a significant increase of nasal cavity and tracheal tumours after intraperitoneal injection of *N*-nitrosopyrrolidine (McCoy *et al.*, 1981). Thus, induction of CYP2E1 by ethanol may participate in the genesis of cancers at several sites via metabolic activation of tobacco carcinogens into reactive species in target tissues.

(b) Other xenobiotic-activating CYPs

In addition to CYP2E1, several CYPs, including CYP3A4 and probably CYP1A2 in humans, and CYP1A1, 2B1 and 3A in rat liver, may be induced by ethanol. Of particular interest are members of the CYP3A family, which have wide substrate specificity and have been implicated in the activation of several known or suspected human carcinogens, including those derived from tobacco (Wojnowski & Kamdem, 2006). Both CYP3A4 and CYP1A2 metabolize NNK (Jalas *et al.*, 2005). Based on the Michaelis constant (Km) data (IARC, 2007a), the relative efficiencies in NNK metabolism by human CYP are (from greatest catalyst to least): 2A13 > 2B6 > 2A6 > 1A2 ~1A1 > 2D6 ~2E1 ~3A4. As the amount of CYP enzymes with overlapping substrate specificity that participate in nitrosamine metabolism varies according to organ and species, it is difficult to determine their individual contribution at target sites.

4.4.2 Effects of inhibition of CYPs by ethanol

Ethanol is a competitive inhibitor of CYP2E1 (reviewed in Anderson, 1992). It also inhibits the activities of CYP1A1, 2B6 and 2C19 but not those of CYP1A2.

Direct inhibition of CYPs by ethanol in target tissues may reduce metabolic activation of xenobiotics and hence local toxic and tumorigenic effects. Thus CYP inhibition in the liver could increase extrahepatic exposure to genotoxic metabolites from tobacco carcinogens that are substrates for these CYP enzymes. This mechanism is supported by several studies.

Ethanol caused a fivefold increase in oesophageal DNA adducts in rats induced by NDEA (Swann, 1984). In monkeys, O^6-methylguanine-DNA adducts after an oral dose of NDMA with or without ethanol were increased by co-exposure to ethanol in all tissues except the liver (Anderson *et al.*, 1996). Effects were seen in the oesophagus (17-fold increase), colonic mucosa (12-fold), pancreas (sixfold), urinary bladder (11-fold), ovary (ninefold), uterus (eightfold), brain (ninefold), spleen (13-fold) and nasal mucosa (fivefold). In these studies, ethanol treatment was acute, so that enzyme induction was improbable, and the oesophagus was not directly exposed to either ethanol or carcinogen. This indicates that a systemic interaction, most likely inhibition of hepatic carcinogen clearance, was responsible for the observed effects in the oesophagus and other extrahepatic tissues. The 17-fold increase in DNA adducts in the monkey oesophagus is similar to the 18-fold increased risk for human oesophageal cancers in tobacco smokers combined with heavy alcohol drinking (Tuyns *et al.*, 1977).

The relevance of increased genotoxic effects in extrahepatic target sites by ethanol is confirmed by many rodent experiments. Oral dosing of mice with NDMA in ethanol resulted in nasal cavity tumours (olfactory neuroblastoma) that were not seen with NDMA or ethanol alone (Griciute

et al., 1981). Ethanol in the drinking-water led to a ninefold increase in oesophageal tumours in rats induced by NDEA (Aze *et al.*, 1993). Ethanol given by gavage to nursing dams together with NDMA or NNK (Chhabra *et al.*, 2000) increased O^6-methylguanine-DNA adducts in maternal mammary glands, by 10-fold with NDMA and to a lesser extent with NNK. In the suckling infants, DNA adducts were detected in the lungs and kidneys after maternal exposure to NDMA and increased about fourfold after maternal co-treatment with ethanol. In mice, ethanol given with NDMA in the drinking-water resulted in a fourfold increase in lung tumours, but had no significant effect when NDMA was given intragastrically, intraperitoneally, subcutaneously or intravenously (Anderson, 1992). These negative findings support that direct inhibition of hepatic carcinogen clearance by ethanol is the main operative mechanism.

There is indirect evidence that ethanol can inhibit the *in vivo* clearance of the carcinogen NDMA in humans: individuals with chronic renal failure showed detectable blood and urine levels of NDMA, which were increased by consumption of ethanol (Dunn *et al.*, 1990). Other studies that involved sources of NDMA from tobacco smoke, diet or pharmaceuticals are consistent with ethanol reducing its clearance rate in humans (Anderson, 1992).

Other possible modifying effects of ethanol in tobacco-related tumorigenesis are presented in Section 4 of the *Monograph* on Consumption of Alcoholic Beverages in this Volume.

4.5 Synthesis

4.5.1 Mechanisms of tobacco-related carcinogenesis

The pathways by which tobacco products cause cancer essentially recapitulate established mechanisms of carcinogenesis by individual compounds, which were elaborated by landmark studies during the second half of the 20th century. These studies demonstrate that most carcinogens, either directly or after metabolism catalyzed by multiple cytochrome P450 enzymes, react with nucleophilic sites in DNA to form covalent binding products called adducts (a contraction for "addition products"). These DNA adducts, if left unrepaired by cellular DNA repair enzymes, persist and cause mistakes during DNA replication leading to incorporation of the wrong base in a DNA strand and consequent permanent mutations. If these permanent mutations occur in important regions of critical growth control genes such as the oncogene *KRAS* or the tumor suppressor gene *p53*, cellular growth processes can become severely unregulated and cancer can result. Multiple studies of mutations in *KRAS*, *p53*, and other growth control genes in lung tumours from smokers, some of which report thousands of mutations, are fully consistent with this overall concept.

It is the complexity of tobacco carcinogenesis which challenges investigators to identify specific mechanisms that fully explain the ways in which tobacco products cause each type of cancer. There are over 70 established carcinogens in cigarette smoke, and analyses of smokers' urine and blood clearly demonstrate higher uptake of these compounds in smokers than in non-smokers. The urine of smokers is consistently mutagenic. Similar considerations apply to smokeless tobacco users, although there are fewer identified carcinogens. Multiple DNA adducts are present in the lungs and other tissues of smokers, and sister chromatid exchanges as well as other genetic effects are consistently observed. But much less is known about the specifics of the process. Only relatively few DNA adducts in smokers' lungs have been structurally characterized and the relationship between specific adducts and the consequent mutations in critical genes is still somewhat unsettled.

There are other processes which contribute to cancer induction by tobacco products, based on

multiple studies in both laboratory animals and humans. These include inflammation, tumor promotion, oxidative damage, co-carcinogenesis, and direct activation of cellular growth pathways by constituents of smoke. Many studies demonstrate the involvement of these processes in tobacco carcinogenesis but the details by which they interact with the DNA damage pathways and their roles in specific cancers caused by tobacco products are still not fully understood.

4.5.2 Genetic polymorphisms

Multiple studies have been carried out on the role of genetic polymorphisms of xenobiotic metabolism in smoking-related carcinogenesis in humans. These studies have covered various cancer types, with lung cancer representing one of the most intensively studied. The polymorphic genes, their variant forms, and the genotype combinations investigated in these studies have similarly been numerous. In addition to the associations with increased risk of cancer, much data have accumulated on relationships between the polymorphisms and the various biomarkers of tobacco carcinogenesis in non-cancer control populations, whether smokers or non-smokers, in subjects with work-related exposure or in patients with other cancers.

Despite the massive body of research, many observations remain ambiguous. Some associations between genetic polymorphism and increased risk for cancer, such as for the *GSTM1* null genotype, alone or in combination with *CYP1A1* polymorphism, in lung cancer, or the *NAT2* slow acetylator genotype in bladder cancer and breast cancer appear stronger and more consistent, but not without controversies. Similarly, the data on the various biomarkers of tobacco-related carcinogenesis exhibit inconsistencies.

The variability in the data is at least partially likely due to differences between the studies in the genes and gene variants included (many of which are still of unknown functional or regulatory consequence), in the types of cancer studied, in levels and sources of exposure, in ethnic backgrounds, in sex, in histological types and in the features of the genome such as haplotype blocks and copy number variation resulting in linkage disequilibrium. In addition, gene-gene interactions and gene-environment interactions are likely to contribute to the discrepancies in current data. Mechanisms of tobacco-related carcinogenesis also involve genes from numerous other classes, such as those encoding for DNA repair proteins and many other regulators of cell cycle and growth. In addition; there are well described mechanistic pathways of carcinogenesis mediated via epigenetic alterations and genetic instability, to mention a few.

4.5.3 Site-specific mechanisms

The Working Group reviewed the mechanistic evidence relative to specific target sites for which there is sufficient evidence of carcinogenicity in humans, i.e. lung, oral cavity, oesophagus, larynx and nasopharynx, pancreas, stomach, liver, urinary bladder, leukaemia, cervix and ovary. Genotoxic effects have been found in eight organ sites at which tobacco smoke causes cancer in humans (DeMarini, 2004).

Sites with limited evidence of carcinogenicity or evidence suggesting lack of carcinogenicity in humans include the breast and the endothelium and relevant mechanisms are presented below.

Breast — There are several plausible mechanisms by which smoking may increase breast cancer risk, and some data support such an effect, including the increased risk among long-term smokers with *NAT2* slow genotype. Despite the overall lack of clear association in epidemiological studies, and the potential anti-estrogenic effects of smoking, the possibility that smoking increases breast cancer risk is biologically plausible.

Endothelium — The mechanisms by which cigarette smoking reduces the risk for endometrial cancer among current smokers, mainly among postmenopausal, remain unclear.

4.5.4 Interaction of ethanol and tobacco carcinogens

Data in rodents and non-human primates on the relationships between a) inhibition of hepatic clearance of nitrosamines by ethanol, b) the formation of promutagenic DNA adducts and c) tumours in extra-hepatic targets, likely also pertain in humans.

5. Evaluation

There is *sufficient evidence* in humans for the carcinogenicity of tobacco smoking.

Tobacco smoking causes cancers of the lung, oral cavity, naso-, oro- and hypopharynx, nasal cavity and accesory sinuses, larynx, oesophagus, stomach, pancreas, colorectum, liver, kidney (body and pelvis), ureter, urinary bladder, uterine cervix and ovary (mucinous), and myeloid leukaemia. Also, a positive association has been observed between tobacco smoking and cancer of the female breast. For cancers of the endometrium (post-menopausal) and of the thyroid, there is *evidence suggesting lack of carcinogenicity*.

There is *sufficient evidence* in humans for the carcinogenicity of parental smoking. Parental smoking causes hepatoblastoma in children. Also, a positive association has been observed between parental smoking and childhood leukaemia (particularly acute lymphocytic leukaemia).

There is *sufficient evidence* in experimental animals for the carcinogenicity of tobacco smoke and of tobacco smoke condensates.

Tobacco smoking is *carcinogenic to humans (Group 1)*.

SECOND-HAND TOBACCO SMOKE

Second-hand tobacco smoke was considered by a previous IARC Working Group in 2002 as "involuntary smoking" (IARC, 2004). Since that time, new data have become available, these have been incorporated into the *Monograph*, and taken into consideration in the present evaluation.

1. Exposure Data

Second-hand tobacco smoke comprises the smoke released from the burning tip of a cigarette (or other burned tobacco product) between puffs (called sidestream smoke (SM)) and the smoke exhaled by the smoker (exhaled mainstream smoke (MS)). Small additional amounts are contributed from the tip of the cigarette and through the cigarette paper during a puff, and through the paper and from the mouth end of the cigarette between puffs (Jenkins *et al.*, 2000).

Second-hand tobacco smoke is also referred as 'environmental tobacco smoke', 'passive smoking' or 'involuntary smoking' (IARC, 2004). The terms 'passive smoking' or 'involuntary smoking' suggest that while involuntary or passive smoking is not acceptable, voluntary or active smoking is acceptable. In this document, we use the term second-hand tobacco smoke (WHO, 2010).

1.1 Chemical composition

Many studies have examined the concentrations of cigarette smoke constituents in mainstream and sidestream smoke. The composition of mainstream and sidestream smoke is qualitatively similar but quantitatively different. The ratios of sidestream to mainstream smoke vary greatly depending on the constituent. Some representative SS:MS ratios are: nicotine, 7.1; carbon monoxide, 4.8; ammonia, 455; formaldehyde, 36.5; acrolein, 18.6; benzo[*a*]pyrene, 16.0; *N*′-nitrosonornicotine (NNN), 0.43; (methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), 0.40 (Jenkins *et al.*, 2000; IARC, 2004).

The physicochemical properties of second-hand tobacco smoke are different from those of mainstream smoke and sidestream smoke because of its rapid dilution and dispersion into the indoor environment (IARC, 2004). Concentrations of individual constituents in second-hand tobacco smoke can vary with time and environmental conditions. Field studies of these constituents and representative data have been extensively summarized (Jenkins *et al.*, 2000; IARC, 2004). Some representative data are presented in Table 1.1 (Jenkins *et al.*, 2000; IARC, 2004; US Department of Health and Human Services, 2006).

Table 1.1 Concentration of selected constituents in second-hand tobacco smoke

Constituent	Concentration
Nicotine	10–100 μg/m^3
Carbon monoxide	5–20 ppm
Benzene	15–30 μg/m^3
Formaldehyde	100–140 μg/m^3
Acetaldehyde	200–300 μg/m^3
1,3-Butadiene	20–40 μg/m^3
Benzo[*a*]pyrene	0.37–1.7 ng/m^3
NNK	0.2–29.3 ng/m^3
NNN	0.7–23 ng/m^3

1.2 Sources of exposure

Second-hand tobacco smoke is present in virtually all places where smoking takes place (Navas-Acien *et al.*, 2004): at home, in the workplace, in bars, restaurants, public buildings, hospitals, public transport and educational institutions. The setting that represents the most important source of exposure differs depending on the population. For example in children, the home environment may constitute a significant source of exposure, while other sources that may contribute are schools and public transportation. Likewise, for most women, the home environment is the primary source of second-hand tobacco smoke, which may be enhanced by exposure at the workplace.

Biomarker studies have evaluated carcinogen uptake in non-smokers to second-hand tobacco smoke. The NNK metabolites NNAL and its glucuronides (total NNAL) are consistently elevated in non-smokers exposed to second-hand tobacco smoke, in studies conducted in various living and occupational environments, and from infancy through adulthood (Hecht *et al.*, 2006; Hecht, 2008). Levels of the biomarker of PAHs, urinary 1-hydroxypyrene, were significantly elevated in a large study of non-smokers exposed to second-hand tobacco smoke (Suwan-ampai *et al.*, 2009).

1.3 Measures of exposure

A conceptual framework for considering exposure to second-hand tobacco smoke is the "microenvironmental model," which takes the weighted sum of the concentrations of second-hand tobacco smoke in the microenvironments where time is spent, with the weights the time spent in each, as a measure of personal exposure (Jaakkola & Jaakkola, 1997). Direct measures of exposure use concentrations of second-hand tobacco smoke components in the air in the home, workplace, or other environments, combined with information on the time spent in the microenvironments where exposure took place. Measurements of tobacco smoke biomarker(s) in biological specimens also represent a direct measure of exposure to second-hand smoke (Samet & Yang, 2001; Table 1.2). Indirect measures are generally obtained by survey questionnaires. These include self-reported exposure and descriptions of the source of second-hand tobacco smoke in relevant microenvironments, most often the home and workplace (Samet & Yang, 2001).

One useful surrogate measure, and the only available in many countries, is the prevalence of smoking among men and women. It provides a measure of the likelihood of exposure. In most countries in Asia and the Middle East,

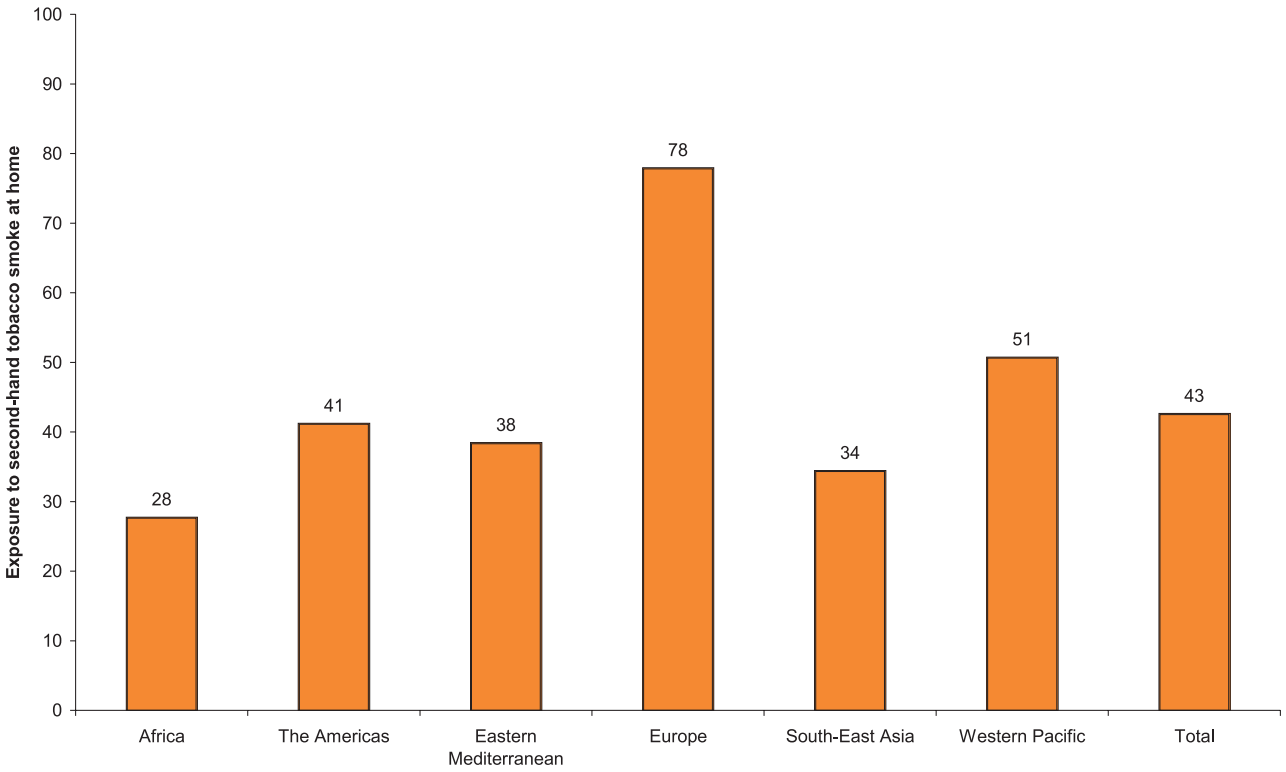
Table 1.2 Types of indicators measuring exposure to second-hand tobacco smoke

Measure	Suggested indicators
Direct	Concentration of second-hand tobacco smoke components in the air: - Nicotine - Respirable particles - Other markers Biomarker concentrations: - Cotinine - Carboxyhaemoglobin
Indirect	Report of second-hand tobacco smoke exposure at: Home - Number of smokers - Smoking of parents - Intensity (number of cigarettes smoked) Workplace - Presence of second-hand tobacco smoke - Number of smokers
Surrogate	Pre Prevalence of smoking tobacco in men and in women Sel Self reported smoking habits of parents Nic Nicotine concentration in house dust

From Samet & Yang (2001) and Whitehead *et al.* (2009)

for example, the very high prevalence of smoking among men combined with the low prevalence among women would imply that most women are exposed to second-hand tobacco smoke at home (Samet & Yang, 2001).

To measure exposure to second-hand tobacco smoke in children, self-reported smoking habits of their parents are used as a surrogate (US Department of Health and Human Services, 2006). More recently, other surrogate measures such as nicotine concentrations in house dust have been considered less biased than parental smoking as they reflect cumulative smoking habits and long-term exposure rather than current patterns of smoking (Whitehead *et al.*, 2009).



1.4 Prevalence of exposure

1.4.1 Exposure among children

(a) Overview

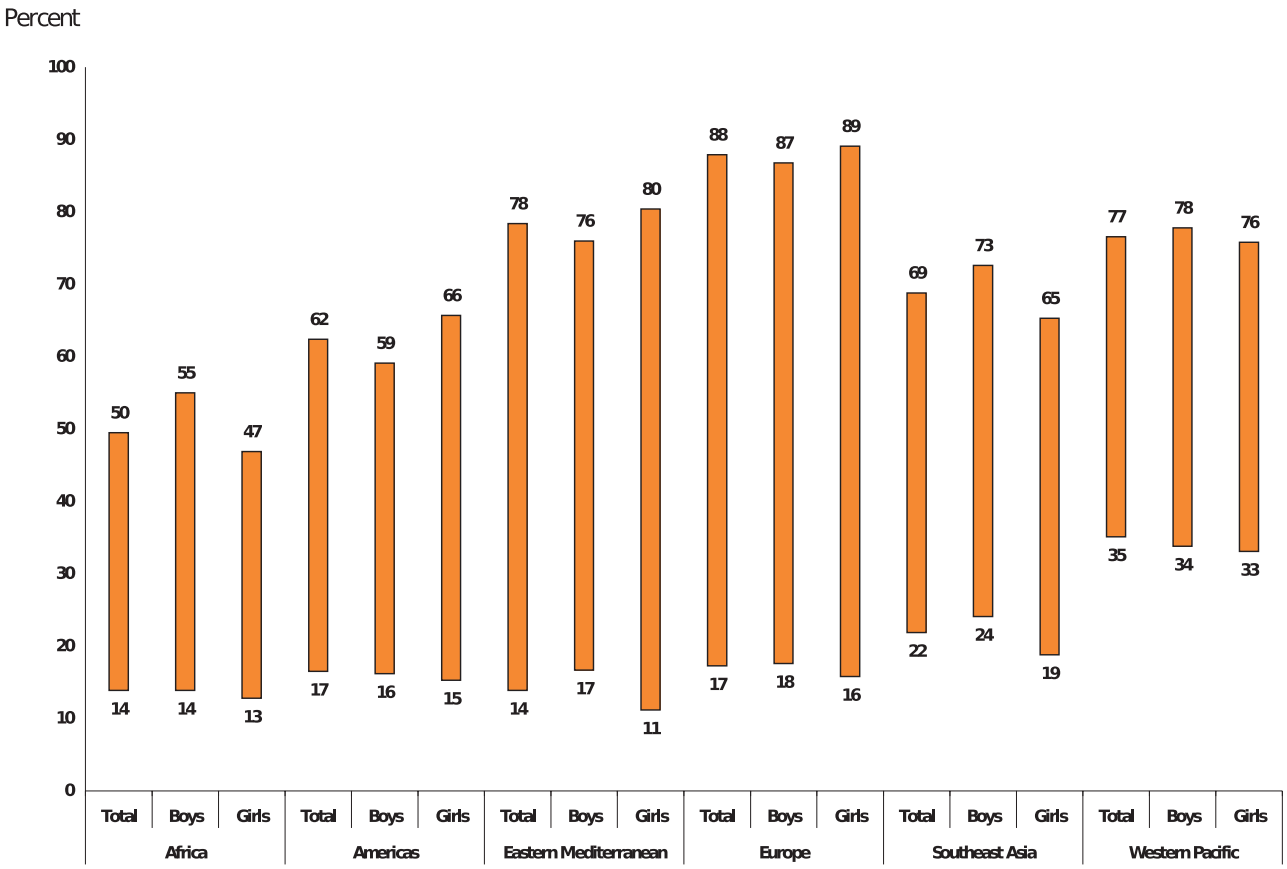
The most extensive population-based data on exposure to second-hand tobacco smoke among children are available through the Global Youth Tobacco Survey (GYTS) (CDC/WHO, 2009). GYTS is part of the Global Tobacco Surveillance System (GTSS), developed by the WHO and the United States' Centers for Disease Control and Prevention (CDC) in 1998. The GYTS is a school-based survey designed to measure tobacco use and some key tobacco control measures among youth (13–15 years) using a common methodology and core questionnaire. While most GYTS are national surveys, in some countries they are limited to subnational locations. Further, countries conduct the GYTS in different years, rendering comparison across countries for the same year difficult. The GYTS questionnaire

Fig. 1.1 Average prevalence (in%) of 13–15 year old children living in a home where others smoke, by WHO region, 2007

From CDC (2008)

asks about children's exposure to second-hand tobacco smoke in their home or in other places in the last 7 days preceding the survey. Since its inception in 1999, over 2 million students in 160 countries representing all six WHO regions have participated in the GYTS (WHO, 2008, 2009a).

Country-level estimates on second-hand tobacco smoke exposure at home and in public places among youth are available in the WHO Reports on the global tobacco epidemic (WHO, 2008, 2009a, 2011).



(b) Exposure at home

Nearly half of youth aged 13–15 years are exposed to second-hand tobacco smoke in their homes (Fig. 1.1; CDC, 2008). Among the six WHO regions, exposure to second-hand tobacco smoke at home was highest in the European Region (77.8%) and lowest in the African region (27.6%). In the other four regions, exposure to second-hand tobacco smoke at home ranged from 50.6% in the Western Pacific Region to 34.3% in the South East Asian Region.

Fig. 1.2 shows the range of exposure to second-hand tobacco smoke at home by WHO region for boys and girls and for both sexes combined. The largest variations are observed in the Eastern Mediterranean Region and the European Region irrespective of sex. These variations are predominantly due to differences in parental smoking prevalence between countries, as well as the impact of the smoke-free places campaigns in place in various countries.

Country-level estimates from the Global Youth Tobacco Survey (1999–2009) are presented in Table 1.3.

Fig. 1.2 Range of prevalence (in%) of exposure of 13–15 year old children to second-hand tobacco smoke at home, by WHO region, 2009

From CDC/WHO (2009)

Öberg and colleagues have estimated the worldwide exposure to second-hand tobacco smoke among children by using parent's current smoking status as an indicator of exposure among children (WHO, 2010). Four out of ten children (approximately 700 million children globally) have at least one parent who currently smokes, predisposing them to exposure to second-hand tobacco smoke at home (Table 1.4). Children in the Western Pacific Region had the highest level of potential exposure (68%) while Africa had the lowest, with about 13% of children having at least one parent who smoked. In the 2010 WHO Report on global estimate of the burden of disease from second-hand smoke (WHO, 2010), country-level estimates were collected or modelled from various sources. [Data partially overlap with those of the Global Youth Tobacco Survey].

(c) Exposure outside home

Similar to second-hand tobacco smoke exposure at home, almost half of the youth are exposed to second-hand tobacco smoke in public places, according to estimates from the Global Youth Tobacco Survey (Fig. 1.3; CDC, 2008). Exposure was highest in Europe (86.1%); for the other five regions, exposure to second-hand tobacco smoke in public places ranged from 64.1% in the Western Pacific to 43.7% in Africa.

Table 1.3 Prevalence of exposure to second-hand tobacco smoke at home and outside home among 13–15 year olds, by country and sex, from the Global Youth Tobacco Survey (participating countries only) — 1999–2009

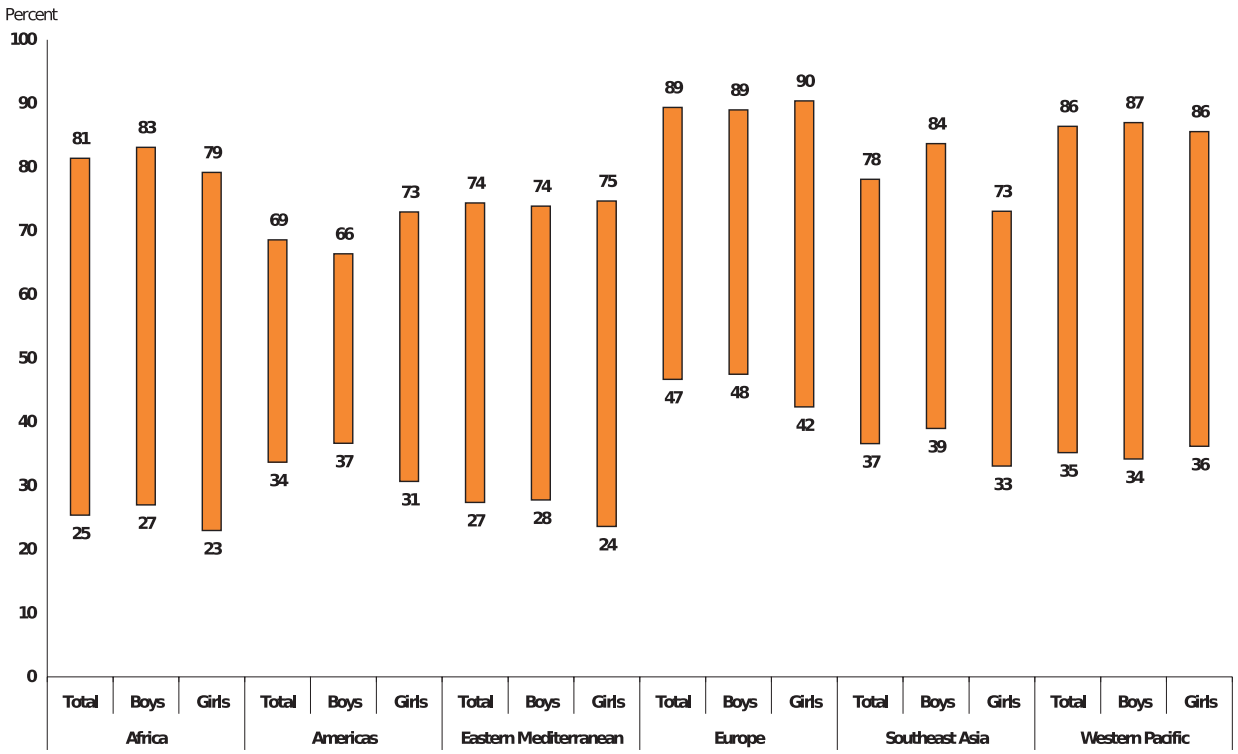
WHO subregional country grouping (adapted from WHO, 2002):
Africa. ***Region D***: Algeria, Angola, Benin, Burkina Faso, Cameroon, Cape Verde, Chad, Comoros, Equatorial Guinea, Gabon, The Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Madagascar, Mali, Mauritania, Mauritius, Niger, Nigeria, Sao Tome and Principe, Senegal, Seychelles, Sierra Leone, Togo; ***Region E***: Botswana, Burundi, Central African Republic, Congo, Côte d'Ivoire, Democratic Republic of the Congo, Eritrea, Ethiopia, Kenya, Lesotho, Malawi, Mozambique, Namibia, Rwanda, South Africa, Swaziland, Uganda, United Republic of Tanzania, Zambia, Zimbabwe
The Americas. ***Region A***: Canada, Cuba, USA; ***Region B***: Antigua and Barbuda, Argentina, Bahamas, Barbados, Belize, Brazil, Chile, Colombia, Costa Rica, Dominica, Dominican Republic, El Salvador, Grenada, Guyana, Honduras, Jamaica, Mexico, Panama, Paraguay, Saint Kitts and Nevis, Saint Lucia, Saint Vincent and the Grenadines, Suriname, Trinidad and Tobago, Uruguay, Venezuela; ***Region D***: Bolivia, Ecuador, Guatemala, Haiti, Nicaragua, Peru
Eastern Mediterranea. ***Region B***: Bahrain, Islamic Republic of Iran, Jordan, Kuwait, Lebanon, Libyan Arab Jamahirya, Oman, Qatar, Saudi Arabia, Syrian Arab Republic, Tunisia, United Arab Emirates; ***Region D***: Afghanistan, Djibouti, Egypt, Iraq, Morocco, Pakistan, Somalia, Sudan, Yemen
Europe. ***Region A***: Andorra, Austria, Belgium, Croatia, Cyprus, Czech Republic, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Israel, Italy, Luxembourg, Malta, Monaco, Netherlands, Norway, Portugal, San Marino, Slovenia, Spain, Sweden, Switzerland, United Kingdom; ***Region B***: Albania, Armenia, Azerbaijan, Bosnia and Herzegovina, Bulgaria, Georgia, Kyrgyzstan, Poland, Romania, Serbia and Montenegro, Slovakia, Tajikistan, Former Yugoslav Republic of The former Yugoslav Republic of Macedonia, Turkey, Turkmenistan, Uzbekistan; ***Region C***: Belarus, Estonia, Hungary, Kazakhstan, Latvia, Lithuania, Republic of the Republic of Moldova, Russian Federation, Ukraine
South-eastern Asia. ***Region B***: Indonesia, Sri Lanka, Thailand; ***Region D***: Bangladesh, Bhutan, Democratic People's Republic of Korea, India, Maldives, Myanmar (Burma), Nepal, Timor-Leste
Western Pacific. ***Region A***: Australia, Brunei Darussalam, Japan, New Zealand, Singapore; ***Region B***: Cambodia, China, Cook Islands, Fiji, Kiribati, Lao People's Democratic Republic, Malaysia, Marshall Islands, Federated States of Micronesia, Mongolia, Nauru, Niue, Palau, Papua New Guinea, Philippines, Republic of Korea, Samoa, Solomon Islands, Tonga, Tuvalu, Vanuatu, Viet Nam
Regions are categorized as follows (WHO-approved classifications): A = very low child mortality and very low adult mortality; B = low child mortality and low adult mortality; C = low child mortality and high adult mortality; D = high child mortality and high adult mortality; E = high child mortality and very high adult mortality.

Fig. 1.3 Average prevalence (in%) of exposure of 13–15 year old children to second-hand tobacco smoke in public places, by WHO region, 2007

From CDC (2008)

Fig. 1.4 presents the range of exposure to second-hand tobacco smoke outside home by WHO region for boys and girls and for both sexes combined. There are wide variations in second-hand tobacco smoke exposure outside home within each region. The largest variations are observed in the African region and the Western Pacific region irrespective of sex. This is largely influenced by the presence of smoke-free legislation for public paces in the countries, as well as levels of enforcement and public's compliance with these laws.



1.4.2. Exposure among adults

(a) Overview

While the GYTS offers a valuable global source for estimating exposure to second-hand tobacco smoke among children, there is no such extensive source of data for adults. Estimates of second-hand tobacco smoke exposure among adults have used the definitions of exposure based on having a spouse who smokes or exposure to tobacco smoke at work. For the countries lacking such data, exposure was estimated using a model based on smoking prevalence among men from the WHO Global InfoBase.

About one third of adults worldwide are regularly exposed to second-hand tobacco smoke (Table 1.5). The highest exposure was estimated in European Region C with 66% of the population

Fig. 1.4 Range of prevalence (in%) of exposure of 13–15 year old children to second-hand tobacco smoke outside their home, by WHO region, 2009

From CDC/WHO (2009)

being regularly exposed to second-hand tobacco smoke. The lowest regional exposure was estimated in the African region (4%). Differences between men and women were generally small, except in Eastern Mediterranean Region D and South East Asia Region B.

(b) Exposure at home

The Global Tobacco Surveillance System, through its adult household survey "Global Adult Tobacco Survey" (GATS), collects information on key tobacco control indicators including information on second-hand tobacco smoke exposure at home, at work and several public places (WHO, 2009b). GATS is a nationally representative survey conducted among persons aged ≥ 15 years using a standardized questionnaire, sample design, data collection method, and analysis protocol. GATS results are available from 14 countries with a high tobacco burden. Additionally since 2008, The WHO STEPwise approach to surveillance (STEPS) surveys have started to collect information on exposure to second-hand tobacco smoke at home and at work, now available for 7 countries (WHO, 2009c).

In the 21 countries that have reported data on exposure to second-hand tobacco smoke, large numbers of people are exposed at home (Fig. 1.5). Exposure was highest in Sierra Leone (74%) and lowest in the British Virgin Islands (3%). Overall, differences between men and women were relatively small in most countries; in China, Cambodia and Mongolia, more women reported being exposed to second-hand tobacco smoke

Table 1.5 Proportion of non-smoking adults exposed regularly to second-hand tobacco smoke, by WHO region (based on survey data and modeling)

	Exposure in men	Exposure in women
WHO Subregion	(%)	(%)
Africa (D)	7	11
Africa (E)	4	9

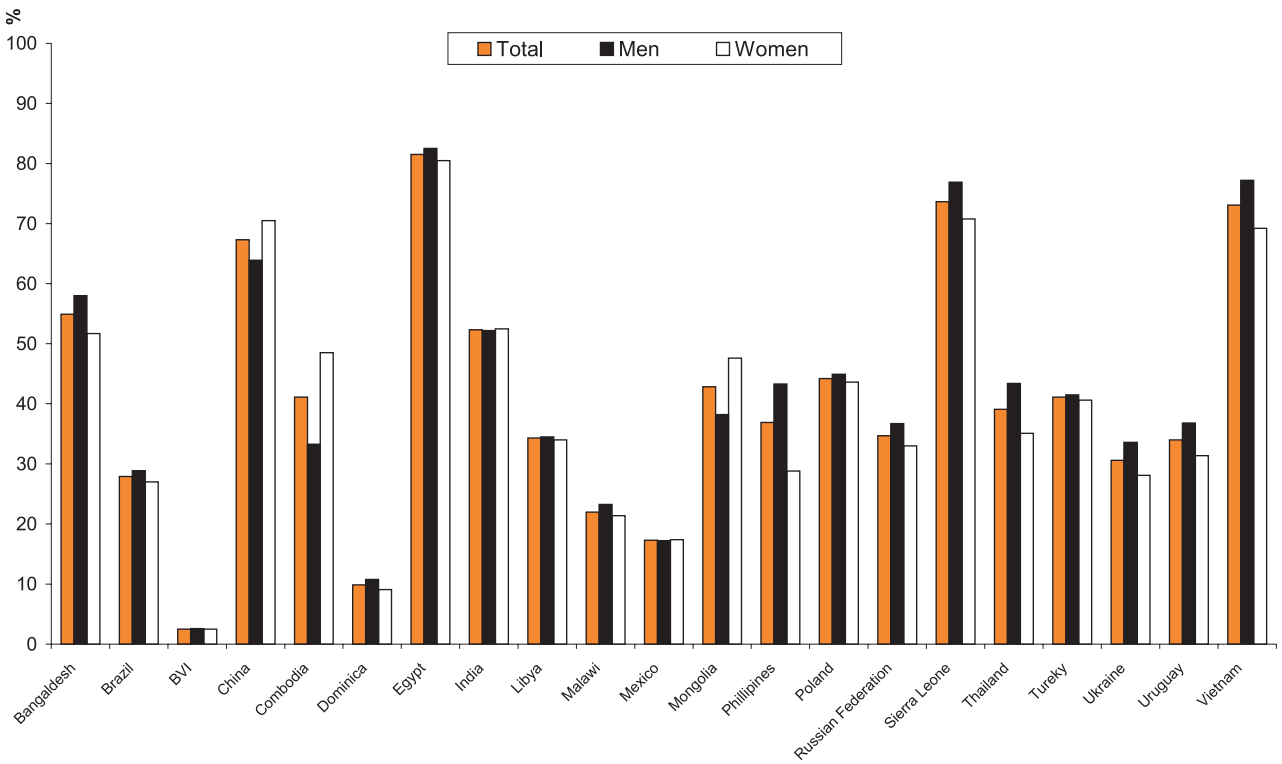
Western Pacific (B)	53	51
GLOBAL	33	31

From WHO (2010)
For the WHO subregional country grouping, see footnote of Table 1.4.

in their homes then men. This lack of difference implies that even when prevalence of smoking among women is low, they are exposed to second-hand tobacco smoke at home as much as men.



(c) Exposure at the workplace

The same magnitude of second-hand tobacco smoke exposure at the workplace was reported as at home (Fig. 1.6). Exposure to second-hand tobacco smoke at the workplace was highest in Sierra Leone (74%) and lowest in the British Virgin Islands (3%). However, more men reported being exposed to others' smoke at their workplace as compared to women in all countries. This difference was most significant in Libyan Arab Jamahirya and Bangladesh. These differences could be explained by the fact that women either tend to work in places where smoking is banned, such as education or health facilities, or work predominantly with other women.

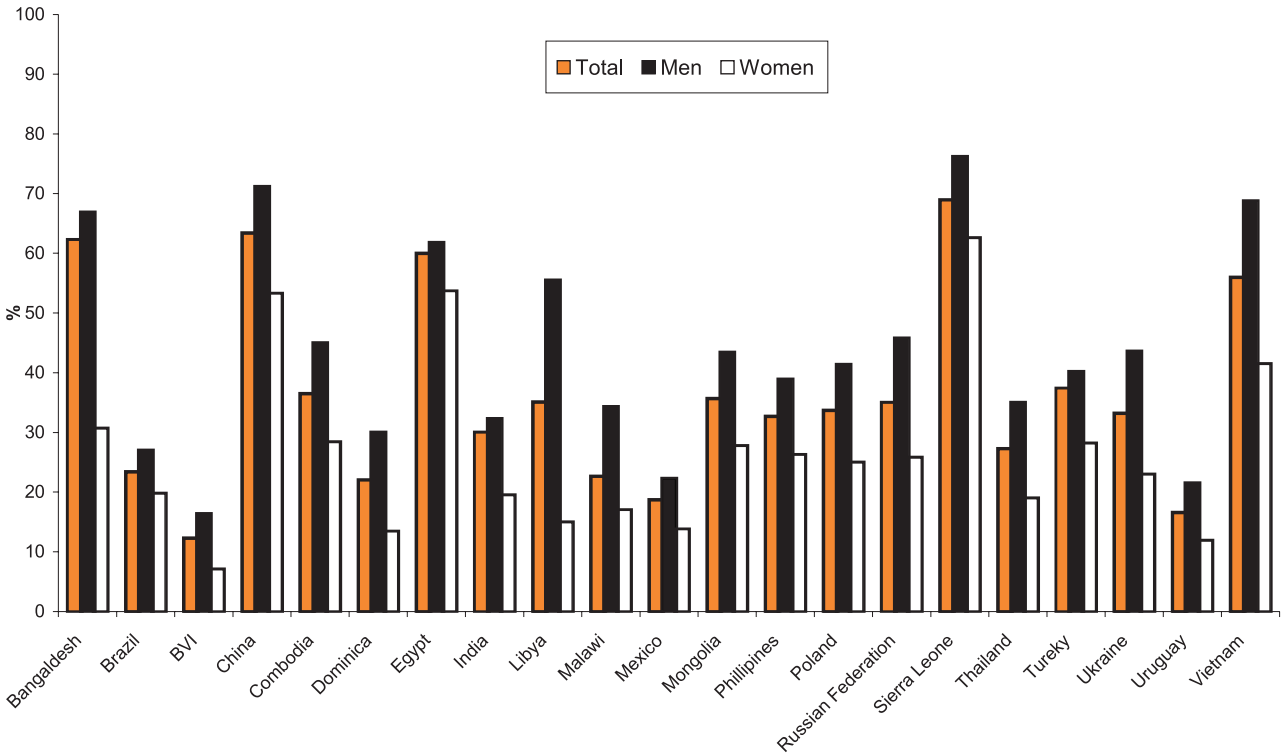
1.5 Regulations

The World Health Organization's Framework Convention on Tobacco Control (WHO FCTC) is a multilateral treaty with legally binding obligations for its 174 Parties (as of November 2011) (WHO, 2003). This comprehensive treaty contains supply and demand reduction measures available to countries to counter the tobacco epidemic. Article 8 of the Treaty specifically addresses the need for protection from second-hand tobacco smoke, and articulates the "adoption and implementation of effective legislative, executive, administrative and /or other measures" by Parties to the Convention to this effect. Guidelines to Article 8 specify key elements needed in legislation to help countries meet the highest standards of protection from second-hand tobacco smoke and provide a clear timeline for Parties to adopt appropriate measures (within five years after entry into Force of the WHO FCTC) (WHO, 2007).

Fig. 1.5 Prevalence of adults exposed to second-hand tobacco smoke in their homes, in the countries that completed the Global Adult Tobacco Survey (GATS) and WHO STEPwise approach to surveillance (STEPS) surveys, 2008–2009

From WHO (2009b, c)
GATS defines second-hand tobacco smoke exposure at home as reporting that smoking inside their home occurs daily, weekly, or monthly.
STEPS defines second-hand tobacco smoke exposure at home as reporting exposure in the home on one or more days in the past 7 days.

All countries, regardless of their FCTC ratification status, are taking steps to reduce second-hand tobacco smoke in public places, through either planning the steps to or implementing national smoke-free laws for public places or workplaces. In 2008, approximately 5% of the world's population (354 million) had national smoke-free laws. Fig. 1.7 provides details on the number of public places with national smoke-free legislation for all WHO Member States.



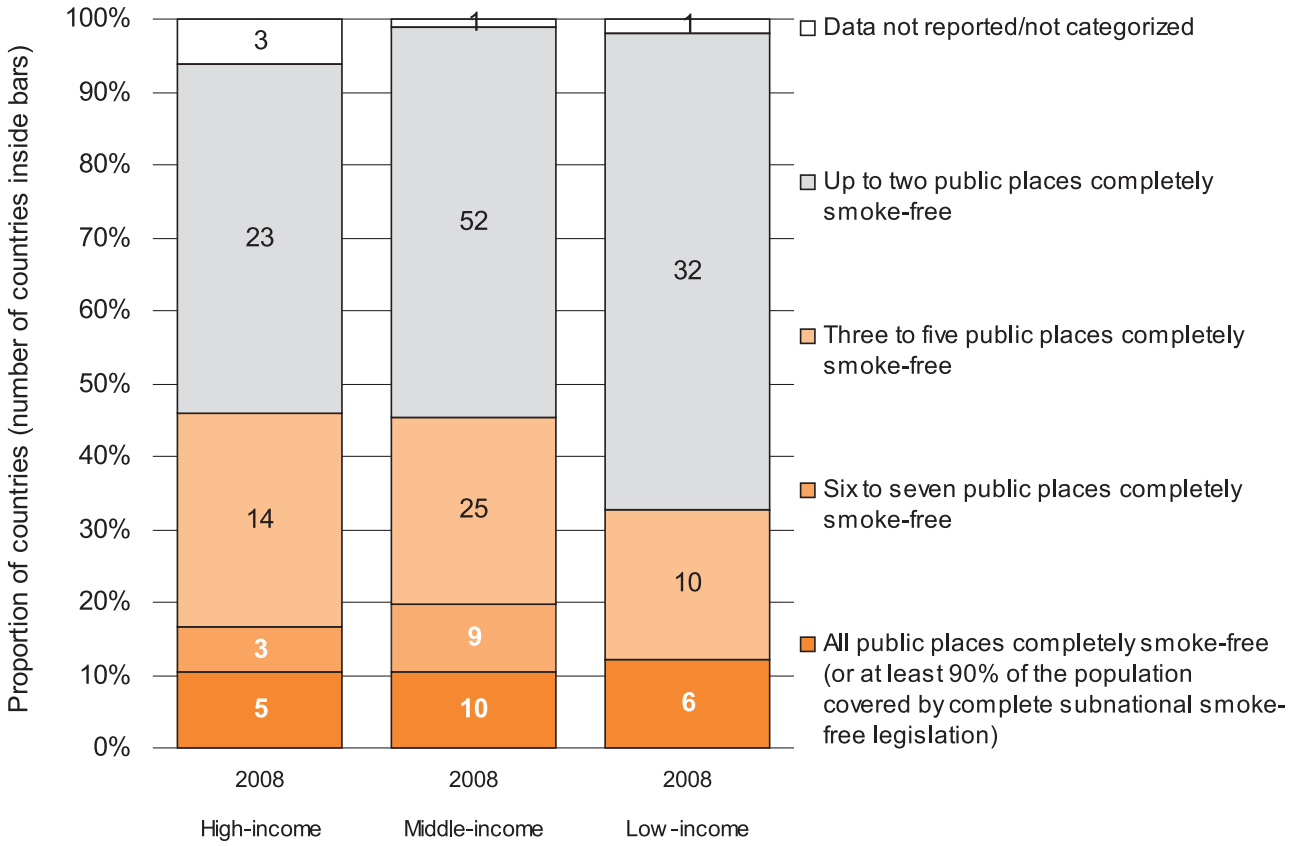
As of December 2008, fifteen countries across the globe have legislation that provide the highest level of protection against second-hand tobacco smoke exposure. These include: Albania, Australia, Bhutan, Canada, Colombia, Guatemala, Islamic Republic of Iran, Ireland, Marshall Islands, New Zealand, Panama, Turkey, Turkmenistan, United Kingdom of Great Britain and Northern Ireland and Uruguay.

2 Cancer in Humans

2.1 Cancer of the lung

More than 50 epidemiological studies since 1981 have examined the association between second-hand tobacco smoke and lung cancer resulting in the conclusion that exposure of non-smokers to second-hand tobacco smoke is causally associated with lung cancer risk (IARC, 2004). Many studies previously

Fig. 1.6 Prevalence of adults exposed to second-hand tobacco smoke in their workplaces, in the countries that completed the Global Adult Tobacco Survey and WHO STEPwise approach to surveillance (STEPS) surveys, 2008–2009



GATS defines second-hand tobacco smoke exposure at work as indoor workers who were exposed at work in the past 30 days.
STEPS defines second-hand tobacco smoke exposure at work as reporting exposure in the workplace on one or more days in the past 7 days
From WHO (2009b, c)

available assessed the lung cancer risk among the nonsmoking spouses of smokers since it is one of the sources of adult exposure to second-hand tobacco smoke that is less likely to be subject to exposure misclassification or other bias. Several important new, cohort, case–control studies and meta-analyses have been published since 2004 that provide additional evidence confirming the causal association (Table 2.1 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.1.pdf, Table 2.2 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.2.pdf, and Table 2.3 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.3.pdf). These new studies also expand our assessment of the effect of second-hand tobacco smoke in the workplace allowing for more refined estimates of lung cancer risk. Preliminary data also suggest significant interactions between several genetic polymorphisms, second-hand tobacco smoke and lung cancer risk.

In a meta-analysis of 55 studies, including 7 cohort, 25 population based case–control studies and 23 hospital based case–control studies the pooled relative risk (RR) for lung cancer for never smoking women exposed to second-hand tobacco smoke from spouses was 1.27 (95%CI: 1.17–1.37). The relative risk for studies in North America was 1.15 (95%CI: 1.03–1.28), in Asia 1.31 (95%CI: 1.16–1.48) and Europe 1.31 (1.24–1.52) (Taylor *et al.*, 2007).

Fig. 1.7 Number and percentage of countries with number of public places covered by smoke free legislations, by income status (as of 31 December 2008)

From WHO (2009a)

In a meta-analysis of 22 studies that assessed the effect of second-hand tobacco smoke exposures at work, the relative risk for lung cancer among exposed non-smokers was 1.24 (95%CI: 1.18–1.29) and among those workers classified as highly exposed to second-hand tobacco smoke at work 2.01 (95%CI: 1.33–2.60) compared to those with no exposure at work (Stayner *et al.*, 2007).

In a large cohort study conducted in 10 European countries (European Prospective Investigation into Cancer and Nutrition, EPIC), it was estimated that the hazard ratio (HR) for lung cancer risk from second-hand tobacco smoke exposure at home and/or at work for never smokers and ex-smokers (at least 10 years) was 1.34 (0.85–2.13) (Vineis *et al.*, 2007a). The main component of this risk was attributable to exposure at the workplace, resulting in a hazard ratio of 1.65 (1.04–2.63). The overall hazard ratio between childhood exposure and the risk of lung cancer in adulthood was 2.00 (0.94–4.28); among children with daily exposure for many hours each day the hazard ratio was 3.63 (1.19–11.12). In a separate analysis of workplace exposure to second-hand tobacco smoke in this cohort women were observed to have a lung cancer hazard ratio of 2.13 (1.6–3.4) (Veglia *et al.*, 2007).

In a large population-based cohort study conducted in Japan, findings confirmed that exposure to second-hand tobacco smoke is

a risk factor for lung cancer among Japanese women (Kurahashi *et al.*, 2008). Compared with women married to never smokers, the hazard ratio for all lung cancer incidence was 1.34 (95%CI:0.81–2.21) and for adenocarcinoma 2.03 (95%CI:1.07–3.86). For adenocarcinoma dose–response relationships were seen for both intensity (*P* for trend = 0.02) and total amount (*P* for trend = 0.03) of the husband's smoking. Exposure to second-hand tobacco smoke at the workplace also increased the risk of lung cancer (HR, 1.32; 95%CI: 0.85–2.04).

Data from a cohort study of women from Shanghai, China also found that exposure to second-hand tobacco smoke is associated with lung cancer mortality. Exposure to second-hand tobacco smoke at work was associated with a significantly increased mortality to lung cancer (HR 1.79, 95%CI: 1.09–2.93) but the risk was not significant for exposure to husband's second-hand tobacco smoke (HR 1.09, 95%CI: 0.74–1.61) (Wen *et al.*, 2006). In a case–control study of lung cancer among lifetime non-smoking Chinese men living in Hong Kong Special Administrative Region a non-significant association between all lung cancer and ever being exposed to household and/or workplace second-hand tobacco smoke was observed (OR, 1.11, 95%CI: 0.74–1.67) but a significant increase was observed for adenocarcinoma (OR, 1.68, 95%CI: 1.00–2.38) (Tse *et al.*, 2009).

In a long-term case–control study of lung cancer cases at the Massachusetts General Hospital, study participants exposed to second-hand tobacco smoke at work and at leisure were at a significantly greater risk (OR, 1.30, 95%CI: 1.08–1.57) if the exposure occurred between birth and 25 years of age. If the exposures occurred after the age of 25 years the risk was not elevated (OR, 0.66, 95%CI: 0.21–1.57) but the confidence limits are wide for this subgroup analysis (Asomaning *et al.*, 2008).

In two other cohort studies, one conducted in California (Enstrom & Kabat, 2003) and another in New Zealand (Hill *et al.*, 2007) no excess risk was observed among lifelong non-smokers exposed to second-hand tobacco smoke. In the California study the relative risk was 0.99 (95%CI: 0.72–1.37) based on 126 lung cancer cases. [The confidence intervals in this study are relatively wide and they include the current IARC estimate of lung cancer risk from second-hand tobacco smoke exposure. In addition the opportunity for substantial misclassification of second-hand tobacco smoke exposure is great because exposures outside the home were not assessed and the second-hand tobacco smoke exposures were not re-evaluated after enrollment into the study.] Hill *et al.* (2007) observed no association between second-hand tobacco smoke exposure in a census enumeration of current second-hand tobacco smoke exposure at home and linkage to cancer registries three years later. The authors suggest that this may be a result of either the misclassification of total second-hand tobacco smoke exposure since exposures outside the home were not assessed and/or the fact that a 3-year follow-up after exposure ascertainment may have been too short to capture important exposures before the diagnosis of lung cancer.

One case–control study (Wenzlaff *et al.*, 2005) and one case-only study (Bonner *et al.*, 2006) assessed lung cancer risk associated with second-hand tobacco smoke exposure and several polymorphisms. In the case–control study, individuals were stratified by household second-hand tobacco smoke exposure (yes/no), those with *CYP1B1 Leu*^{432}*Val* genotype alone or in combination with Phase II enzyme polymorphisms were more strongly associated with lung cancer risk if they also were exposed to at least some household second-hand tobacco smoke exposure compared to those that had no exposure. In the case-only study a significant interaction was observed between lung cancer risk, second-hand tobacco smoke and a GSTM1 (null) genotype (OR, 2.28, 95%CI:1.15–4.51).

2.2 Cancer of the breast

2.2.1 Overview of studies

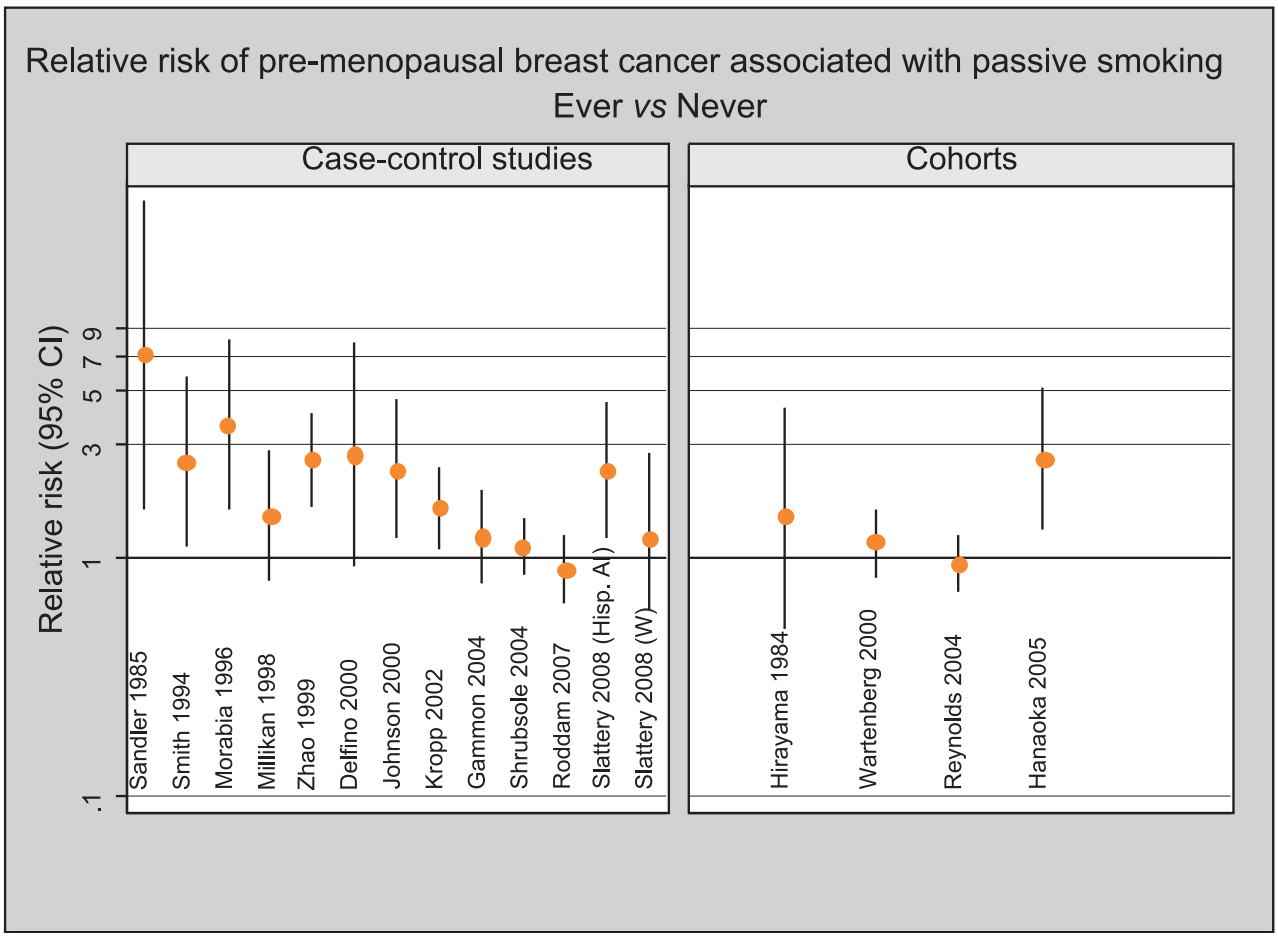
The relationship between exposure to second-hand tobacco smoke and breast cancer has been comprehensively reviewed in the peer reviewed literature (Johnson, 2005; Miller *et al.*, 2007) and in reports from national and international committees (IARC, 2004, 2009; California Environmental Protection Agency, 2005; US. Department of Health and Human Services, 2006; Collishaw *et al.*, 2009). These reviews have drawn different conclusions. IARC (2004) characterized the evidence as "inconsistent," based on studies published or in press by June, 2002. A US Surgeon General Report (2006) concluded that the evidence was "suggestive but not sufficient" to infer a causal relationship between second-hand tobacco smoke and breast cancer, whereas reviews by the California Environmental Protection Agency (CalEPA) in 2005 and by a panel of researchers in this area convened in Canada (Collishaw *et al.*, 2009) designated the evidence for second-hand tobacco smoke as "consistent with a causal association in younger primarily premenopausal women."

A total of 16 new studies have been published since the previous *IARC Monograph* (IARC, 2004). These include three cohort studies (Reynolds *et al.*, 2004; Hanaoka *et al.*, 2005; Pirie *et al.*, 2008) (Table 2.4 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.4.pdf), and 13 new case–control studies (Lash & Aschengrau, 2002; Alberg *et al.*, 2004; Gammon *et al.*, 2004; Shrubsole *et al.*, 2004; Bonner *et al.*, 2005; Sillanpää *et al.*, 2005; Lissowska *et al.*, 2006; Mechanic *et al.*, 2006; Roddam *et al.*, 2007; Rollison *et al.*, 2008; Slattery *et al.*, 2008; Ahern *et al.*, 2009; Young *et al.*, 2009) (Table 2.5 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.5.pdf). Table 2.5 also presents two case–control studies not discussed previously (Zhao *et al.*, 1999; Liu *et al.*, 2000). Several meta-analyses have also been published as new data became available (California Environmental Protection Agency, 2005; Johnson, 2005; US. Department of Health and Human Services, 2006; Pirie *et al.*, 2008; IARC, 2009).

The largest of the cohort studies, identified 2518 incident breast cancers among 224917 never smokers followed for an average of 3.5 years in the British Million Women Study (Pirie *et al.*, 2008). The cohort was drawn from women, age 50–64 years, participating in mammography screening programmes. Nearly all cases were post-menopausal and the overall analyses pertain to postmenopausal breast cancer. No relationship was observed between breast cancer risk and smoking by a parent at the time of birth and/or age 10 years (HR, 0.98; 95%CI: 0.88–1.08); the results were also null for smoking by a current partner (HR, 1.02; 95%CI: 0.89–1.16) or exposure to the combination of parental and spousal smoking (HR, 1.03; 95%CI: 0.90–1.19). Pirie *et al.* (2008) also present a meta-analysis of studies of second-hand smoke and breast cancer risk, separating studies by cohort or case–control design. No overall association was observed in the cohort studies. These largely represent post-menopausal breast cancer, so the analysis was not stratified by menopausal status. An overall association was seen in the case–control studies, similar to the findings of other meta-analyses (California Environmental Protection Agency, 2005; US. Department of Health and Human Services, 2006; IARC, 2009). [Pirie *et al.* (2008) focus on the discrepancy between the cohort and case–control results and propose that the associations observed in early case–control studies can likely be explained by recall bias. The study has been criticized for the lack of information on occupational exposures to second-hand smoke (Collishaw *et al.*, 2009).]

A second large cohort study (Reynolds *et al.*, 2004) identified 1998 women diagnosed with breast cancer during five years of follow-up of the

California Teachers Study. Analyses were based on 433 women with pre/peri-menopausal breast cancer and 1361 women with postmenopausal cancer. No association was observed between post-menopausal breast cancer and residential exposure to second-hand tobacco smoke in childhood or adulthood. No association was initially reported with pre/peri-menopausal breast cancer in analyses based on menopausal status at enrollment (RR 0.93, 95%CI: 0.71–1.22). When menopausal status was defined by age at diagnosis rather than by age at enrollment, the hazard ratio for premenopausal breast cancer among women exposed in both childhood and adulthood increased to 1.27 (95%CI: 0.84–1.92) (Reynolds *et al.*, 2006).



Hanaoka *et al.* (2005) identified 162 incident breast cancer cases during a nine-year follow-up of 20169 Japanese women, age 40–59 years, who reported no history of active smoking when enrolled in the Japan Public Health Center (JPHC) study in 1990. Nearly three quarters (72%) of the women reported exposure to second-hand tobacco smoke. About half of the women were premenopausal when enrolled in the study, although there were only nine unexposed cases among the pre-menopausal women. The multivariate-adjusted relative risk for breast cancer among all exposed women irrespective of menopausal status was 1.1 (95%CI: 0.8–1.6) compared to those classified as unexposed. The corresponding relative risks for women who were pre- or postmenopausal at baseline were 2.6 (95%CI: 1.3–5.2) and 0.7 (95%CI: 0.4–1.0), respectively.

Six of the 13 new population-based case–control studies included more than 1000 cases each (Shrubsole *et al.*, 2004; Bonner *et al.*, 2005; Lissowska *et al.*, 2006; Mechanic *et al.*, 2006; Slattery *et al.*, 2008; Young *et al.*, 2009; Table 2.5 on-line). None of these 13 studies showed an overall increase in breast cancer risk associated with second-hand tobacco smoke exposure in Caucasians. The incidence of premenopausal breast cancer was associated with one or more indices of second-hand tobacco smoke exposure in all four studies that stratified the results by menopausal status (Gammon *et al.*, 2004; Shrubsole *et al.*, 2004; Bonner *et al.*, 2005; Slattery *et al.*, 2008) although the association was not always statistically significant (Gammon *et al.*, 2004; Bonner *et al.*, 2005; Fig. 2.1). Associations were also reported between second-hand tobacco smoke exposure and overall breast cancer risk in African Americans (Mechanic *et al.*, 2006) and with premenopausal breast cancer in Hispanics/American Indians (Slattery *et al.*, 2008). The associations observed in these case–control studies are generally weaker than those reported in earlier case–control studies. Whereas the relative risk estimates reported in the earlier studies often equalled or exceeded 2.0 (Sandler *et al.*, 1985a; Lash & Aschengrau, 1999; Zhao *et al.*, 1999; Johnson & Repace, 2000; Liu *et al.*, 2000) or 3.0 (Smith *et al.*, 1984; Morabia *et al.*, 1996; Liu *et al.*, 2000; Morabia *et al.*, 2000), the estimates in the later studies were mostly under 1.5, even in studies that reported positive associations.

2.2.2 Issues affecting the interpretation of studies

One important consideration in evaluating these data has been the lack of a strong and convincing relationship between active smoking and breast cancer. Several theories have been advanced to explain why second-hand tobacco smoke might have a stronger effect on breast cancer than active smoking (California Environmental Protection Agency, 2005; Johnson, 2005; Collishaw *et al.*, 2009). Central to these is the hypothesis that active smoking may have counterbalancing protective and detrimental effects on breast cancer risk that, in combination, produce little or no overall association, whereas second-hand tobacco smoke may have only an adverse effect on risk. The weakness of this theory is that there is little direct evidence (see Section 4) identifying the

Fig. 2.1 Relative risk of pre-menopausal breast cancer associated with second-hand tobacco smoke. Ever versus never.

Study sorted by calendar year

mechanism by which active smoking may cause the proposed [protective] antiestrogenic effects. Without knowing the mechanism, it has been impossible to prove that active smoking has this effect but exposure to second-hand tobacco smoke does not. A second hypothesis that has been advanced is that second-hand tobacco smoke may have a greater effect on pre- than on postmenopausal breast cancer. This theory was proposed by CalEPA in 2005 (Johnson & Glantz, 2008) based on analyses of studies available at the time, and was subsequently questioned by some (US. Department of Health and Human Services, 2006) but not all (Collishaw *et al.*, 2009) subsequent reviews. [Because this arose as an a posteriori observation rather than as an a priori hypothesis, it must be confirmed by independent studies.] The strongest support for the hypothesis comes from a cohort study in Japan (Hanaoka *et al.*, 2005), which reported significantly increased risk (RR 2.6, 95%CI: 1.3–5.2) of premenopausal breast cancer in women who previously reported having ever lived with a regular smoker or ever being exposed to second-hand tobacco smoke for at least one hour per day in settings outside the home. However, the

referent group in this analysis included only nine unexposed cases. No associations were observed with post-menopausal breast cancer. A weak association between second-hand tobacco smoke exposure and premenopausal breast cancer was reported in the California Teachers cohort, when menopausal status was defined by age at diagnosis rather than age at entry into the study (Reynolds *et al.*, 2006). In case–control studies published since the CalEPA review (California Environmental Protection Agency, 2005) that reported results stratified by menopausal status, Bonner *et al.* (2005) and Slattery *et al.* (2008) reported stronger associations with pre- than with post-menopausal breast cancer, although the only statistically significant association with premenopausal breast cancer was in Hispanic or American Indian women who had second-hand tobacco smoke exposure of more than ten hours per week (OR, 2.3, 95%CI:1.2–4.5) (Slattery *et al.*, 2008). In a case–control study of breast cancer in women age 36–45 years Roddam *et al.* (2007) observed no increased risk in premenopausal women who, since age 16, were married to or lived with a boyfriend who smoked for at least one year.

Two other explanations for inconsistencies in the evidence relate to the fundamental design differences between cohort and case–control studies. A critical advantage of cohort studies is that they collect information on exposures before the disease of interest is diagnosed, thus preventing knowledge of disease status influencing how participants recall and/or report their exposures. Recall bias is especially challenging in case–control studies of exposures that are difficult to measure, when recollection of the frequency and intensity of exposure is necessarily subjective. In counterpart, an important advantage of case–control studies is that they can collect more detailed information on the exposure of interest than is usually possible in cohort studies. Together, these factors create what has been described as "a tension" between the potential for recall or selection bias in case–control studies, and the reduced possibility of collecting full "lifetime exposure histories" in cohort studies (Collishaw *et al.*, 2009). The discrepancy in the results from case–control and cohort studies is seen especially in the earlier case–control studies, which found much stronger associations than those observed in most recent studies. Five studies in particular (Smith *et al.*, 1984; Morabia *et al.*, 1996; Zhao *et al.*, 1999; Johnson & Repace, 2000; Kropp & Chang-Claude, 2002) were considered by Collishaw *et al.* (2009) as having the most complete information on lifetime exposure to second-hand tobacco smoke from all sources. At the same time, these studies are among the most susceptible to recall bias for two reasons. The first is a general problem of case–control studies, in that cases are more likely to remember and report potentially hazardous exposures than controls. Second, recall bias is potentially more problematic when subjective considerations can influence reporting. It is easier to report smoking by a parent or spouse than it is to remember exposures from other sources that possibly occurred many years ago in daily life. Exposure to second-hand tobacco smoke was highly prevalent in the decades following World War II in Europe and North America. It would be unusual for someone not to be exposed. The studies that the California Environmental Protection Agency (2005) considered to have the best information on exposure to second-hand tobacco smoke are also those which rely more heavily on recall of past exposures outside the home. Moreover, inclusion in the referent group in these studies is also vulnerable to recall bias. Previous reviews by IARC (2004) and the US Surgeon General (US. Department of Health and Human Services, 2006) have expressed concern about potential biases that may be introduced by relying on a small and unusual subgroup (the unexposed to active smoking and second-hand tobacco smoke) as the referent category in these studies. Recall bias remains a plausible explanation for why the

association with second-hand tobacco smoke is stronger in studies that collect "lifetime exposure histories" than in those that rely on parental or spousal smoking. In addition, publication bias cannot be ruled out because the reporting of association limited by subgroup (pre-menopausal) could have been selective.

[The Working Group noted that adjustment for potential confounders using the questionnaire data on other established risk factors for breast cancer did not eliminate the association with second-hand tobacco smoke in these studies. However, this does not resolve concerns about the possibility of recall or publication bias.]

Several meta-analyses have been published, largely showing similar results but leading to substantially different interpretations of the evidence (California Environmental Protection Agency, 2005; US Department of Health and Human Services, 2006; Johnson, 2007; IARC, 2009). The California Environmental Protection Agency (2005) calculated a pooled estimate for second-hand tobacco smoke and breast cancer risk of 1.11 (95%CI: 1.04–1.19) in all women and 1.38 (95%CI: 1.21–1.56) in premenopausal women, based on 19 studies and a fixed effects model. These estimates increased to 1.89 (95%CI: 1.57–2.27) for all women and 2.18 (95%CI: 1.70–2.79) in premenopausal women when the analysis was restricted to the subset of studies considered to have the best exposure data.

Based on these analyses, the California Environmental Protection Agency (2005) and Collishaw *et al.* (2009) emphasized the positive association with premenopausal breast cancer in their conclusion that the evidence is "consistent with a causal relationship" whereas the US Surgeon General (US Department of Health and Human Services, 2006) was more cautious in characterizing the evidence as "suggestive but not sufficient."

[The Working Group noted that the criterion used by IARC specifies "sufficient evidence of carcinogenicity in which chance, bias and confounding could be ruled out with reasonable confidence." This is a more stringent definition than "consistent with a causal relationship."]

2.3 Cancers of the upper aerodigestive tract

2.3.1 Upper areodigestive tract combined

Cancers of the upper aerodigestive tract traditionally comprise cancers of the oral cavity, pharynx, larynx and oesophagus. However, some epidemiological studies have examined only head and neck cancers restricted to tumours of the oral cavity, pharynx and larynx. Four case–control studies (Tan *et al.*, 1997; Zhang *et al.*, 2000; Lee *et al.*, 2008; Ramroth *et al.*, 2008) assessed the effects of second-hand tobacco smoke on head and neck cancers combined and separately for oral cavity, oropharynx or larynx cancers (Table 2.6 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.6.pdf).

In a hospital-based case–control study in the USA, including only non smoking cases and controls, Tan *et al.* (1997) detected high risk of head and neck cancer among those ever exposed to second-hand tobacco smoke at home or at work. Women presented higher risk at home (OR, 7.3; $P < 0.001$) than men (OR, 1.1; $P < 0.79$). On the other hand, men showed higher risk at work (OR, 11.6; $P < 0.001$) than women (OR, 8.9; $P < 0.002$). [The authors did not provide the percentages of the telephone interviews done with the spouses of cases and controls. Probably, this is the main weakness of this study and differential misclassification of exposure to second-hand tobacco smoke could not be excluded. The analysis was performed without adjustment for potential confounding variables.] In a study in the USA, Zhang *et al.* (2000) observed an increased risk (OR, 2.4; 95%CI: 0.9–6.8) with lifetime second-hand tobacco smoke exposure (ever/never) for head and neck cancers, adjusted for age, sex, ethnicity, education, alcohol drinking,

pack-years of cigarette smoking, and marijuana consumption.

Lee *et al.* (2008) pooled the data from several studies including cases of head and neck cancers and controls (population and hospital) from central Europe, Latin America and United States. Two groups were examined separately, never tobacco users and never tobacco and alcohol users. Among never tobacco users, no association was observed between ever exposure to second-hand tobacco smoke at home or at work and the risk for head and neck cancers. Among never tobacco and alcohol users, a non-statistically significant risk (or 1.30; 95%ci: 0.94–1.81) was observed. When considering specific anatomical sites, only laryngeal cancer risk was increased when ever exposed to second-hand tobacco smoke in a lifetime, detected among never tobacco users (OR, 1.71; 95%CI: 0.98–3.00) and among never tobacco and alcohol users (OR, 2.90; 95%CI: 1.09–7.73).

In Germany, in a population-based case–control study on laryngeal cancer, Ramroth *et al.* (2008) observed a non-statistically significant risk (OR, 2.0; 95%CI: 0.39–10.7) for exposure to second-hand tobacco smoke (ever/never) at home and in workplaces among nonsmokers.

(a) Evidence of a dose–response

Zhang *et al.* (2000) observed a dose–response relationship with the intensity of exposure to second-hand tobacco smoke (never, moderate and heavy) on head and neck cancers ($P = 0.025$); those at heavy level of exposure at home or at work showed highest risk for head and neck cancer (OR, 3.6; 95%CI: 1.1–11.5). However, the classification of exposure to second-hand tobacco smoke at work as never, occasionally or regularly did not show any dose–response effect; and the risk for the groups of occasionally or regularly exposed at home were similar and non statistically significant.

Lee *et al.* (2008) explored the intensity and duration of sexposure to second-hand tobacco smoke. For intensity the number of hours of exposure per day was considered at home (0–3 hours, > 3 hours) or at the workplace (never, 1–3 hours and > 3 hours). Among both groups of never tobacco users and never tobacco and alcohol users non-statistically significant risks of head and neck cancers were observed for those exposed for > 3 hours per day at home or at work. For duration the number of years of exposure at home and at work was considered (never, 1–15 years, and > 15 years). Among never tobacco users, there was a trend of increase in risk for head and neck cancers with greater number of years of exposure at home, but not at work. Among never tobacco and alcohol users, the duration of exposure showed a trend for exposure both at work or at home.

Considering specific anatomical sites, for cancer of the oral cavity no dose–response effect was observed with increasing number of years of exposure to second-hand tobacco smoke at home or at work. For cancer of the pharynx, a dose–response effect was observed with increasing number of years of exposure to second-hand tobacco smoke with only at home, in both never tobacco users and never tobacco and alcohol users. For cancer of the larynx, a dose–response effect was noted with increasing number of years of exposure to second-hand tobacco smoke at home among never tobacco users and at work among never tobacco and alcohol users. Among never tobacco and alcohol users, all the odd ratios (OR) were statistically significantly elevated for > 15 years of exposure at home or at work for head and neck cancers overall and separately for cancer of the pharynx, and only at work for cancer of the larynx.

2.3.2 Cancers of the nasopharynx, and nasal cavity and sinonasal cavity

The relationship between exposure to second-hand tobacco smoke and risk for these rare cancers of the upper respiratory tract has

been examined in one cohort study (Hirayama, 1984; Table 2.7 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.7.pdf) and five case–controls studies (Fukuda & Shibata, 1990; Yu *et al.*, 1990; Zheng *et al.*, 1993; Cheng *et al.*, 1999; Yuan *et al.*, 2000; Table 2.6 on-line). A positive association was found in most of these studies.

Hirayama (1984) found an increased risk of sinonasal cancer in women (histology not noted) associated with increasing numbers of cigarettes smoked by husbands of nonsmoking women. When compared with nonsmoking women married to nonsmokers, wives whose husbands smoked had a relative risk of 1.7 (95%CI: 0.7–4.2) for 1–14 cigarettes per day, 2.0 (95%CI: 0.6–6.3) for 15–19 cigarettes per day and 2.55 (95%CI: 1.0–6.3) for ≥ 20 cigarettes per day (*P* for trend = 0.03).

Fukuda & Shibata (1990) reported the results of a Japanese case–control study based on 169 cases of squamous-cell carcinoma of the maxillary sinus and 338 controls matched on sex, age and residence in Hokkaido, Japan. Among nonsmoking women, a relative risk of 5.4 ($P < 0.05$) was associated with exposure in the household to second-hand tobacco smoke from one or more smokers. Active smoking was associated with an increased risk for squamous-cell carcinoma of the maxillary sinus in men in the same study.

Zheng *et al.* (1993) used data from the 1986 US National Mortality Followback Survey to assess risk for cancer of the nasal cavity and sinuses in relation to exposure to second-hand tobacco smoke in white men. A total of 147 deaths from cancer of the nasal cavity and sinuses was compared to 449 controls who had died from other causes (excluding any causes strongly linked to alcohol and/or tobacco use). Data were obtained from postal questionnaires completed by next-of-kins. Among nonsmokers, patients with nasal cancer were more likely to have a spouse who smoked cigarettes (RR, 3.0; 95%CI: 1.0–8.9) after adjustment for age and alcohol use. When the analysis of cases was restricted to those with cancer of the maxillary sinus, the risk was somewhat higher (RR 4.8; 95%CI: 0.9–24.7). The risks reported for active smoking and exposure to second-hand tobacco smoke were of similar magnitude in this study.

Neither second-hand tobacco smoke exposure during childhood nor exposure during adulthood were positively associated with an increased risk for nasopharyngeal cancer in a study in Taiwan, China (Cheng *et al.*, 1999). Although histological type was not specified, all cases were histologically confirmed. Among never-smokers, the risk estimates for cumulative exposure to second-hand tobacco smoke (pack-person-years) in childhood declined as exposure increased (*P* for trend = 0.05); a similar but non-significant inverse relationship was found for exposure during adulthood. Significant elevations in risk for nasopharyngeal cancer were observed for active smokers in this study. [The Working Group noted that the exposure assessment was relatively detailed and that the estimates of relative risk were adjusted for age, sex, education and family history of nasopharyngeal cancer.]

A large population-based case–control study conducted in Shanghai, China, included 935 cases of nasopharyngeal carcinoma and 1032 population controls randomly selected from a population-registry and frequency-matched by sex and 5-year age group (Yuan *et al.*, 2000). All cases were histologically confirmed, but the cell type was not specified. The study subjects were interviewed face to face, and the response rates were 84% for cases and 99% for controls. In female never-smokers, a consistent increase in risk related to exposure to second-hand tobacco smoke during childhood was noted. The relative risk was 3.4 (95%CI: 1.4–8.1) if the mother smoked; 3.0 (95%CI: 1.4–6.2) if the father smoked; 2.7 (95%CI: 1.1–6.9) if another household member smoked and 3.0 (95%CI: 1.4–6.2)

if any household member smoked. Risks associated with exposure to second-hand tobacco smoke during adulthood in women were also statistically significantly increased. For male never-smokers, the associations were weaker and were not statistically significantly elevated for exposure during childhood and adulthood. [The Working Group noted that this was a large, well conducted study that included a detailed exposure assessment and adjustment for numerous potential confounders.]

2.4 Leukaemia and lymphomas

Kasim *et al.* (2005) analysed the risk of leukaemia in adults after exposure to second-hand tobacco smoke (Table 2.8 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.8.pdf). This case–control study was based on postal questionnaires. There was a slightly increased risk (*P* for trend = 0.001) with increasing duration of exposure to second-hand tobacco smoke. The association was limited to chronic lymphocytic leukaemia and was stronger for occupational exposures to second-hand tobacco smoke.

2.5 Other cancers in adults

2.5.1 All cancer combined

Hirayama (1984), Sandler *et al.* (1985b), and Miller (1990) observed a significant association between exposure to second-hand tobacco smoke and overall cancer incidence or mortality. Nishino *et al.* (2001) also studied all cancers combined and reported a relative risk of 1.1 (95%CI: 0.92–1.4) associated with husband's smoking.

2.5.2 Cancers of the gastrointestinal tract

In addition to the studies reviewed previously (Sandler *et al.* 1988; Gerhardsson de Verdier *et al.*, 1992; Mao et.al., 2002), ten new studies have been identified: two cohort (Nishino *et al.*, 2001; Hooker *et al.*, 2008; Table 2.13 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.13.pdf); seven case–control (Sandler *et al.*, 1985a, b; Slattery *et al.*, 2003; Lilla *et al.*, 2006; Wang *et al.*, 2006; Duan *et al.*, 2009; Verla-Tebit *et al.*, 2009; Table 2.14 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.14.pdf) and one case-only study (Peppone *et al.*, 2008; Table 2.15 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.15.pdf). Two studies (Sandler *et al.*, 1985a; Wang *et al.*, 2006) did not provide risk estimates of gastrointestinal cancers for never smokers and are not discussed further. [No data for these studies are included in the tables.]

Sandler *et al.* (1985b) observed a relative risk of 0.7 and 1.3 for cancer of the digestive system from exposure to maternal and paternal passive smoke, respectively. [No CIs were provided and the numbers of never smokers exposed were small.] Verla-Tebit *et al.* (2009) found no evidence of an increased risk for colorectal cancer associated with exposure to second-hand tobacco smoke overall.

(a) Cancer of the colorectum

Nishino *et al.* (2001) observed no association with husband's smoking for cancer of the colon (RR 1.3; CI: 0.65–2.4) or of the rectum (RR 1.8; 0.85–3.9).

Four studies investigated risk for cancer or the colon and/or rectum by sex. Sandler *et al.* (1988) reported an increased risk for colorectal cancer in men (RR 3.0; 95%CI: 1.8–5.0) but a protective effect in women (RR 0.7; 95%CI: 0.6–1.0). Slattery *et al.* (2003) noted that rectal cancer was significantly associated with exposure to second-hand tobacco smoke in men (OR, 1.5; 95%CI: 1.1–2.2 for never smokers) but not in women. Hooker *et al.* (2008) reported an effect among men only, with a significantly increased risk for rectal cancer in the 1963 cohort (RR 5.8, 95%CI: 1.8–18.4) but not

the 1975 cohort. Gerhardsson de Verdier *et al.* (1992) found an increased risk for rectal cancer in men (RR 1.9; 95%CI: 1.0–3) and for colon cancer in women (RR 1.8; 95%CI: 1.2–2.8). [The Working Group noted that it is unclear whether the analysis was restricted to never-smokers.]

When analysing different sources of exposure to second-hand tobacco smoke, Verla-Tebit *et al.* (2009) found no evidence of an increased risk for cancer of the colorectum associated with exposure to second-hand tobacco smoke specifically during childhood or at work, but observed a significant increase in risk associated with spousal exposure.

Peppone *et al.* (2008) noted that considerable exposure to second-hand tobacco smoke, especially during childhood, was more likely to lead to an earlier-age diagnosis of cancer of the colorectum.

In exploring the association of cancer of the colorectum with exposure to second-hand tobacco smoke and NAT1 and NAT2 status, Lilla *et al.* (2006) noted that risk may only be relevant among genetically susceptible (NAT1 and NAT2 status) individuals.

(b) Cancer of the stomach

Nishino *et al.* (2001) observed no association with husband's smoking for cancer of the stomach (RR, 0.95; 95%CI: 0.58–1.6).

The two studies on the association of exposure to second-hand tobacco smoke with stomach cancer by subsite (cardia versus distal) gave contradictory results. In one study (Mao *et al.*, 2002) a positive trend ($P = 0.03$) in risk for cancer of the gastric cardia was associated with lifetime exposure to second-hand tobacco smoke (residential plus occupational) in never smoking men, with a relative risk of 5.8 (95%CI: 1.2–27.5) at the highest level of exposure (≥ 43 years); no increased risks or trends were observed for distal gastric cancer. In the other study, Duan *et al.* (2009) an increased risk for distal gastric cancer was found, but not for gastric cardia [Data were not analysed by sex due to small sample size].

2.5.3 Cancer of the pancreas

Six studies have been identified on the association of exposure to second-hand tobacco smoke with cancer of the pancreas: three cohort (Nishino *et al.*, 2001; Gallicchio *et al.*, 2006; Bao *et al.*, 2009; the latter two are summarized in Table 2.17 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.17.pdf) and three case–control (Villeneuve *et al.*, 2004; Hassan *et al.*, 2007; Lo *et al.*, 2007; the former two studies are summarized in Table 2.18 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.18.pdf).

(a) Exposure in adulthood

Data from the majority of the studies (Nishino *et al.*, 2001; Villeneuve *et al.*, 2004; Gallicchio *et al.*, 2006; Hassan *et al.*, 2007; Bao *et al.*, 2009) suggested lack of an association of cancer of the pancreas with never smokers exposed to second-hand tobacco smoke in adulthood at home or at work. (RR 1.2 (95%CI: 0.45–3.1) and 1.21 (95%CI: 0.60–2.44) respectively).

Lo *et al.* (2007) reported an odd ratio of 6.0 (95%CI: 2.4 –14.8) for never smokers (both sexes combined) exposed to second-hand tobacco smoke in Egypt. [The Working Group noted the small numbers of cases, the use of hospital controls and the small proportion of the cases (35%) with histopathological confirmation. Data are not included in Table 2.18 on-line].

(b) Exposure during childhood

In the Nurses' Health Study, Bao *et al.* (2009) noted an increased risk for cancer of the pancreas (RR 1.42; 95%CI: 1.07–1.89) for maternal but not for paternal smoking (RR 0.97; 95%CI: 0.77–1.21) during childhood.

2.5.4 Cancer of the kidney (renal cell carcinoma)

Two case–control studies have been published on the association of exposure to second-hand tobacco smoke with cancer of the kidney (specifically renal cell carcinoma) since IARC (2004) (Hu *et al.*, 2005; Theis *et al.*, 2008; Table 2.19 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.19.pdf). In both studies a significantly increased risk associated with exposure to second-hand tobacco smoke among never smokers was reported.

2.5.5 Cancer of the urinary bladder

A total of seven studies and one meta-analysis have considered the association between exposure to second-hand tobacco smoke and cancer of the urinary bladder: three cohort studies (Zeegers *et al.*, 2002; Bjerregaard *et al.*, 2006; Alberg *et al.*, 2007; Table 2.9, available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.9.pdf), four case–control studies (Burch *et al.*, 1989; Chen *et al.*, 2005a; Samanic *et al.*, 2006; Jiang *et al.*, 2007; Table 2.10 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.10.pdf), and one meta-analysis (Van Hemelrijck *et al.*, 2009).

(a) Population-based exposure-response relationship

Burch *et al.* (1989) and Zeegers *et al.* (2002) reported no increased risk for cancer of the urinary bladder [Data are not included in the Tables]. Van Hemelrijck *et al.* (2009) reported a meta-relative risk of 0.99 (95%CI: 0.86–1.14) for never smokers exposed to second-hand tobacco smoke. [Data not included in Table. The Working Group noted the marked variation in risk in the analyses by sex and by timing of exposure to second-hand tobacco smoke during adulthood or childhood].

In the European Prospective Investigation into Cancer and Nutrition (EPIC) study, Bjerregaard *et al.* (2006) compared ever versus never exposed to second-hand tobacco smoke as an adult or a child: the risk for cancer of the urinary bladder increased for exposures during childhood (OR, 1.38; 95%CI: 1.00–1.90), and was stronger for never-smokers (OR, 2.02; 95%CI: 0.94–4.35).

Alberg *et al.* (2007) analysed data from two cohorts of non-smoking women in the USA exposed to second-hand smoke at home. An association with exposure to second-hand tobacco smoke was found in the 1963 cohort (RR, 2.3; 95%CI: 1.0–5.4) but not in the 1975 cohort (RR, 0.9; 95%CI: 0.4–2.3). [The Working Group noted the small number of cases available for some of the risk estimates.]

In a study assessing occupational exposure to second-hand tobacco smoke (Samanic *et al.*, 2006), the risk for cancer of the urinary bladder was increased in the highest exposure category among women (RR, 3.3; 95%CI: 1.1–9.5) but not among men (RR, 0.6; 95%CI: 0.2–1.4).

(b) Molecular-based exposure-response relationship

4-aminobiphenyl (4-ABP) can form DNA adducts and induce mutations, and cigarette smoke is the most prominent source of exposure to 4-aminobiphenyl in humans (see Section 4). Jiang *et al.* (2007) used variation in 4-ABP-haemoglobin adducts levels to assess exposure to second-hand tobacco smoke and reported a significantly increased risk with increasing lifetime exposure among never-smoking women exposed in adulthood or childhood.

Chen *et al.* (2005a) hypothesized that the ability to detoxify arsenic (a risk factor urinary bladder cancer) through methylation may modify risk related to second-hand tobacco smoke exposure. Results of the adjusted analyses show that a high primary methylation index associates with lower risk of cancer of the urinary bladder (OR, 0.37; 95%CI: 0.14–0.96, p interaction = 0.11) in second-hand tobacco smoke exposed subjects

compared to unexposed. In endemic area the ability to methylate arsenic may play a role in reducing the risk of cancer of the urinary bladder associated with second-hand tobacco smoke exposure. [The Working Group noted that the small number of cases and the use of hospital controls limit the validity of inferences from this study].

Using case–control data for never and former smokers nested within the EPIC study Vineis *et al.* (2007b) examined susceptibility in genes involved in oxidative stress (such as *NQO1*, *MPO*, *COMT*, *MnSOD*), in phase I (such as *CYP1A1* and *CYP1B1*) and phase II (such as *GSTM1*, and *GSTT1*) metabolizing genes, and in methylene-tetrahydrofolate (*MTHFR*). *GSTM1* deletion was strongly associated with risk for urinary bladder cancer in never smokers (OR, 1.75; 95%CI: 0.89–3.43), and a similar association was noted for former smokers and for men.

2.5.6 Cancer of the cervix

The cohort studies evaluated previously (Hirayama, 1984; Jee *et al.*, 1999; Nishino *et al.*, 2001) consistently indicated the lack of association between exposure to second-hand tobacco smoke and cancer of the uterine cervix, while the informative case–control studies (Sandler *et al.*, 1985b; Slattery *et al.*, 1989; Scholes *et al.*, 1999) suggested a non-statistically significant increase in risk.

A total of 10 new studies have been identified: one cohort study (Table 2.11 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.11.pdf) and nine case–control studies (Buckley *et al.*, 1981; Brown *et al.*, 1982; Hellberg *et al.*, 1986; Hirose *et al.*, 1996; Coker *et al.*, 2002; Wu *et al.*, 2003; Tay & Tay, 2004; Sobti *et al.*, 2006; Tsai *et al.*, 2007; Table 2.12 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.12.pdf). Three early case–control studies (Buckley *et al.*, 1981; Brown *et al.*, 1982; Hellberg *et al.*, 1986) did not look at risk of exposure to second-hand tobacco smoke in never smoking women, and are not further discussed.

(a) Squamous cell carcinoma of the cervix

A significant increase risk for invasive cancer of the uterine cervix associated with exposure to second-hand tobacco smoke during adulthood was found in three case–control studies (Hirose *et al.*, 1996; Wu *et al.*, 2003; Tay & Tay, 2004) and one cohort study (Trimble *et al.*, 2005).

(b) Cervical intraepithelial lesions and neoplasia

An earlier case–control study (Coker *et al.*, 1992) found no statistically significant association between exposure to second-hand tobacco smoke and CIN II/III in non-smokers, after adjustment for age, race, education, number of partners, contraceptive use, history of sexually transmitted disease and history of Pap smear. A later study (Coker *et al.*, 2002) looked at risk of low grade and high grade cervical squamous intraepithelial lesions (LSIL and HSIL, respectively) in HPV positive never-smokers and reported a significant association with exposure to second-hand tobacco smoke. In a community-based case–control study, Tsai *et al.* (2007) observed a markedly increased risk for both CIN1 and CIN2 in both HPV-positive and HPV-negative women exposed to second-hand tobacco smoke. Only Coker *et al.* (2002) and Tsai *et al.* (2007) controlled for HPV status in women.

Sobti *et al.* (2006) reported that cervical cancer risk is increased in individuals exposed to second-hand tobacco smoke with *GSTM1* (null), *GSTT1* (null) and *GSTP1* ($Ile^{105}Val$) genotypes, with odd ratios ranging from 6.4 to 10.2.

2.5.7 Cancer of the ovary

One cohort study (Nishino *et al.*, 2001) and two case–control studies (Goodman & Tung, 2003; Baker *et al.*, 2006; Table 2.16 available at http://monographs.iarc.fr/ENG/Monographs/

vol100E/100E-02-Table2.16.pdf) have been published on the association of exposure to second-hand tobacco smoke with cancer of the ovary. In all three studies a null or inverse association of cancer of the ovary for never smokers exposed to second-hand tobacco smoke was found. Nishino *et al.* (2001) observed no association with husband's smoking (RR 1.7; 95%CI: 0.6- 5.2). Goodman & Tung (2003) reported no association of exposure to second-hand tobacco smoke during childhood with risk of cancer of the ovary. Baker *et al.* (2006) reported a decreased risk of cancer of the ovary for never smokers exposed to second-hand tobacco smoke (OR, 0.68; 95%CI: 0.46–0.99), with similar findings for former and current smokers.

2.5.8 Tumours of the brain and CNS

A total of three case–control studies (Ryan *et al.*, 1992; Hurley *et al.*, 1996; Phillips *et al.*, 2005) have considered the association of second-hand tobacco smoke and cancers of the brain and central nervous system. Ryan *et al.* (1992) reported an increased risk of meningioma associated with spousal exposure, particularly among women (RR 2.7; 95%CI: 1.2–6.1). In a case–control study of gliomas in Australia no association was found for exposure to second-hand tobacco smoke in never smokers (RR 0.97, 95%CI: 0.61–1.53) (both sexes combined) (Hurley *et al.*, 1996). However Phillips *et al.* (2005) found that spousal smoking was associated with an increased risk for intracranial meningioma in both sexes combined (OR, 2.0; 95%CI: 1.1–3.5), the risk increased with increasing duration of exposure (*P* for trend = 0.02).

2.5.9 Other cancers

One case–control study on hepatocellular cancer (Hassan *et al.*, 2008) and one on cancer of the testis (McGlynn *et al.*, 2006) were published since IARC (2004). Hassan *et al.* (2008) did not find an association with exposure to second-hand tobacco smoke and hepatocellular cancer, while that of McGlynn *et al.* (2006) did not support the hypothesis that maternal smoking is related to the development of cancer of the testis (Table 2.20 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.20.pdf). However, these studies provide limited information on the association of exposure to second-hand tobacco smoke with the risk of these cancers.

2.6 Parental tobacco smoking and childhood cancers

2.6.1. Overview

A large number of studies have evaluated the association of cancer risk in childhood with exposure to parental smoking. However, childhood cancers are extremely heterogeneous, both between major cancer sites and within subtypes. In addition, given the rarity of childhood cancers, studies of specific cancer sites and subtypes that have adequate sample sizes and detailed exposure assessments are difficult to achieve.

(a) Smoking exposure assessment

Parental smoking before and during pregnancy exposes germ cells (spermatozoa and ova) and/or the fetus to the same chemical mixture and levels of tobacco smoke as during active smoking, while post-natal exposure to parental tobacco smoking exposes the offspring to second-hand tobacco smoke. Some studies distinguish whether exposure to parental smoking was preconceptional, *in utero* or postnatal. Even when a study reports only on one time period, exposure may have occurred at all three periods. Exposures to tobacco smoking during each of these periods tend to correlate, in particular, paternal smoking is less likely to change during and after pregnancy. In addition, paternal and

maternal smoking habits are highly correlated (Boffetta *et al.*, 2000).

Most studies assessed the number of cigarettes smoked per day (e.g. 0–10, 11–20, 20+) and, when data were available, some assessed continuous consumption of cigarettes per day. One study reported exposure in pack-years (Lee *et al.*, 2009). The SEARC international case–control study assessed polycyclic aromatic hydrocarbons (PAHs) as the main exposure of interest and obtained information on both tobacco smoke and occupational exposures (Cordier *et al.*, 2004).

(b) Bias and confounding

Whitehead *et al.* (2009) evaluated the adequacy of self-reported smoking histories on 469 homes of leukaemia cases and controls and found that nicotine concentrations derived from interview responses to a structured questionnaire strongly correlated to measured levels in dust samples.

The major confounders for the relationship between parental smoking and childhood cancers were markers of socioeconomic status, race or ethnicity, birth weight or gestational age, parental age, sex and age of the case child. In most studies matching or adjusting for these confounders was performed as appropriate. In some studies matching was performed for birth order and centre of diagnosis.

2.6.2 All childhood cancers combined

In addition to the four cohort and 10 case–control studies reviewed by IARC (2004), three case–control studies have examined the role of second-hand tobacco smoke in relation to risk for all childhood cancers combined (Sorahan *et al.*, 2001; Pang *et al.*, 2003; Sorahan & Lancashire, 2004; Table 2.21 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.21.pdf).

(a) Intensity and timing of parental smoking

In a follow-up of the Inter-Regional Epidemiological Study of Childhood Cancer (IRESCC) by McKinney *et al.* (1987), a statistically significant positive trend with daily paternal smoking before pregnancy was observed when cases were compared with controls selected from General Practitioners' (GPs') lists, but not from hospitals; an inverse trend was noted for maternal smoking before pregnancy when cases were compared with hospital, but not with General Practitioners, controls (Sorahan *et al.*, 2001).

In the United Kingdom Childhood Cancer Study (UKCCS), Pang *et al.* (2003) observed a similar pattern of increasing risk with increasing intensity of paternal preconception smoking, and of decreasing risk for increasing maternal smoking before and during pregnancy for all diagnoses combined, and for most individual diagnostic groups.

In the most recent report from the Oxford Survey of Childhood Cancers (OSCC), the risk of death from all childhood cancers combined was not associated with maternal smoking, but was consistently associated with paternal smoking alone or in combination with maternal smoking, in both adjusted and unadjusted analyses [Ex-smokers of more than 2 years before birth of the survey child were assimilated to non-smokers] (Sorahan & Lancashire, 2004).

(b) Bias and confounding

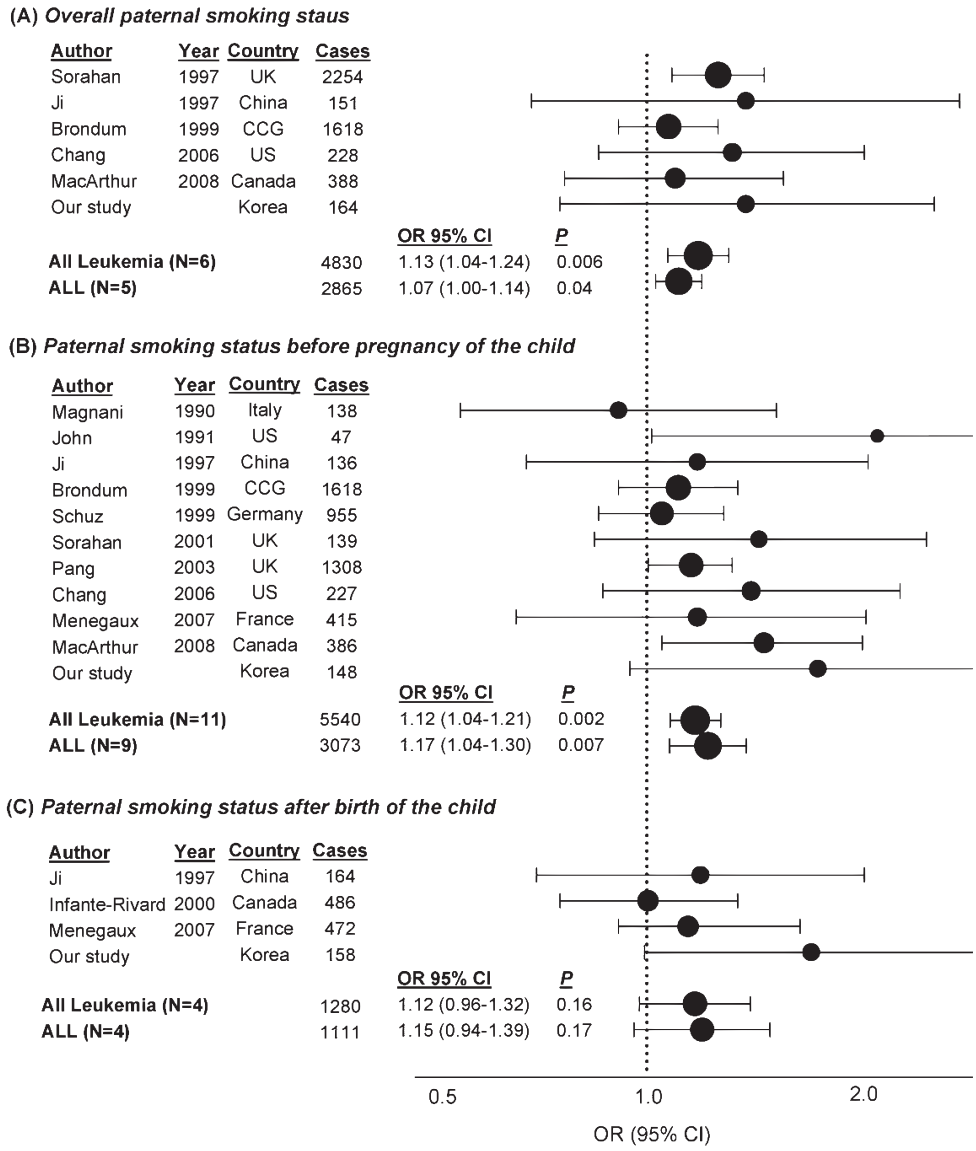
The significant trends observed by Sorahan *et al.* (2001) and Pang & Birch (2003) did not diminish when adjusted for potential confounding covariates or with simultaneous analysis of parental smoking habits. The relationship between maternal smoking and birth weight reported by Sorahan *et al.* (2001) suggested that self-reported maternal smoking was equally reliable for cases and for controls. However, comparisons of smoking patterns with national data suggested that control parents in this study were heavier smokers.

2.6.3 Leukaemias and lymphomas

Since IARC (2004), one cohort study (Mucci *et al.*, 2004) (Table 2.22 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.22.pdf), eleven case–control studies (Table 2.23 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.23.pdf), and one meta-analysis (Lee *et al.*, 2009) (Table 2.24 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.24.pdf) have evaluated the association of parental tobacco smoking with the risk for lymphatic and haematopoietic cancers.

(a) Duration and intensity of exposure

From a meta-analysis of 30 studies published before 1999 Boffetta *et al.* (2000) reported no statistically significant association for all lymphatic and haematopoietic neoplasms and noted evidence of publication bias for the available data.



Lee *et al.* (2009) performed a meta-analysis of twelve studies on paternal smoking and risk of childhood leukaemia. Paternal smoking before conception of the index child was significantly associated with the risk for acute leukaemia (AL) and acute lymphoblastic leukaemia (ALL) (Fig. 2.2).

In a cohort study, maternal smoking was associated with a lower risk of acute lymphoblastic leukaemia, a higher risk of acute myeloid leukaemia (AML) particularly among heavy smokers, and a slight excess risk for non-Hodgkin lymphoma (NHL) (Mucci *et al.*, 2004).

Because of the diversity of types of exposure (paternal, maternal, parental), of timing of exposure (preconception, *in utero*, post-natally) and of the outcome, the case–control studies are briefly summarized individually.

Schüz *et al.* (1999) showed that the risk for acute childhood leukaemias was inversely related to maternal smoking during pregnancy. Paternal smoking before pregnancy showed no association with leukaemia risk for any smoking category. Sorahan *et al.* (2001) reported a non-significant positive association between risk for acute lymphoblastic leukaemia and daily cigarette smoking by fathers before pregnancy, and a non-significant inverse association between risk for acute lymphoblastic leukaemia and daily smoking by mothers before pregnancy. Down Syndrome children are highly susceptible to the development of acute leukaemia. In a case–control study of 27 children with acute leukaemia and Down Syndrome compared with 58 Down Syndrome children without acute leukaemia Mejía-Aranguré *et al.* (2003) found that paternal smoking of more than 10 cigarettes/day, both preconception and after birth of the index child was associated with acute leukaemia. In the UKCC case–control study (Pang *et al.*, 2003), paternal but not maternal preconception tobacco smoking of 1–19 cigarettes/day was associated with an increased risk of leukaemia, and a similar pattern was reported for lymphoma. Menegaux *et al.* (2005) reported no increased risk of acute lymphoblastic leukaemia or acute nonlymphocytic leukaemia (ANLL) associated with any category of post-natal exposure to tobacco smoking (i.e. maternal smoking during breastfeeding or after, paternal smoking after birth, other smokers at home), except for an increased risk of acute nonlymphocytic leukaemia with paternal smoking. In a later study, (Menegaux *et al.*, 2007) reported no association between acute and parental smoking, by subtype (acute myeloid leukaemia or acute lymphoblastic leukaemia) or by time of exposure, with the exception of an increased risk of acute lymphoblastic leukaemia associated with maternal smoking during pregnancy. Chang *et al.* (2006) reported no risk for acute leukaemia, acute lymphoblastic leukaemia or acute myeloid leukaemia associated with maternal smoking either by period of smoking (preconception, during pregnancy, post-natally) or by amount smoked. Paternal preconception smoking was strongly associated

Fig. 2.2 Meta-analysis of the association between paternal smoking and childhood leukaemia

with risk for acute myeloid leukaemia both by period and intensity of smoking. When both paternal preconception smoking and maternal postnatal smoking were considered, the risk for acute lymphoblastic leukaemia was stronger. Rudant *et al.* (2008) reported a significant positive association between paternal smoking and acute lymphoblastic leukaemia, acute myeloid leukaemia, Burkitt lymphoma, and anaplastic large cell non-Hodgkin lymphoma, with increasing relative risks (RR) with increasing number of cigarettes smoked. No associations with Hodgkin lymphoma or other types of non-Hodgkin lymphoma were observed. Non-significantly elevated risks were observed for maternal smoking during pregnancy for acute lymphoblastic leukaemia and non-Hodgkin lymphoma, but not in the highest category of 10 or more cigarettes/day. MacArthur *et al.* (2008) reported non-significantly elevated risk estimates for acute lymphoblastic leukaemia and acute myeloid leukaemia with maternal smoking, but

not with paternal smoking, before and during pregnancy. Lee *et al.* (2009) in Seoul, Republic of Korea, reported that paternal smoking was associated with a significantly increased risk of acute leukaemia and acute lymphoblastic leukaemia in a dose–response manner. The proportion of mothers who smoked was too low (6.1% in controls) to analyse risk in association with maternal smoking.

(b) Potential confounders

In the study of Down Syndrome children (Mejía-Aranguré *et al.*, 2003), the adjustment models did not show any interaction between paternal alcoholism and smoking. Menegaux *et al.* (2005) examined the association of parental smoking and maternal alcohol and coffee intake during pregnancy with the risk for childhood leukaemia. They found no association of acute lymphoblastic leukaemia or acute nonlymphocytic leukaemia with maternal smoking during pregnancy but an association with maternal alcohol and coffee consumption.

(c) Effect modification

Cigarette smoke is a known germ-cell mutagen in mice (Yauk *et al.*, 2007), a likely germ-cell mutagen in humans (see Section 4.1.3a) and alters gene expression (see Section 4.1.4). Infante-Rivard *et al.* (2000) first assessed the role of parental smoking and *CYP1A1* genetic polymorphisms with leukaemia and reported no statistically significant association with leukaemia overall. However, a case-only subanalysis suggested that the effect of parental smoking may be modified by variant alleles in the *CYP1A1* gene: *CYP1A1*2B* tended to decrease risks and *CYP1A1*2A* and *CYP1A1*4* increased the risks associated with smoking in the second and third trimesters of pregnancy. Clavel *et al.* (2005) examined the role of metabolic polymorphisms in the *CYP1A1*, *GSTM1*, *GSTP1*, *GSTT1* and *NQO1* genes. The slow *EPHX1* allele (exon 3 homozygous genotype) was negatively associated with leukaemia, in particular acute lymphoblastic leukaemia, whereas the fast *EPHX1* allele (exon 4 homozygous genotype) was positively associated with leukaemia overall. A non-significant association with acute lymphoblastic leukaemia was noted for the homozygous *NQO1*2* genotype. There was a significant interaction of the *CYP1A1*2A* allele with smoking in the case-only analysis and a not significant interaction, but similar in magnitude, in the case–control analysis. A significant interaction was also observed with the *GSTM1* deletion in the case-only analysis, but not in the case–control analysis. Lee *et al.* (2009) genotyped five single-nucleotide *CYP1A1* polymorphisms: acute lymphoblastic leukaemia risk was significantly increased for cases without the *CGACC* haplotype and with paternal smoking or the presence of at least one smoker in the home.

RAS is the second most mutated gene in smoking-associated lung tumours (Section 4.1.3b). *RAS* mutations have been consistently correlated with myeloid leukaemias in adults and children, in particular with occupationally-associated adult myeloid leukemias (Taylor *et al.*, 1992; Barletta *et al.*, 2004). Wiemels *et al.* (2005) studied the relationship of *RAS* mutations, hyperdiploidy (> 50 chromosomes) and smoking in a case series of 191 acute leukaemia. Smoking was negatively associated with hyperdiploidy (possibly due to the sensitivity of the hyperdiploid clone and consequent differential survival) and hyperdiploid acute leukaemia cases had the highest rates of *RAS* mutations. [Paternal smoking in the three months before pregnancy was less frequent among hyperdiploids than among non-hyperdiploids.]

2.6.4 Cancers of the brain and central nervous system

Since IARC (2004), the association of exposure to parental smoking and risk for childhood brain and central nervous system (CNS) tumours has been examined in one cohort study (Brooks

et al., 2004; Table 2.25 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.25.pdf), six case–control studies (Schüz *et al.*, 1999; Sorahan *et al.*, 2001; Filippini *et al.*, 2002; Pang *et al.*, 2003; Cordier *et al.*, 2004; Plichart *et al.*, 2008; Table 2.26 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.26.pdf), and one meta-analysis (Huncharek *et al.*, 2002; Table 2.27 available at http://monographs.iarc.fr/ENG/Monographs/vol100E/100E-02-Table2.27.pdf).

A meta-analysis of 30 studies published before 1999 indicated no significant increase in risk for CNS tumours associated with maternal smoking during pregnancy and an increased risk for brain tumours with paternal smoking (Boffetta *et al.*, 2000).

Huncharek *et al.* (2002) included one cohort and eleven case–control studies in a meta-analysis and found no clear association of maternal smoking during pregnancy with risk for childhood brain tumours, and a null risk estimate for all CNS tumours (even when the analysis was restricted to astrocytomas, the main brain tumour type). The results were comparable and consistently null for all sensitivity analyses conducted (Table 2.27 on-line).

Brooks *et al.* (2004) analysing the Swedish birth cohort study observed that children, in particular those aged 2–4 years, whose mother smoked during pregnancy, had an increased incidence of childhood brain tumours; the increase in risk was similar for benign and malignant brain tumours and most apparent for astrocytomas (Table 2.25 on-line).

Schüz *et al.* (1999) evaluated parental smoking and CNS tumour risk in children < 15 years from the German Childhood Cancer Registry (see Table 2.26 on-line). No association with risk of CNS tumours was observed for either maternal smoking during pregnancy or paternal smoking before pregnancy. Sorahan *et al.* (2001) found no significant association or trends of risk of CNS tumours with either paternal or maternal smoking, except for low level of maternal exposure [the latter analysis is based on only eleven exposed cases and one control, yielding a very wide confidence interval]. Filippini *et al.* (2002) observed no association between risk of childhood brain tumours and parental smoking before pregnancy, maternal smoking, regular maternal exposure to second-hand tobacco smoke during pregnancy, or exposure of the child to second-hand tobacco smoke during its first year of life. The results did not vary by child's age at diagnosis, type of CNS tumour or study centre. Plichart *et al.* (2008) reported no association for maternal smoking during pregnancy with CNS tumours, while paternal smoking preconception showed a significant association, especially for astrocytomas. When assessing parental exposure to PAHs, Cordier *et al.* (2004) observed an association of paternal exposure to occupational PAHs preconception with all childhood brain tumours and with astroglial tumours, but no trend of increasing risk with increased exposure. Paternal smoking alone was associated with a risk for astroglial tumours when compared with non-smoking, non-occupationally-exposed fathers. Pang *et al.* (2003) found a decreased CNS risk with maternal smoking of more than 20 cigarettes/day preconception, in both unadjusted and adjusted analyses. In the analyses by histological subgroups a statistically significant decreased risk was associated with maternal smoking during pregnancy for primitive neuroectodermal tumours.

2.6.5 Hepatoblastoma

Hepatoblastoma is an embryonal tumour presumably of fetal origin and prenatal exposures are likely more important than post-natal. In some children, a diagnosis of hepatoblastoma is evident at birth or shortly thereafter, with a median age at diagnosis of 12 months. The ability of hepatoblastoma tumour cells to synthesize α-fetoprotein (AFP), a major serum protein

synthesized by fetal liver cells, also suggests a fetal origin. Also, hepatoblastomas, like many other embryonal tumours, are associated with Beckwith-Wiedemann syndrome and hemihypertrophy, further suggesting a gestational oncogenic event (DeBaun & Tucker, 1998). Data were available for both maternal and paternal exposures from two studies (Pang *et al.*, 2003; Sorahan & Lancashire, 2004) while two other studies (McLaughlin *et al.*, 2006; Pu *et al.*, 2009) were limited to data on maternal smoking, available from birth certificates and medical records, respectively (Table 2.28). Most of these studies had limited sample sizes given the extreme rarity of these tumours.

(a) Parental smoking exposure

After adjustment for relevant covariates, Pang *et al.* (2003) observed a statistically significant increased risk of hepatoblastoma in association with maternal preconception smoking (OR, 2.68; 95%CI: 1.16–6.21, $P = 0.02$) in a somewhat dose-dependent manner ($P = 0.058$). The association with parental smoking was strongest (relative to neither parent smoking) when both parents smoked (OR, 4.74; 95%CI: 1.68–13.35, $P = 0.003$). Sorahan & Lancashire (2004) found no increased risk associated with maternal or paternal smoking alone compared to non-smokers, in both adjusted and unadjusted analyses. In contrast, parental smoking (paternal and maternal smoking combined) was strongly and consistently associated with an increased risk for hepatoblastoma in both adjusted and unadjusted analyses.

In a record-based case–cohort study only maternal smoking was examined (McLaughlin *et al.*, 2006). Extremely low birth weight (< 1000 g) was strongly associated with hepatoblastoma. After adjustement for birth weight, a statistically significant elevated risk for hepatoblastoma was found with maternal smoking (RR 2.1; 95%CI: 1.0–4.2). The increased risk was stronger for children diagnosed at the age of two years or older (RR 6.0 versus 1.4). Also, the relarive risk for maternal smoking and hepatoblastoma was stronger for children with normal birth weight [> 2500 g] than for low birth weight children. For cases of hepatoblastoma diagnosed after the age of two years, the relative risk for maternal smoking among children with normal birth weight was also stronger than that among children with low birth weight.

Another study on maternal smoking only was conducted in Chonquing, China (Pu *et al.*, 2009). After adjustment for birth weight, a significantly increased risk for hepatoblastoma was found for maternal smoking (RR 2.9; 95%CI: 1.1–4.2). Adjustments for maternal age, maternal body mass index and sex of the baby did not change the odd ratios. When analyses were stratified by birth weight, the odd ratio associated with maternal smoking for children with a birth weight greater than 2500 g was increased almost fourfold. Stratification by age at diagnosis showed that the risk increased almost fivefold with diagnosis at the age of two years or over. [The Working Group noted that since information regarding mother's smoking status for both cases and controls was obtained before diagnosis the potential for biased recall of maternal exposures during pregnancy is reduced].

(b) Bias and confounding

The known risk factors for hepatoblastoma include low and very low birth weights (< 2000 g and < 1000 g, respectively), maternal age and use of assisted reproductive technologies. All studies adjusted for maternal age, and low birth weight was addressed in three of them (Pang & Birch, 2003; McLaughlin *et al.*, 2006; Pu *et al.*, 2009). Assisted reproductive technologies were not considered to be an important potential confounder of these studies.

Spector & Ross (2003) argued that the association of hepatoblastoma with parental smoking observed by Pang *et al.* (2003) might be confounded by birth weight. In their response,

Table 2.28 Studies of parental tobacco smoking and childhood hepatoblastoma

Reference, study location and period	Characteristics of cases	Characteristics of controls	Exposure assessment	Exposure categories (case/control)	(Cases/ controls)	OR (95% CI)* * $P < 0.05$ ** $P < 0.01$	Adjustment for potential confounders	Comments
Pang *et al.* (2003) United Kingdom	3838 childhood cancer cases, of which 28 hepatoblastoma; Hospital based; < 15 yr of age; 1991–94 in Scotland; 1992–94 in England and Wales	7581 controls; matched for sex, date of birth and geographical area of residence at diagnosis; randomly selected from Family Health Services Authorities in England and Wales and Health boards in Scotland	Face-to-face structured interviews; Computerized self-administered questionnaires to parents of index child	*Parental smoking*			Deprivation and parental age at birth of index child	Underreporting of smoking by case mothers

d, day or days; yr, year or years

Pang & Birch (2003) showed evidence supporting their initial conclusion: the comparable results for maternal smoking, smoking by both parents and maternal smoking for cases diagnosed at an older age, i.e. one year or older, before and after adjustment for birth weight, appear to rule out low birth weight as an explanation for the association.

Also, both later studies (McLaughlin *et al.*, 2006; Pu *et al.*, 2009) reported higher relative risks for children with normal birth weight compared to those with low birth weight, particularly in cases diagnosed after the age of two years.

2.6.6 Other childhood cancers

Several other childhood cancers have been studied in relation to parental tobacco smoke exposures, namely neuroblastoma, nephroblastoma, bone tumours, Wilms tumour, soft tissue sarcomas, other neoplasms of the reticuloendothelial system, and childhood germ cell tumours. The data are few and inconsistent (Schüz *et al.*, 1999; Sorahan *et al.*, 2001; Chen *et al.*, 2005b; Table 2.28).

2.7 Synthesis

2.7.1 Lung

The totality of evidence available to date firmly establishes that exposure to second-hand tobacco smoke at home and at the workplace is causally associated with lung cancer risk in both men and women. This association has been observed in studies from North America, Europe, and Asia. Emerging evidence is also suggesting that exposure to second-hand tobacco smoke among children significantly enhances the risk of lung cancer in adulthood.

2.7.2 Breast

A large number of cohort studies, case–control studies and meta-analyses have assessed the association between exposure to second-hand tobacco smoke and breast cancer. Recent large cohort studies in Europe and North America showed no association between second-hand tobacco smoke and breast cancer. Positive associations in one or more subgroups were reported from some case–control studies; however, these associations were weaker in more recent studies compared with earlier studies.

Explorative analyses focusing on premenopausal breast cancer have suggested that second-hand tobacco smoke may preferentially cause premenopausal breast cancer. Positive associations were largely reported from case–control studies, in which both recall and publication bias cannot be ruled out. Case–control studies that collect a lifetime exposure history are particularly vulnerable to subjective and differential reporting of exposures that occurred long in the past from sources that are difficult to quantify. Overall, the results for an association with premenopausal breast cancer are also inconsistent.

2.7.3 Upper aerodigestive tract combined

Most evidence of the association between second-hand tobacco smoke and upper aerodigestive tract cancers, and the subsites of the oral cavity, pharynx and larynx, comes from a pooled analysis. Overall, the association between second-hand tobacco smoke exposure and cancers of the larynx and pharynx is less than causal.

2.7.4 Nasopharynx, and nasal cavity and accesory sinuses

There is some evidence from a cohort and case–control study that exposure to second-hand tobacco smoke increases the risk of sinonasal cancer; for cancer of the nasopharynx, the evidence is contradictory.

2.7.5 Others sites

Overall, data are conflicting and sparse for the association of exposure to second-hand tobacco smoke with all cancers combined, cancers of the gastrointestinal tract combined, and cancers of the stomach, colon, rectum, pancreas, liver (hepatocellular carcinoma), kidney (renal cell carcinoma), urinary bladder, cervix, ovary, testes, and brain and central nervous system.

2.7.6 Childhood cancers

(a) All childhood cancers combined

Four cohort studies, 13 case–control studies and one meta-analysis have assessed the association of parental tobacco smoking with childhood cancers, all sites combined, in offspring. Most of the early studies only assessed the contribution of maternal smoking, whereas recent studies generally assessed both paternal and maternal smoking, and at various time periods (preconception, during pregnancy, post-natally). Overall, the evidence for an association between parental smoking and childhood cancer (all sites combined) remains inconsistent and may be subject to bias. Nevertheless, a fairly consistent association of paternal tobacco smoking with childhood cancers is beginning to emerge, which is stronger in studies with more specific exposure assessments.

(b) Leukaemias and lymphomas

Two cohort studies, 27 case–control studies and 2 meta-analyses have examined the association of childhood haematopoietic malignancies (leukaemia and lymphoma) with exposure to parental smoking (paternal, maternal or both). All studies examined leukaemia, and a large number of these addressed non-Hodgkin lymphoma.

The body of evidence suggests a consistent association of leukaemia (and lymphoma) with paternal smoking preconception and with combined parental smoking, with risk ratios ranging from 1.5 to 4.0. Maternal tobacco smoking during pregnancy generally showed modest increases in risk, or null or inverse relationships. The combined effects of preconception and post-conception exposures to tobacco smoke were highly significant.

Several studies on lymphoma risk associated with parental smoking showed significantly elevated risks associated with paternal tobacco smoking preconception. The analyses had small samples sizes, and biases due to participation, recall and response, especially related to exposure, cannot be ruled out.

(c) Brain and central nervous system

The association of childhood tumours of the brain and central nervous system with parental smoking was assessed in two cohort studies, 21 case–control studies and 2 meta-analyses. Overall these studies do not show an association with either paternal smoking, largely preconception, or maternal smoking prior, during or after pregnancy, or by CNS types, gliomas and primitive neuroectodermal tumours. The strongly positive associations noted in some studies for paternal tobacco smoking with astrocytomas are offset by the lack of association with childhood brain tumours reported by the large UK Childhood Cancer Study.

(d) Hepatoblastoma

Four informative case–control studies provided data on the association between parental smoking and hepatoblastomas. Two studies reported on both maternal and paternal smoking, while the two others assessed only maternal smoking. In one study where a large number of categories of childhood cancers ($n = 25$) were assessed, the only childhood cancer that showed an association with parental smoking was hepatoblastoma. This original observation was confirmed in three later studies, with relative risks ranging from 2.0 to 5.5. Chance, bias and

confounding were adequately addressed in the data from the studies available. The evidence for the association of parental smoking with hepatoblastoma is convincing, with an emphasis on prenatal exposures.

(e) Other childhood cancers

Most of the associations reported for the other childhood cancers, notably soft tissue sarcomas, rhabdomyosarcomas, Ewing's sarcoma, neuroblastoma, Wilms tumour, reticuloendothelial sarcomas and germ cell tumours were null, with a few isolated and inconsistent positive observations.

3. Cancer in Experimental Animals

3.1 Simulated second-hand tobacco smoke

Simulated second-hand tobacco smoke, frequently a mixture of 89% sidestream and 11% mainstream smoke, generated from cigarettes by smoking machines (Teague *et al.*, 1994) has been tested for carcinogenicity in adult mice of strains that are genetically susceptible to induction of lung tumours (Malkinson, 1992). Mice were exposed in inhalation chambers. Several studies reported no increase in lung tumour incidence or multiplicity in mice exposed to simulated second-hand tobacco smoke for 5–9 months and killed immediately thereafter (Witschi *et al.*, 1995, 1997a; Finch *et al.*, 1996). It was suggested that the lack of tumour response in simulated second-hand tobacco smoke-exposed mice might be due to treatment-induced stress (as determined by the increased plasma corticosterone level) that has been shown to attenuate lung tumorigenesis (Stinn *et al.*, 2005a).

In subsequent studies from several laboratories (Table 3.1), an increased multiplicity and often increased incidence of lung tumours was reported in male and female A/J mice exposed for five months and kept in filtered air for another four months (Witschi *et al.*, 1997a, b, 1998, 1999; D'Agostini *et al.*, 2001) or longer (Witschi *et al.*, 2006) before the mice were killed. Similar results were obtained with Swiss albino mice (Witschi *et al.*, 2002). In these studies, no nasal tumours were observed in smoke-exposed mice.

In one study, male and female transgenic mice with a dominant negative *p53* mutation on an A/J background were exposed to simulated second-hand tobacco smoke for 9.5 continuous months or for 5 months followed by recovery in air for 4.5 months. Transgenic mice exposed by either regimen developed significantly higher incidence and multiplicity of lung tumours than sham-exposed control transgenic mice (DeFlora *et al.*, 2003). Neither lung tumour incidence nor multiplicity was increased in smoke-exposed wild-type control mice in this study.

In one study, male and female rats exposed to room-aged sidestream cigarette smoke by nose-only inhalation for 24 months and then killed had no increased incidence of lung or other tumours in comparison with fresh-air controls. Lung tumours were not significantly increased in rats exposed for 24 months and kept until 30 months of age (Stinn *et al.*, 2005b).

3.2 Sidestream smoke condensate

In one study, sidestream cigarette smoke condensate applied to the shaved skin of female NMRI mice lower back, at total weekly doses of 5, 10 and 15 mg, for 3 months caused benign and malignant skin tumours and mammary carcinomas in mice observed for their lifespan and was more potently carcinogenic in this assay than mainstream smoke condensate. No cutaneous or subcutaneous tumours developed in any of three control groups ($P < 0.001$) (Mohtashamipur *et al.*, 1990). In one study, fractionated sidestream cigarette smoke condensates were implanted into the lungs of female rats. The fraction containing

d, day or days; F, female; h, hour or hours; M, male; mo, month or months; NR, not reported; NS, not significant; wk, week or weeks

PAHs with four and more rings (dose, 1.06 mg/rat) induced 5 lung carcinomas in 35 treated rats; fractions containing no PAHs or PAHs with two or three rings (16 mg/rat) had little or no carcinogenic effect (Grimmer *et al.*, 1988).

3.3 Observational studies of companion animals

In one study, sinonasal cancers occurred more frequently in pet dogs of long-nosed breeds which lived in homes with at least one smoker (Reif *et al.*, 1998), but no such excess risk was seen in a second study (Bukowski *et al.*, 1998). A marginal excess risk of lung cancer was observed in dogs aged 10 years or less and exposed to household tobacco smoke in one study (Reif *et al.*, 1992). Risk of bladder cancer in dogs was not related to exposure to household cigarette smoke in another study (Glickman *et al.*, 1989).

Risk of malignant lymphoma was increased in pet cats exposed to household tobacco smoke in one study (Bertone *et al.*, 2002), but the conclusion that this association was causal has been questioned (Denson, 2003). In another study by the same group (Bertone *et al.*, 2003), exposure of pet cats to household tobacco smoke was also associated with a non-significant 2-fold increase in risk of oral squamous cell carcinoma.

3.4 Synthesis

Several studies showed consistent increases in lung tumour multiplicity and often lung tumour incidence in inbred strain A/J mice and in transgenic mice with a dominant negative *p53* tumour suppressor gene exposed by inhalation. In addition, in one report, skin and mammary tumours were induced in NMRI mice exposed to sidestream cigarette smoke condensate applied topically to the skin.

4. Other Relevant Data

See Section 4 of the *Monograph* on Tobacco Smoking in this volume.

5. Evaluation

There is *sufficient evidence* in humans for the carcinogenicity of second-hand tobacco smoke. Second-hand tobacco smoke causes cancer of the lung. Also, a positive association has been observed between exposure to second-hand tobacco smoke and cancers of the larynx and the pharynx.

There is *sufficient* evidence in experimental animals for the carcinogenicity of mixtures of mainstream and sidestream tobacco smoke.

There is *sufficient* evidence in experimental animals for the carcinogenicity of sidestream tobacco smoke condensates.

Second-hand tobacco smoke is *carcinogenic to humans (Group 1).*

Tobacco Smoke and Involuntary Smoking

Summary of Data Reported and Evaluation

Tobacco smoking and tobacco smoke

Involuntary smoking

Last updated: 24 July 2002

TOBACCO SMOKING AND TOBACCO SMOKE
(Group 1)

5. Summary of Data Reported and Evaluation

For definition of groups, see Preamble.

VOL.: 83 (2002)

5.1 Exposure data

Smoking of tobacco is practised worldwide by over one thousand million people. However, while smoking prevalence has declined in many developed countries, it remains high in others and is increasing among women and in developing countries. Between one-fifth and two-thirds of men in most populations smoke. Women's smoking rates vary more widely but rarely equal male rates.

Tobacco is most commonly smoked as cigarettes, both manufactured — which are a highly sophisticated nicotine delivery system — and hand-rolled. Pipes, cigars, bidis and other products are used to a lesser extent or predominantly in particular regions. Cigarettes are made from fine-cut tobaccos which are wrapped in paper or a maize leaf. Cigars consist of cut tobacco filler formed in a binder leaf and with a wrapper leaf rolled spirally around the bunch. Bidis contain shredded tobacco wrapped in non-tobacco leaves, usually dried *temburni* leaves.

The chemical composition of tobacco smoke, although influenced by the specific manner in which individuals smoke, is primarily determined by the type of tobacco. It is also influenced by the design of the smoking device or product and, for cigarettes, by the presence or absence of filters, and by other factors including ventilation, paper porosity and types of additives. As a result, concentrations of individual chemicals in smoke vary. Analysis of the ways in which people smoke modern cigarettes shows that actual doses of nicotine, carcinogens and toxins depend on the intensity and method of smoking and have little relation to stated tar yields. The total volume of smoke drawn from cigarettes as a result of specific smoking patterns is the principal determinant of dose to the smoker. All presently available tobacco products that are smoked deliver substantial amounts of established carcinogens to their users.

The yields of tar, nicotine and carbon monoxide from cigarettes, as measured by standard machine-smoking tests, have fallen over recent decades in cigarettes sold in most parts of the world, but have remained higher in some countries. The tar and nicotine yields as currently measured are misleading and have only little value in the assessment of human exposure to carcinogens.

The regulation of smoking and smoke yields varies widely around the world in scope and degree of enforcement. Certain regulatory actions, such as taxes and workplace smoking bans, are effective in reducing smoking rates and protecting nonsmokers.

5.2 Human carcinogenicity data

In the previous 1986 *IARC Monograph* on tobacco smoking, cancers of the lung, oral cavity, pharynx, larynx, oesophagus (squamous-cell carcinoma), pancreas, urinary bladder and renal pelvis were identified as caused by cigarette smoking. Many more studies published since this earlier Monograph support these causal links. In addition, there is now sufficient evidence for a causal association between cigarette smoking and cancers of the nasal cavities and nasal sinuses, oesophagus (adenocarcinoma), stomach, liver, kidney (renal-cell carcinoma), uterine cervix and myeloid leukaemia.

In cancer sites that were causally linked to cigarette smoking in the previous *IARC Monograph* on tobacco smoking, the observed relative risks ranged generally from approximately 3 for pancreatic cancer to more than 20 for lung cancer. For those cancer sites that were now also linked to cigarette smoking in this Monograph,

generally two- to threefold increased risks were observed.

Cigarettes

Lung

Lung cancer is the most common cause of death from cancer in the world. The total number of cases is now estimated to be 1.2 million annually and is still increasing. The major cause of lung cancer is tobacco smoking, primarily of cigarettes. In populations with prolonged cigarette use, the proportion of lung cancer cases attributable to cigarette smoking has reached 90%.

The duration of smoking is the strongest determinant of lung cancer in smokers. Hence, the earlier the age of starting and the longer the continuation of smoking in adulthood, the greater the risk. Risk of lung cancer also increases in proportion to the numbers of cigarettes smoked.

Tobacco smoking increases the risk of all histological types of lung cancer including squamous-cell carcinoma, small-cell carcinoma, adenocarcinoma (including bronchiolar/alveolar carcinoma) and large-cell carcinoma. The association between adenocarcinoma of the lung and smoking has become stronger over time. The carcinogenic effects of cigarette smoking appear similar in both women and men.

Stopping smoking at any age avoids the further increase in risk of lung cancer incurred by continued smoking. The younger the age at cessation, the greater the benefit.

Urinary tract

Tobacco smoking is a major cause of transitional-cell carcinomas of the bladder, ureter and renal pelvis. Risk increases with the duration of smoking and number of cigarettes smoked. As for lung cancer, stopping smoking at any age avoids the further increase in risk incurred by continued smoking.

Evidence from several cohort and case–control studies published since the previous *IARC Monograph* on tobacco smoking has indicated that renal-cell carcinoma is associated with tobacco smoking in both men and women. The association is not explained by confounding. A dose–response relationship with the number of cigarettes smoked has been noted in most studies, and a few also noted a reduction in risk after cessation.

Oral cavity

Tobacco smoking, including cigarette smoking, is causally associated with cancer of the oral cavity (including lip and tongue) in both men and women. Since the previous *IARC Monograph* on tobacco smoking, evidence from many more studies has accumulated that further confirms this association. Use of smokeless tobacco and/or alcohol in combination with tobacco smoking greatly increases the risk of oral cancer. Risk increases substantially with duration of smoking and number of cigarettes smoked. Risk among former smokers is consistently lower than among current smokers and there is a trend of decreasing risk with increasing number of years since quitting.

Nasal cavity and paranasal sinuses

An increased risk of sinonasal cancer among cigarette smokers has been reported in all nine case–control studies for which results are available. Of seven studies that have analysed dose–response relationships, a positive trend was found in five and was suggested in the other two. In all the five studies that have analysed squamous-cell carcinoma and adenocarcinoma separately, the relative risk was clearly increased for squamous-cell carcinoma.

Nasopharynx

An increased risk for nasopharyngeal cancer among cigarette smokers was reported in one cohort study and nine case–control studies. Increased relative risks were reported in both high- and low-risk geographical regions for nasopharyngeal cancer. A dose–response relationship was detected with either duration or amount of smoking. A reduction in risk after quitting was also detected. The potential confounding effect of infection with Epstein–Barr virus was not controlled for in these studies; however, such an effect was not considered to be plausible. No important role was shown for other potential confounders.

Oropharynx and hypopharynx

Oropharyngeal and hypopharyngeal cancer are causally associated with cigarette smoking. The risk increased with increased duration of smoking and daily cigarette consumption and decreased with increasing time since quitting.

Oesophagus

Tobacco smoking is causally associated with cancer of the oesophagus, particularly squamous-cell carcinoma. Tobacco smoking is also causally associated with adenocarcinoma of the oesophagus. In most of the epidemiological studies, the risk for all types of oesophageal cancer increased with numbers of cigarettes smoked daily and duration of smoking. However, risk for oesophageal cancer remains elevated many years after cessation of smoking.

Tobacco and alcohol in combination with tobacco smoking greatly increase the risk for squamous-cell carcinoma of the oesophagus. In India, use of smokeless tobacco in combination with smoking also greatly increases the risk.

Larynx

Laryngeal cancer is causally associated with cigarette smoking. The risk increases substantially with duration and number of cigarettes smoked. Use of alcohol in combination with tobacco smoking greatly increases the risk for laryngeal cancer. A few studies also reported that relative risks for cancer of the larynx increased with decreasing age at start of smoking. The relative risk decreased with increasing time since quitting smoking.

Pancreas

Cancer of the pancreas is causally associated with cigarette smoking. The risk increases with duration of smoking and number of cigarettes smoked daily. The risk remains elevated after allowing for potential confounding factors such as alcohol consumption. The relative risk decreased with increasing time since quitting smoking.

Stomach

The data available in 1986 did not permit the earlier IARC Working Group to conclude that the association between tobacco smoking and stomach cancer was causal. Since that time, further studies have shown a consistent association of cancer of the stomach with cigarette smoking in both men and women in many cohort and case–control studies conducted in various parts of the world. Confounding by other factors (e.g. alcohol consumption, *Helicobacter pylori* infection and dietary factors) can be reasonably ruled out. Risk increases with duration of smoking and number of cigarettes smoked, and decreases with increasing duration of successful quitting. In studies that had adequate numbers, the relative risks for men and women were similar.

Liver

In the previous *IARC Monograph* on tobacco smoking, a causal relationship between liver cancer and smoking could not be established, chiefly due to possible confounding from alcohol intake and hepatitis B and hepatitis C virus infections. Many cohort studies and case–control studies have provided additional information on smoking and liver cancer since then. Most of the cohort studies and the largest case–control studies (most notably those that included community controls) showed a moderate association between tobacco smoking and risk of liver cancer. In many studies, the risk for liver cancer increased with the duration of smoking or the number of cigarettes smoked daily. Former smokers who had stopped smoking for more than 10 years showed a decline in liver cancer risk. Confounding from alcohol can be ruled out, at least in the best case–control studies, by means of careful adjustment for drinking habits. An association with smoking has also been demonstrated among non-drinkers. Many studies, most notably from Asia, have shown no attenuation of the association between smoking and liver cancer after adjustment/stratification for markers of hepatitis B/hepatitis C virus infection. There is now sufficient evidence to judge the association between tobacco smoking and liver cancer as causal.

Cervix

An association of invasive cervical squamous-cell carcinoma with smoking has been observed in the large number of studies reviewed. The most recent studies have controlled for infection with human papillomavirus, a known cause of cervical cancer. The effect of smoking was not diminished by the adjustment for human papillomavirus infection, or analysis restricted to cases and controls both positive for human papillomavirus (as ascertained by human papillomavirus DNA or human papillomavirus serological methods). There is now sufficient evidence to establish a causal association of squamous-cell cervical carcinoma with smoking. In the small number of studies available for adeno- and adeno-squamous-cell carcinoma, no consistent association was observed.

Leukaemia

Myeloid leukaemia in adults was observed to be causally related to smoking. Risk increased with amount of tobacco smoked in a substantial number of adequate studies. No clear evidence of any risk was seen for lymphoid leukaemia/lymphoma.

Support for a causal relationship of smoking with myeloid leukaemia is provided by the finding of known leukaemogens in tobacco smoke, one of which (benzene) is present in sufficient amounts to account for up to half of the estimated excess of acute myeloid leukaemia.

Colorectal cancer

There is some evidence from prospective cohort studies and case–control studies that the risk of colorectal cancer is increased among tobacco smokers. However, it is not possible to conclude that the association between tobacco smoking and colorectal cancer is causal. Inadequate adjustment for various potential confounders could account for some of the small increase in risk that appears to be associated with smoking.

Female breast

Most epidemiological studies have found no association with active smoking, after controlling for established risk factors (e.g. age at time of first birth, parity, family history of breast cancer and alcohol). The large multicentre pooled analysis of the association of smoking with breast cancer in non-drinkers confirms the lack of an increased risk of breast cancer associated with smoking.

Endometrium

Cigarette smoking is not associated with an increased risk for endometrial cancer.

An inverse relationship of cigarette smoking with endometrial cancer is observed consistently in most case–control and cohort studies, after adjustment for major confounders. This pattern is stronger in post-menopausal women.

Prostate

No clear evidence of any risk for prostate cancer is seen in case–control studies or in studies of incident cases in cohort studies. The small excess observed in some analytical mortality studies can reasonably be explained by bias in the attribution of the underlying cause of death.

Other

There is inconsistent and/or sparse evidence for association between cigarette smoking and other cancer sites that were considered by the Working Group.

Cigars and pipes

Cigar and/or pipe smoking is strongly related to cancers of the oral cavity, oropharynx, hypopharynx, larynx and oesophagus, the magnitude of risk being similar to that from cigarette smoking. These risks increase with the amount of cigar and/or pipe smoking and with the combination of alcohol and tobacco consumption. Cigar and/or pipe smoking is causally associated with cancer of the lung and there is evidence that cigar and/or pipe smoking are also causally associated with cancers of the pancreas, stomach and urinary bladder.

Bidi

Bidi smoking is the most common form of tobacco smoking in India and is also prevalent in other south-Asian countries and an emerging problem in the USA. Bidi smoke was considered as carcinogenic in the earlier *IARC Monograph* on tobacco smoking, and later studies have provided further evidence of causality. Case–control studies demonstrated a strong association at various sites: oral cavity (including subsites), pharynx, larynx, oesophagus, lung and stomach. Almost all studies show significant trends with duration of bidi smoking and number of bidis smoked.

Synergy

For public health purposes, synergy should be characterized as a positive departure from additivity. The epidemiological literature often inadequately describes combined effects of smoking with co-exposures to other carcinogenic agents and in many studies power is limited for characterizing combined effects. The issue of synergistic effects can be appropriately addressed by epidemiological studies that show stratified analysis and have sufficient power. The studies reviewed found evidence of synergy between smoking and several occupational causes of lung cancer (arsenic, asbestos and radon), and between smoking and alcohol consumption for cancers of the oral cavity, pharynx, larynx and oesophagus and between smoking and human papillomavirus infection for cancer of the cervix. Data were inadequate to evaluate the evidence for synergy between smoking and other known causes of cancer (e.g. hepatitis B and alcohol for liver cancer).

5.3 Animal carcinogenicity data

Cigarette smoke has been tested for carcinogenicity by inhalation studies in rodents, rabbits and dogs. The model systems for animal exposure to tobacco smoke do not fully simulate human exposure to tobacco smoke, and the tumours that develop in animals are not completely representative of human cancer. Nevertheless, the animal data provide valuable insights regarding the carcinogenic potential of tobacco smoke.

The most compelling evidence for a positive carcinogenic effect of tobacco smoke in animals is the

reproducible increase observed in several studies in the occurrence of laryngeal carcinomas in hamsters exposed to whole tobacco smoke or to its particulate phase. In four of five studies in rats, exposure to whole smoke led to modest increases in the occurrence of malignant and/or benign lung tumours. Similarly, in four of eight studies in mice of varying susceptibility to lung tumour development, exposure to whole smoke led to a modest increase in the frequency of lung adenomas. An increased incidence of lung 'tumours' has also been reported in dogs exposed to tobacco smoke, but it is uncertain whether the histopathological features of the lesions are consistent with malignancy. In hamsters exposed to both cigarette smoke and chemical carcinogens (*N*-nitrosodiethylamine and 7,12-dimethylbenz[*a*]anthracene), the tumour response in the respiratory tract was higher than in hamsters exposed to either agent alone. The same is true in rats exposed simultaneously to cigarette smoke and radionuclides (radon progeny and plutonium oxide).

Cigarette smoke condensate both initiates and promotes tumour development in animals. It reproducibly induces both benign and malignant skin tumours in mice following topical application. Similarly, it produces skin tumours in rabbits following topical application. Topical application to the oral mucosa also produced an increased incidence of lung tumours and lymphomas in mice. In rats, cigarette smoke condensate produced lung tumours after intrapulmonary injection. In initiation/promotion assays in mouse skin, a single topical application of cigarette smoke condensate followed by application of croton oil was sufficient to initiate both benign and malignant skin tumours. Smoke condensates of Indian bidi administered to mice by gavage were found to induce tumours in a number of organs. Collectively, these data provide evidence of the carcinogenic effect of mainstream tobacco smoke in experimental animals.

5.4 Other relevant data

Causal associations have been clearly established between active smoking and adverse reproductive outcomes and numerous non-neoplastic diseases, including chronic obstructive pulmonary disease and cardiovascular diseases.

Tobacco smoking is addictive, and nicotine has been established as the major addictive constituent of tobacco products. Measurement of the nicotine metabolite, cotinine, in human blood, urine or saliva provides a specific and sensitive test for exposure to tobacco smoke and can be used to distinguish active and passive smokers from nonsmokers.

Active smoking raises the concentrations of carbon monoxide, benzene and volatile organic compounds in exhaled air. The concentrations of urinary metabolites of some important tobacco smoke carcinogens and related compounds are consistently higher in smokers than in nonsmokers. These include metabolites of benzene, a known carcinogen in humans, as well as metabolites of several carcinogens that cause lung tumours in rodents. Covalent binding to blood proteins by carcinogens present in tobacco smoke has been demonstrated to occur at significantly higher levels in smokers than in nonsmokers. The adducts are derived from various compounds including aromatic amines (e.g. 4-aminobiphenyl), polycyclic aromatic hydrocarbons (e.g. benzo[*a*]pyrene), tobacco-specific nitrosamines (e.g. 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone), benzene, acrylamide and acrylonitrile.

Smoking-related DNA adducts have been detected by a variety of analytical methods in the respiratory tract, urinary bladder, cervix and other tissues. In many studies the levels of carcinogen-DNA adducts have been shown to be higher in tissues of smokers than in tissues of nonsmokers. Some but not all studies have demonstrated elevated levels of these adducts in the peripheral blood and in full-term placenta. Smoking-related adducts have also been detected in cardiovascular tissues. Collectively, the available biomarker data provide convincing evidence that carcinogen uptake, activation and binding to cellular macromolecules, including DNA, are higher in smokers than in nonsmokers.

The exposure of experimental animals, primarily rodents, to mainstream tobacco smoke results in a number of biological effects that include (i) increases or decreases in the activities of phase I and phase II enzymes involved in carcinogen metabolism, (ii) increases in the activation of antioxidant enzymes, (iii) increased expression of nitric oxide synthase and of various protein kinases and collagenase, (iv) the formation of tobacco smoke-related DNA adducts in several tissues and (v) reduced clearance of particulate material from the lung.

Smoking is known to have inhibitory or inducing effects on the activities of many enzymes in human tissues. These include xenobiotic metabolizing enzymes, which affect drug and carcinogen metabolism. Numerous studies have reported effects on enzymes in cells treated in culture with tobacco smoke or tobacco smoke condensates.

In humans, smoking produces gene mutations and chromosomal abnormalities. Urine from smokers is mutagenic. Relative to nonsmokers, lung tumours of smokers contain higher frequencies of *TP53* and *KRAS* mutations, and the spectrum of mutations has unique features. Most of the genetic effects seen in smokers are also observed in cultured cells or in experimental animals exposed to tobacco smoke or smoke condensate. Tobacco smoke is genotoxic in humans and in experimental animals.

5.5 Evaluation

There is *sufficient evidence* in humans that tobacco smoking causes cancer of the lung, oral cavity, naso-, oro- and hypopharynx, nasal cavity and paranasal sinuses, larynx, oesophagus, stomach, pancreas, liver, kidney (body and pelvis), ureter, urinary bladder, uterine cervix and bone marrow (myeloid leukaemia).

There is *evidence suggesting lack of carcinogenicity* of tobacco smoking in humans for cancers of the female breast and endometrium.

There is *sufficient evidence* in experimental animals for the carcinogenicity of tobacco smoke and tobacco smoke condensates.

Overall evaluation

Tobacco smoking and tobacco smoke *are carcinogenic to humans (Group 1).*

For definition of the italicized terms, see Preamble.

INVOLUNTARY SMOKING
(Group 1)

For definition of groups, see Preamble.

VOL.: 83 (2002)

5. Summary of Data Reported and Evaluation

5.1 Exposure data

Involuntary (or passive) smoking is exposure to secondhand tobacco smoke, which is a mixture of exhaled mainstream smoke and sidestream smoke released from the smouldering cigarette or other smoking device (cigar, pipe, bidi, etc.) and diluted with ambient air. Involuntary smoking involves inhaling carcinogens, as well as other toxic components, that are present in secondhand tobacco smoke. Secondhand tobacco smoke is sometimes referred to as 'environmental' tobacco smoke. Carcinogens that occur in secondhand tobacco smoke include benzene, 1,3-butadiene, benzo[*a*]pyrene, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone and many others.

Secondhand tobacco smoke consists of a gas phase and a particulate phase; it changes during its dilution and distribution in the environment and upon ageing. The concentrations of respirable particles may be elevated substantially in enclosed spaces containing secondhand tobacco smoke. The composition of tobacco smoke inhaled involuntarily is variable quantitatively and depends on the smoking patterns of the smokers who are producing the smoke as well as the composition and design of the cigarettes or other smoking devices. The secondhand tobacco smoke produced by smoking cigarettes has been most intensively studied.

Secondhand tobacco smoke contains nicotine as well as carcinogens and toxins. Nicotine concentrations in the air in homes of smokers and in workplaces where smoking is permitted typically range on average from 2 to 10 micrograms/m^3.

5.2 Human carcinogenicity data

Lung cancer

Involuntary smoking involves exposure to the same numerous carcinogens and toxic substances that are present in tobacco smoke produced by active smoking, which is the principal cause of lung cancer. As noted in the previous *IARC Monograph* on tobacco smoking, this implies that there will be some risk of lung cancer from exposure to secondhand tobacco smoke.

More than 50 studies of involuntary smoking and lung cancer risk in never-smokers, especially spouses of smokers, have been published during the last 25 years. These studies have been carried out in many countries. Most showed an increased risk, especially for persons with higher exposures. To evaluate the information collectively, in particular from those studies with a limited number of cases, meta-analyses have been conducted in which the relative risk estimates from the individual studies are pooled together. These meta-analyses show that there is a statistically significant and consistent association between lung cancer risk in spouses of smokers and exposure to secondhand tobacco smoke from the spouse who smokes. The excess risk is of the order of 20% for women and 30% for men and remains after controlling for some potential sources of bias and confounding. The excess risk increases with increasing exposure. Furthermore, other published meta-analyses of lung cancer in never-smokers exposed to secondhand tobacco smoke at the workplace have found a statistically significant increase in risk of 12–19%. This evidence is sufficient to conclude that involuntary smoking is a cause of lung cancer in never-smokers. The magnitudes of the observed risks are reasonably consistent with predictions based on studies of active smoking in many populations.

Breast cancer

The collective evidence on breast cancer risk associated with involuntary exposure of never-smokers to tobacco smoke is inconsistent. Although four of the 10 case–control studies found statistically significant increases in risks, prospective cohort studies as a whole and, particularly, the two large cohort studies in the USA of nurses and of volunteers in the Cancer Prevention Study II provided no support for a causal relation between involuntary exposure to tobacco smoke and breast cancer in never-smokers. The lack of a positive dose–response also argues against a causal interpretation of these findings. Finally, the lack of an association of breast cancer with active smoking weighs heavily against the possibility that involuntary smoking increases the risk for breast cancer, as no data are available to establish that different mechanisms of carcinogenic action operate at the different dose levels of active and of involuntary smoking.

Childhood cancer

Overall, the findings from studies of childhood cancer and exposure to parental smoking are inconsistent and are likely to be affected by bias. There is a suggestion of a modest association between exposure to maternal tobacco smoke during pregnancy and childhood cancer for all cancer sites combined; however, this is in contrast with the null findings for individual sites. Studies on paternal tobacco smoking suggest a small increased risk for lymphomas, but bias and confounding cannot be ruled out.

Other cancer sites

Data are conflicting and sparse for associations between involuntary smoking and cancers of the nasopharynx, nasal cavity, paranasal sinuses, cervix, gastrointestinal tract and cancers at all sites combined. It is unlikely that any effects are produced in passive smokers that are not produced to a greater extent in active smokers or that types of effects that are not seen in active smokers will be seen in passive smokers.

5.3 Animal carcinogenicity data

Secondhand tobacco smoke for carcinogenicity studies in animals is produced by machines that simulate human active smoking patterns and combine mainstream and sidestream smoke in various proportions. Such mixtures have been tested for carcinogenicity by inhalation studies in rodents. The experimental model systems for exposure to secondhand tobacco smoke do not fully simulate human exposures, and the tumours that develop in animals are not completely representative of human cancer. Nevertheless, the animal data provide valuable insights regarding the carcinogenic potential of secondhand tobacco smoke.

A mixture of 89% sidestream smoke and 11% mainstream smoke has been tested for carcinogenic activity in mouse strains that are highly susceptible to lung tumours (strains A/J and Swiss). In strain A/J mice, this mixture consistently produces a significant, modest increase in lung tumour incidence and lung tumour multiplicity when the mice are exposed for 5 months followed by a 4-month recovery period. These lung tumours are predominantly adenomas. Continuous exposure of strain A/J mice to the above mixture of mainstream and sidestream tobacco smoke for 9 months with no recovery period did not increase the incidence of lung tumours. In Swiss strain mice, the same mixture induced lung tumours by both protocols, i.e. when the animals were exposed for 5 months followed by a 4-month recovery period and when they were exposed continuously for 9 months with no recovery period. In addition, exposure of Swiss mice to the tobacco smoke mixture for a shorter period was sufficient to induce lung tumours.

Condensates of sidestream and of mainstream cigarette smoke have been tested for carcinogenicity. Both kinds of condensates produced a spectrum of benign and malignant skin tumours in mice following topical application, and the sidestream condensate exhibited higher carcinogenic activity. Sidestream smoke condensate was shown to produce a dose-dependent increase in lung tumours in rats following implantation into the lungs.

Increased relative risks for lung and sinonasal cancer have been reported in companion animals

(dogs) exposed to secondhand tobacco smoke in homes.

5.4 Other relevant data

Involuntary smoking has been associated with a number of non-neoplastic diseases and adverse effects in never-smokers, including both children and adults. Epidemiological studies have demonstrated that exposure to secondhand tobacco smoke is causally associated with coronary heart disease. From the available meta-analyses, it has been estimated that involuntary smoking increases the risk of an acute coronary heart disease event by 25–35%. Adverse effects of involuntary smoking on the respiratory system have also been detected. In adults, the strongest evidence for a causal relation exists for chronic respiratory symptoms. Some effects on lung function have been detected, but their medical relevance is uncertain.

Data on the hormonal and metabolic effects of involuntary smoking are sparse. However, female involuntary smokers do not appear to weigh less than women who are not exposed to secondhand tobacco smoke, a pattern that contrasts with the findings for active smoking. No consistent association of maternal exposure to secondhand smoke with fertility or fecundity has been identified. There is no clear association of passive smoking with age at menopause.

Maternal cigarette smoking has repeatedly been associated with adverse effects on fetal growth; full-term infants born to women who smoke weigh about 200 g less than those born to nonsmokers. A smaller adverse effect has been attributed to maternal passive smoking.

Cotinine, and its parent compound nicotine, are highly specific for exposure to secondhand smoke. Because of its favourable biological half-life and the sensitivity of techniques for quantifying it, cotinine is currently the most suitable biomarker for assessing recent exposure to secondhand tobacco smoke uptake and metabolism in adults, children and newborns.

Several studies in humans have shown that concentrations of adducts of carcinogens to biological macromolecules, including haemoglobin adducts of aromatic amines and albumin adducts of polycyclic aromatic hydrocarbons, are higher in adult involuntary smokers and in the children of smoking mothers than in individuals not exposed to secondhand tobacco smoke. Protein adduct concentrations in fetal cord blood correlate with those in maternal blood but are lower. Fewer studies have investigated DNA adduct levels in white blood cells of exposed and unexposed nonsmokers, and most studies have not shown clear differences.

In studies of urinary biomarkers, metabolites of the tobacco-specific carcinogen, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, have been found to be consistently elevated in involuntary smokers. Levels of these metabolites are 1–5% as great as those found in smokers. The data demonstrating uptake of 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, a lung carcinogen in rodents, by nonsmokers are supportive of a causal link between exposure to secondhand tobacco smoke and development of lung cancer.

The exposure of experimental animals, primarily rodents, to secondhand tobacco smoke has several biological effects that include (i) increases or decreases in the activity of phase I enzymes involved in carcinogen metabolism; (ii) increased expression of nitric oxide synthase, xanthine oxidase and various protein kinases; (iii) the formation of smoke-related DNA adducts in several tissues; and (iv) the presence of urinary biomarkers of exposure to tobacco smoke.

In adult experimental animals, sidestream tobacco smoke has been found to produce changes that are similar to those observed with exposure of humans to secondhand tobacco smoke. These include inflammatory changes in the airways and accelerated formation of arteriosclerotic plaques. Although the changes are often comparatively minor and require exposure to rather elevated concentrations of sidestream smoke, they support the results of human epidemiological studies. During pre- and postnatal exposure, sidestream smoke produces intrauterine growth retardation, changes the pattern of metabolic enzymes in the developing lung, and gives rise to hyperplasia of the pulmonary neuroendocrine cell population. In addition, it adversely affects pulmonary compliance and airway responsiveness to pharmacological challenges.

In humans, involuntary smoking is associated with increased concentrations of mutagens in urine. Some studies have shown a correlation of urinary mutagenicity with concentrations of urinary cotinine. Increased levels of sister chromatid exchanges have not been observed in involuntary smokers; however, there is some indication of elevated levels in exposed children. Lung tumours from nonsmokers exposed to tobacco smoke contain *TP53* and *KRAS* mutations that are similar to those found in tumours from smokers. The genotoxicity of sidestream smoke, 'environmental' tobacco smoke, sidestream smoke condensate or a mixture of sidestream and mainstream smoke condensates has been demonstrated in experimental systems *in vitro* and *in vivo*.

5.5 Evaluation

There is *sufficient evidence* that involuntary smoking (exposure to secondhand or 'environmental' tobacco smoke) causes lung cancer in humans.

There is *limited evidence* in experimental animals for the carcinogenicity of mixtures of mainstream and sidestream tobacco smoke.

There is *sufficient evidence* in experimental animals for the carcinogenicity of sidestream smoke condensates.

In addition, the Working Group noted that there are published reports on possible carcinogenic effects of secondhand tobacco smoke in household pet dogs.

Overall evaluation

Involuntary smoking (exposure to secondhand or 'environmental' tobacco smoke) is *carcinogenic to humans (Group 1)*.

2004

IARC MONOGRAPHS

In 1969, the International Agency for Research on Cancer (IARC) initiated a programme on the evaluation of the carcinogenic risk of chemicals to humans involving the production of critically evaluated monographs on individual chemicals. The programme was subsequently expanded to include evaluations of carcinogenic risks associated with exposures to complex mixtures, life-style factors and biological and physical agents, as well as those in specific occupations.

The objective of the programme is to elaborate and publish in the form of monographs critical reviews of data on carcinogenicity for agents to which humans are known to be exposed and on specific exposure situations; to evaluate these data in terms of human risk with the help of international working groups of experts in chemical carcinogenesis and related fields; and to indicate where additional research efforts are needed.

The lists of IARC evaluations are regularly updated and are available on Internet: http://monographs.iarc.fr/

This project was supported by Cooperative Agreement 5 UO1 CA33193 awarded by the United States National Cancer Institute, Department of Health and Human Services. Additional support has been provided since 1993 by the United States National Institute of Environmental Health Sciences.

This project was funded in part by the European Commission, Directorate-General EMPL (Employment and Social Affairs), Health, Safety and Hygiene at Work Unit.

Cover design by Georges Mollon, IARC

... And for the vanities committed in this filthy custom, is it not both great vanity and uncleanness, that at the table, a place of respect, of cleanliness, of modesty, men should not be ashamed, to sit tossing of tobacco pipes, and puffing of the smoke of tobacco one to another, making the filthy smoke and stink thereof, to exhale across the dishes, and infect the air, when very often men that abhor it are at their repast? ... It makes a kitchen also often-times in the inward parts of men, soiling and infecting them, with an ... oily kind of soot, as has been found in some great tobacco takers, that after their death were opened .... Have you not reason then to be ashamed and to forbear this filthy novelty ... a custom loathsome to the eye, hateful to the nose, harmful to the brain, dangerous to the lungs, and in the black stinking fume thereof, nearest resembling the horrible Stygian smoke of the Pit that is bottomless ?

LIST OF ABBREVIATIONS USED IN THIS VOLUME 1415

CUMULATIVE INDEX TO THE *MONOGRAPHS* SERIES.....1419

NOTE TO THE READER

The term ‘carcinogenic risk’ in the *IARC Monographs* series is taken to mean the probability that exposure to an agent will lead to cancer in humans.

Inclusion of an agent in the *Monographs* does not imply that it is a carcinogen, only that the published data have been examined. Equally, the fact that an agent has not yet been evaluated in a monograph does not mean that it is not carcinogenic.

The evaluations of carcinogenic risk are made by international working groups of independent scientists and are qualitative in nature. No recommendation is given for regulation or legislation.

Anyone who is aware of published data that may alter the evaluation of the carcinogenic risk of an agent to humans is encouraged to make this information available to the Unit of Carcinogen Identification and Evaluation, International Agency for Research on Cancer, 150 cours Albert Thomas, 69372 Lyon Cedex 08, France, in order that the agent may be considered for re-evaluation by a future Working Group.

Although every effort is made to prepare the monographs as accurately as possible, mistakes may occur. Readers are requested to communicate any errors to the Unit of Carcinogen Identification and Evaluation, so that corrections can be reported in future volumes.

IARC WORKING GROUP ON THE EVALUATION OF CARCINOGENIC RISKS TO HUMANS: TOBACCO SMOKE AND INVOLUNTARY SMOKING

Lyon, 11–18 June 2002

LIST OF PARTICIPANTS

Members[1]

Michael Alavanja, Division of Cancer Epidemiology & Genetics, National Cancer Institute, 6120 Executive Boulevard, Room 8000, Rockville, MD 20892, USA

John A. Baron, Biostatistics/Epidemiology, Evergreen Center, 46 Centerra Parkway, Lebanon, NH 03756, USA

Ross C. Brownson, Saint Louis University School of Public Health, Salus Center Room 469, 3545 Lafayette Avenue, St Louis, MO 63104, USA

Patricia A. Buffler, School of Public Health, University of California at Berkeley, 140 Earl Warren Hall, Berkeley, CA 94720-7360, USA

David M. DeMarini, Environmental Carcinogenesis Division (MD-68), US Environmental Protection Agency, 86 Alexander Drive, Research Triangle Park, NC 27711, USA

Mirjana V. Djordjevic, Tobacco Control Research Branch, Division of Cancer Control & Population Sciences, National Cancer Institute, 6130 Executive Boulevard, EPN 4044, MSC 7337, Bethesda, MD 20852-7337, USA

Richard Doll, Clinical Trial Service Unit & Epidemiological Studies Unit, Nuffield Department of Clinical Medicine, University of Oxford, Harkness Building, Radcliffe Infirmary, Oxford OX2 6HE, United Kingdom

PREAMBLE

IARC MONOGRAPHS PROGRAMME ON THE EVALUATION OF CARCINOGENIC RISKS TO HUMANS

PREAMBLE

1. BACKGROUND

In 1969, the International Agency for Research on Cancer (IARC) initiated a programme to evaluate the carcinogenic risk of chemicals to humans and to produce monographs on individual chemicals. The *Monographs* programme has since been expanded to include consideration of exposures to complex mixtures of chemicals (which occur, for example, in some occupations and as a result of human habits) and of exposures to other agents, such as radiation and viruses. With Supplement 6 (IARC, 1987a), the title of the series was modified from *IARC Monographs on the Evaluation of the Carcinogenic Risk of Chemicals to Humans* to *IARC Monographs on the Evaluation of Carcinogenic Risks to Humans*, in order to reflect the widened scope of the programme.

The criteria established in 1971 to evaluate carcinogenic risk to humans were adopted by the working groups whose deliberations resulted in the first 16 volumes of the *IARC Monographs series*. Those criteria were subsequently updated by further ad-hoc working groups (IARC, 1977, 1978, 1979, 1982, 1983, 1987b, 1988, 1991a; Vainio *et al.*, 1992).

2. OBJECTIVE AND SCOPE

The objective of the programme is to prepare, with the help of international working groups of experts, and to publish in the form of monographs, critical reviews and evaluations of evidence on the carcinogenicity of a wide range of human exposures. The *Monographs* may also indicate where additional research efforts are needed.

The *Monographs* represent the first step in carcinogenic risk assessment, which involves examination of all relevant information in order to assess the strength of the available evidence that certain exposures could alter the incidence of cancer in humans. The second step is quantitative risk estimation. Detailed, quantitative evaluations of epidemiological data may be made in the *Monographs*, but without extrapolation beyond the range of the data available. Quantitative extrapolation from experimental data to the human situation is not undertaken.

The term ‘carcinogen’ is used in these monographs to denote an exposure that is capable of increasing the incidence of malignant neoplasms; the induction of benign neo-

plasms may in some circumstances (see p. 19) contribute to the judgement that the exposure is carcinogenic. The terms 'neoplasm' and 'tumour' are used interchangeably.

Some epidemiological and experimental studies indicate that different agents may act at different stages in the carcinogenic process, and several mechanisms may be involved. The aim of the *Monographs* has been, from their inception, to evaluate evidence of carcinogenicity at any stage in the carcinogenesis process, independently of the underlying mechanisms. Information on mechanisms may, however, be used in making the overall evaluation (IARC, 1991a; Vainio *et al.*, 1992; see also pp. 25–27).

The *Monographs* may assist national and international authorities in making risk assessments and in formulating decisions concerning any necessary preventive measures. The evaluations of IARC working groups are scientific, qualitative judgements about the evidence for or against carcinogenicity provided by the available data. These evaluations represent only one part of the body of information on which regulatory measures may be based. Other components of regulatory decisions vary from one situation to another and from country to country, responding to different socioeconomic and national priorities. **Therefore, no recommendation is given with regard to regulation or legislation, which are the responsibility of individual governments and/or other international organizations.**

The *IARC Monographs* are recognized as an authoritative source of information on the carcinogenicity of a wide range of human exposures. A survey of users in 1988 indicated that the *Monographs* are consulted by various agencies in 57 countries. About 2500 copies of each volume are printed, for distribution to governments, regulatory bodies and interested scientists. The Monographs are also available from IARC*Press* in Lyon and via the Marketing and Dissemination (MDI) of the World Health Organization in Geneva.

3. SELECTION OF TOPICS FOR MONOGRAPHS

Topics are selected on the basis of two main criteria: (a) there is evidence of human exposure, and (b) there is some evidence or suspicion of carcinogenicity. The term 'agent' is used to include individual chemical compounds, groups of related chemical compounds, physical agents (such as radiation) and biological factors (such as viruses). Exposures to mixtures of agents may occur in occupational exposures and as a result of personal and cultural habits (like smoking and dietary practices). Chemical analogues and compounds with biological or physical characteristics similar to those of suspected carcinogens may also be considered, even in the absence of data on a possible carcinogenic effect in humans or experimental animals.

The scientific literature is surveyed for published data relevant to an assessment of carcinogenicity. The IARC information bulletins on agents being tested for carcinogenicity (IARC, 1973–1996) and directories of on-going research in cancer epidemiology (IARC, 1976–1996) often indicate exposures that may be scheduled for future meetings. Ad-hoc working groups convened by IARC in 1984, 1989, 1991, 1993 and

1998 gave recommendations as to which agents should be evaluated in the IARC Monographs series (IARC, 1984, 1989, 1991b, 1993, 1998a,b).

As significant new data on subjects on which monographs have already been prepared become available, re-evaluations are made at subsequent meetings, and revised monographs are published.

4. DATA FOR MONOGRAPHS

The *Monographs* do not necessarily cite all the literature concerning the subject of an evaluation. Only those data considered by the Working Group to be relevant to making the evaluation are included.

With regard to biological and epidemiological data, only reports that have been published or accepted for publication in the openly available scientific literature are reviewed by the working groups. In certain instances, government agency reports that have undergone peer review and are widely available are considered. Exceptions may be made on an ad-hoc basis to include unpublished reports that are in their final form and publicly available, if their inclusion is considered pertinent to making a final evaluation (see pp. 25–27). In the sections on chemical and physical properties, on analysis, on production and use and on occurrence, unpublished sources of information may be used.

5. THE WORKING GROUP

Reviews and evaluations are formulated by a working group of experts. The tasks of the group are: (i) to ascertain that all appropriate data have been collected; (ii) to select the data relevant for the evaluation on the basis of scientific merit; (iii) to prepare accurate summaries of the data to enable the reader to follow the reasoning of the Working Group; (iv) to evaluate the results of epidemiological and experimental studies on cancer; (v) to evaluate data relevant to the understanding of mechanism of action; and (vi) to make an overall evaluation of the carcinogenicity of the exposure to humans.

Working Group participants who contributed to the considerations and evaluations within a particular volume are listed, with their addresses, at the beginning of each publication. Each participant who is a member of a working group serves as an individual scientist and not as a representative of any organization, government or industry. In addition, nominees of national and international agencies and industrial associations may be invited as observers.

6. WORKING PROCEDURES

Approximately one year in advance of a meeting of a working group, the topics of the monographs are announced and participants are selected by IARC staff in consultation with other experts. Subsequently, relevant biological and epidemiological data are

collected by the Carcinogen Identification and Evaluation Unit of IARC from recognized sources of information on carcinogenesis, including data storage and retrieval systems such as MEDLINE and TOXLINE.

For chemicals and some complex mixtures, the major collection of data and the preparation of first drafts of the sections on chemical and physical properties, on analysis, on production and use and on occurrence are carried out under a separate contract funded by the United States National Cancer Institute. Representatives from industrial associations may assist in the preparation of sections on production and use. Information on production and trade is obtained from governmental and trade publications and, in some cases, by direct contact with industries. Separate production data on some agents may not be available because their publication could disclose confidential information. Information on uses may be obtained from published sources but is often complemented by direct contact with manufacturers. Efforts are made to supplement this information with data from other national and international sources.

Six months before the meeting, the material obtained is sent to meeting participants, or is used by IARC staff, to prepare sections for the first drafts of monographs. The first drafts are compiled by IARC staff and sent before the meeting to all participants of the Working Group for review.

The Working Group meets in Lyon for seven to eight days to discuss and finalize the texts of the monographs and to formulate the evaluations. After the meeting, the master copy of each monograph is verified by consulting the original literature, edited and prepared for publication. The aim is to publish monographs within six months of the Working Group meeting.

The available studies are summarized by the Working Group, with particular regard to the qualitative aspects discussed below. In general, numerical findings are indicated as they appear in the original report; units are converted when necessary for easier comparison. The Working Group may conduct additional analyses of the published data and use them in their assessment of the evidence; the results of such supplementary analyses are given in square brackets. When an important aspect of a study, directly impinging on its interpretation, should be brought to the attention of the reader, a comment is given in square brackets.

7. EXPOSURE DATA

Sections that indicate the extent of past and present human exposure, the sources of exposure, the people most likely to be exposed and the factors that contribute to the exposure are included at the beginning of each monograph.

Most monographs on individual chemicals, groups of chemicals or complex mixtures include sections on chemical and physical data, on analysis, on production and use and on occurrence. In monographs on, for example, physical agents, occupational exposures and cultural habits, other sections may be included, such as: historical perspectives, description of an industry or habit, chemistry of the complex mixture or taxonomy. Mono-

graphs on biological agents have sections on structure and biology, methods of detection, epidemiology of infection and clinical disease other than cancer.

For chemical exposures, the Chemical Abstracts Services Registry Number, the latest Chemical Abstracts primary name and the IUPAC systematic name are recorded; other synonyms are given, but the list is not necessarily comprehensive. For biological agents, taxonomy and structure are described, and the degree of variability is given, when applicable.

Information on chemical and physical properties and, in particular, data relevant to identification, occurrence and biological activity are included. For biological agents, mode of replication, life cycle, target cells, persistence and latency and host response are given. A description of technical products of chemicals includes trade names, relevant specifications and available information on composition and impurities. Some of the trade names given may be those of mixtures in which the agent being evaluated is only one of the ingredients.

The purpose of the section on analysis or detection is to give the reader an overview of current methods, with emphasis on those widely used for regulatory purposes. Methods for monitoring human exposure are also given, when available. No critical evaluation or recommendation of any of the methods is meant or implied. The IARC published a series of volumes, *Environmental Carcinogens: Methods of Analysis and Exposure Measurement* (IARC, 1978–93), that describe validated methods for analysing a wide variety of chemicals and mixtures. For biological agents, methods of detection and exposure assessment are described, including their sensitivity, specificity and reproducibility.

The dates of first synthesis and of first commercial production of a chemical or mixture are provided; for agents which do not occur naturally, this information may allow a reasonable estimate to be made of the date before which no human exposure to the agent could have occurred. The dates of first reported occurrence of an exposure are also provided. In addition, methods of synthesis used in past and present commercial production and different methods of production which may give rise to different impurities are described.

Data on production, international trade and uses are obtained for representative regions, which usually include Europe, Japan and the United States of America. It should not, however, be inferred that those areas or nations are necessarily the sole or major sources or users of the agent. Some identified uses may not be current or major applications, and the coverage is not necessarily comprehensive. In the case of drugs, mention of their therapeutic uses does not necessarily represent current practice, nor does it imply judgement as to their therapeutic efficacy.

Information on the occurrence of an agent or mixture in the environment is obtained from data derived from the monitoring and surveillance of levels in occupational environments, air, water, soil, foods and animal and human tissues. When available, data on the generation, persistence and bioaccumulation of the agent are also included. In the case of mixtures, industries, occupations or processes, information is given about all

agents present. For processes, industries and occupations, a historical description is also given, noting variations in chemical composition, physical properties and levels of occupational exposure with time and place. For biological agents, the epidemiology of infection is described.

Statements concerning regulations and guidelines (e.g., pesticide registrations, maximal levels permitted in foods, occupational exposure limits) are included for some countries as indications of potential exposures, but they may not reflect the most recent situation, since such limits are continuously reviewed and modified. The absence of information on regulatory status for a country should not be taken to imply that that country does not have regulations with regard to the exposure. For biological agents, legislation and control, including vaccines and therapy, are described.

8. STUDIES OF CANCER IN HUMANS

(*a*) *Types of studies considered*

Three types of epidemiological studies of cancer contribute to the assessment of carcinogenicity in humans — cohort studies, case–control studies and correlation (or ecological) studies. Rarely, results from randomized trials may be available. Case series and case reports of cancer in humans may also be reviewed.

Cohort and case–control studies relate the exposures under study to the occurrence of cancer in individuals and provide an estimate of relative risk (ratio of incidence or mortality in those exposed to incidence or mortality in those not exposed) as the main measure of association.

In correlation studies, the units of investigation are usually whole populations (e.g. in particular geographical areas or at particular times), and cancer frequency is related to a summary measure of the exposure of the population to the agent, mixture or exposure circumstance under study. Because individual exposure is not documented, however, a causal relationship is less easy to infer from correlation studies than from cohort and case–control studies. Case reports generally arise from a suspicion, based on clinical experience, that the concurrence of two events — that is, a particular exposure and occurrence of a cancer — has happened rather more frequently than would be expected by chance. Case reports usually lack complete ascertainment of cases in any population, definition or enumeration of the population at risk and estimation of the expected number of cases in the absence of exposure. The uncertainties surrounding interpretation of case reports and correlation studies make them inadequate, except in rare instances, to form the sole basis for inferring a causal relationship. When taken together with case–control and cohort studies, however, relevant case reports or correlation studies may add materially to the judgement that a causal relationship is present.

Epidemiological studies of benign neoplasms, presumed preneoplastic lesions and other end-points thought to be relevant to cancer are also reviewed by working groups. They may, in some instances, strengthen inferences drawn from studies of cancer itself.

(*b*) *Quality of studies considered*

The Monographs are not intended to summarize all published studies. Those that are judged to be inadequate or irrelevant to the evaluation are generally omitted. They may be mentioned briefly, particularly when the information is considered to be a useful supplement to that in other reports or when they provide the only data available. Their inclusion does not imply acceptance of the adequacy of the study design or of the analysis and interpretation of the results, and limitations are clearly outlined in square brackets at the end of the study description.

It is necessary to take into account the possible roles of bias, confounding and chance in the interpretation of epidemiological studies. By 'bias' is meant the operation of factors in study design or execution that lead erroneously to a stronger or weaker association than in fact exists between disease and an agent, mixture or exposure circumstance. By 'confounding' is meant a situation in which the relationship with disease is made to appear stronger or weaker than it truly is as a result of an association between the apparent causal factor and another factor that is associated with either an increase or decrease in the incidence of the disease. In evaluating the extent to which these factors have been minimized in an individual study, working groups consider a number of aspects of design and analysis as described in the report of the study. Most of these considerations apply equally to case–control, cohort and correlation studies. Lack of clarity of any of these aspects in the reporting of a study can decrease its credibility and the weight given to it in the final evaluation of the exposure.

Firstly, the study population, disease (or diseases) and exposure should have been well defined by the authors. Cases of disease in the study population should have been identified in a way that was independent of the exposure of interest, and exposure should have been assessed in a way that was not related to disease status.

Secondly, the authors should have taken account in the study design and analysis of other variables that can influence the risk of disease and may have been related to the exposure of interest. Potential confounding by such variables should have been dealt with either in the design of the study, such as by matching, or in the analysis, by statistical adjustment. In cohort studies, comparisons with local rates of disease may be more appropriate than those with national rates. Internal comparisons of disease frequency among individuals at different levels of exposure should also have been made in the study.

Thirdly, the authors should have reported the basic data on which the conclusions are founded, even if sophisticated statistical analyses were employed. At the very least, they should have given the numbers of exposed and unexposed cases and controls in a case–control study and the numbers of cases observed and expected in a cohort study. Further tabulations by time since exposure began and other temporal factors are also important. In a cohort study, data on all cancer sites and all causes of death should have been given, to reveal the possibility of reporting bias. In a case–control study, the effects of investigated factors other than the exposure of interest should have been reported.

Finally, the statistical methods used to obtain estimates of relative risk, absolute rates of cancer, confidence intervals and significance tests, and to adjust for confounding should have been clearly stated by the authors. The methods used should preferably have been the generally accepted techniques that have been refined since the mid-1970s. These methods have been reviewed for case–control studies (Breslow & Day, 1980) and for cohort studies (Breslow & Day, 1987).

(*c*) *Inferences about mechanism of action*

Detailed analyses of both relative and absolute risks in relation to temporal variables, such as age at first exposure, time since first exposure, duration of exposure, cumulative exposure and time since exposure ceased, are reviewed and summarized when available. The analysis of temporal relationships can be useful in formulating models of carcinogenesis. In particular, such analyses may suggest whether a carcinogen acts early or late in the process of carcinogenesis, although at best they allow only indirect inferences about the mechanism of action. Special attention is given to measurements of biological markers of carcinogen exposure or action, such as DNA or protein adducts, as well as markers of early steps in the carcinogenic process, such as proto-oncogene mutation, when these are incorporated into epidemiological studies focused on cancer incidence or mortality. Such measurements may allow inferences to be made about putative mechanisms of action (IARC, 1991a; Vainio *et al.*, 1992).

(*d*) *Criteria for causality*

After the individual epidemiological studies of cancer have been summarized and the quality assessed, a judgement is made concerning the strength of evidence that the agent, mixture or exposure circumstance in question is carcinogenic for humans. In making its judgement, the Working Group considers several criteria for causality. A strong association (a large relative risk) is more likely to indicate causality than a weak association, although it is recognized that relative risks of small magnitude do not imply lack of causality and may be important if the disease is common. Associations that are replicated in several studies of the same design or using different epidemiological approaches or under different circumstances of exposure are more likely to represent a causal relationship than isolated observations from single studies. If there are inconsistent results among investigations, possible reasons are sought (such as differences in amount of exposure), and results of studies judged to be of high quality are given more weight than those of studies judged to be methodologically less sound. When suspicion of carcinogenicity arises largely from a single study, these data are not combined with those from later studies in any subsequent reassessment of the strength of the evidence.

If the risk of the disease in question increases with the amount of exposure, this is considered to be a strong indication of causality, although absence of a graded response is not necessarily evidence against a causal relationship. Demonstration of a decline in

risk after cessation of or reduction in exposure in individuals or in whole populations also supports a causal interpretation of the findings.

Although a carcinogen may act upon more than one target, the specificity of an association (an increased occurrence of cancer at one anatomical site or of one morphological type) adds plausibility to a causal relationship, particularly when excess cancer occurrence is limited to one morphological type within the same organ.

Although rarely available, results from randomized trials showing different rates among exposed and unexposed individuals provide particularly strong evidence for causality.

When several epidemiological studies show little or no indication of an association between an exposure and cancer, the judgement may be made that, in the aggregate, they show evidence of lack of carcinogenicity. Such a judgement requires first of all that the studies giving rise to it meet, to a sufficient degree, the standards of design and analysis described above. Specifically, the possibility that bias, confounding or misclassification of exposure or outcome could explain the observed results should be considered and excluded with reasonable certainty. In addition, all studies that are judged to be methodologically sound should be consistent with a relative risk of unity for any observed level of exposure and, when considered together, should provide a pooled estimate of relative risk which is at or near unity and has a narrow confidence interval, due to sufficient population size. Moreover, no individual study nor the pooled results of all the studies should show any consistent tendency for the relative risk of cancer to increase with increasing level of exposure. It is important to note that evidence of lack of carcinogenicity obtained in this way from several epidemiological studies can apply only to the type(s) of cancer studied and to dose levels and intervals between first exposure and observation of disease that are the same as or less than those observed in all the studies. Experience with human cancer indicates that, in some cases, the period from first exposure to the development of clinical cancer is seldom less than 20 years; studies with latent periods substantially shorter than 30 years cannot provide evidence for lack of carcinogenicity.

9. STUDIES OF CANCER IN EXPERIMENTAL ANIMALS

All known human carcinogens that have been studied adequately in experimental animals have produced positive results in one or more animal species (Wilbourn *et al.*, 1986; Tomatis *et al.*, 1989). For several agents (aflatoxins, 4-aminobiphenyl, azathioprine, betel quid with tobacco, bischloromethyl ether and chloromethyl methyl ether (technical grade), chlorambucil, chlornaphazine, ciclosporin, coal-tar pitches, coal-tars, combined oral contraceptives, cyclophosphamide, diethylstilboestrol, melphalan, 8-methoxypsoralen plus ultraviolet A radiation, mustard gas, myleran, 2-naphthylamine, nonsteroidal estrogens, estrogen replacement therapy/steroidal estrogens, solar radiation, thiotepa and vinyl chloride), carcinogenicity in experimental animals was established or highly suspected before epidemiological studies confirmed their carcinogenicity in humans (Vainio *et al.*, 1995). Although this association cannot establish that all agents

and mixtures that cause cancer in experimental animals also cause cancer in humans, nevertheless, **in the absence of adequate data on humans, it is biologically plausible and prudent to regard agents and mixtures for which there is *sufficient evidence* (see p. 24) of carcinogenicity in experimental animals as if they presented a carcinogenic risk to humans**. The possibility that a given agent may cause cancer through a species-specific mechanism which does not operate in humans (see p. 27) should also be taken into consideration.

The nature and extent of impurities or contaminants present in the chemical or mixture being evaluated are given when available. Animal strain, sex, numbers per group, age at start of treatment and survival are reported.

Other types of studies summarized include: experiments in which the agent or mixture was administered in conjunction with known carcinogens or factors that modify carcinogenic effects; studies in which the end-point was not cancer but a defined precancerous lesion; and experiments on the carcinogenicity of known metabolites and derivatives.

For experimental studies of mixtures, consideration is given to the possibility of changes in the physicochemical properties of the test substance during collection, storage, extraction, concentration and delivery. Chemical and toxicological interactions of the components of mixtures may result in nonlinear dose–response relationships.

An assessment is made as to the relevance to human exposure of samples tested in experimental animals, which may involve consideration of: (i) physical and chemical characteristics, (ii) constituent substances that indicate the presence of a class of substances, (iii) the results of tests for genetic and related effects, including studies on DNA adduct formation, proto-oncogene mutation and expression and suppressor gene inactivation. The relevance of results obtained, for example, with animal viruses analogous to the virus being evaluated in the monograph must also be considered. They may provide biological and mechanistic information relevant to the understanding of the process of carcinogenesis in humans and may strengthen the plausibility of a conclusion that the biological agent under evaluation is carcinogenic in humans.

(*a*) *Qualitative aspects*

An assessment of carcinogenicity involves several considerations of qualitative importance, including (i) the experimental conditions under which the test was performed, including route and schedule of exposure, species, strain, sex, age, duration of follow-up; (ii) the consistency of the results, for example, across species and target organ(s); (iii) the spectrum of neoplastic response, from preneoplastic lesions and benign tumours to malignant neoplasms; and (iv) the possible role of modifying factors.

As mentioned earlier (p. 11), the *Monographs* are not intended to summarize all published studies. Those studies in experimental animals that are inadequate (e.g., too short a duration, too few animals, poor survival; see below) or are judged irrelevant to

the evaluation are generally omitted. Guidelines for conducting adequate long-term carcinogenicity experiments have been outlined (e.g. Montesano *et al.*, 1986).

Considerations of importance to the Working Group in the interpretation and evaluation of a particular study include: (i) how clearly the agent was defined and, in the case of mixtures, how adequately the sample characterization was reported; (ii) whether the dose was adequately monitored, particularly in inhalation experiments; (iii) whether the doses and duration of treatment were appropriate and whether the survival of treated animals was similar to that of controls; (iv) whether there were adequate numbers of animals per group; (v) whether animals of each sex were used; (vi) whether animals were allocated randomly to groups; (vii) whether the duration of observation was adequate; and (viii) whether the data were adequately reported. If available, recent data on the incidence of specific tumours in historical controls, as well as in concurrent controls, should be taken into account in the evaluation of tumour response.

When benign tumours occur together with and originate from the same cell type in an organ or tissue as malignant tumours in a particular study and appear to represent a stage in the progression to malignancy, it may be valid to combine them in assessing tumour incidence (Huff *et al.*, 1989). The occurrence of lesions presumed to be preneoplastic may in certain instances aid in assessing the biological plausibility of any neoplastic response observed. If an agent or mixture induces only benign neoplasms that appear to be end-points that do not readily progress to malignancy, it should nevertheless be suspected of being a carcinogen and requires further investigation.

(*b*) *Quantitative aspects*

The probability that tumours will occur may depend on the species, sex, strain and age of the animal, the dose of the carcinogen and the route and length of exposure. Evidence of an increased incidence of neoplasms with increased level of exposure strengthens the inference of a causal association between the exposure and the development of neoplasms.

The form of the dose–response relationship can vary widely, depending on the particular agent under study and the target organ. Both DNA damage and increased cell division are important aspects of carcinogenesis, and cell proliferation is a strong determinant of dose–response relationships for some carcinogens (Cohen & Ellwein, 1990). Since many chemicals require metabolic activation before being converted into their reactive intermediates, both metabolic and pharmacokinetic aspects are important in determining the dose–response pattern. Saturation of steps such as absorption, activation, inactivation and elimination may produce nonlinearity in the dose–response relationship, as could saturation of processes such as DNA repair (Hoel *et al.*, 1983; Gart *et al.*, 1986).

(*c*) *Statistical analysis of long-term experiments in animals*

Factors considered by the Working Group include the adequacy of the information given for each treatment group: (i) the number of animals studied and the number examined histologically, (ii) the number of animals with a given tumour type and (iii) length of survival. The statistical methods used should be clearly stated and should be the generally accepted techniques refined for this purpose (Peto *et al.*, 1980; Gart *et al.*, 1986). When there is no difference in survival between control and treatment groups, the Working Group usually compares the proportions of animals developing each tumour type in each of the groups. Otherwise, consideration is given as to whether or not appropriate adjustments have been made for differences in survival. These adjustments can include: comparisons of the proportions of tumour-bearing animals among the effective number of animals (alive at the time the first tumour is discovered), in the case where most differences in survival occur before tumours appear; life-table methods, when tumours are visible or when they may be considered 'fatal' because mortality rapidly follows tumour development; and the Mantel-Haenszel test or logistic regression, when occult tumours do not affect the animals' risk of dying but are 'incidental' findings at autopsy.

In practice, classifying tumours as fatal or incidental may be difficult. Several survival-adjusted methods have been developed that do not require this distinction (Gart *et al.*, 1986), although they have not been fully evaluated.

10. OTHER DATA RELEVANT TO AN EVALUATION OF CARCINOGENICITY AND ITS MECHANISMS

In coming to an overall evaluation of carcinogenicity in humans (see pp. 25–27), the Working Group also considers related data. The nature of the information selected for the summary depends on the agent being considered.

For chemicals and complex mixtures of chemicals such as those in some occupational situations or involving cultural habits (e.g. tobacco smoking), the other data considered to be relevant are divided into those on absorption, distribution, metabolism and excretion; toxic effects; reproductive and developmental effects; and genetic and related effects.

Concise information is given on absorption, distribution (including placental transfer) and excretion in both humans and experimental animals. Kinetic factors that may affect the dose–response relationship, such as saturation of uptake, protein binding, metabolic activation, detoxification and DNA repair processes, are mentioned. Studies that indicate the metabolic fate of the agent in humans and in experimental animals are summarized briefly, and comparisons of data on humans and on animals are made when possible. Comparative information on the relationship between exposure and the dose that reaches the target site may be of particular importance for extrapolation between species. Data are given on acute and chronic toxic effects (other than cancer), such as

organ toxicity, increased cell proliferation, immunotoxicity and endocrine effects. The presence and toxicological significance of cellular receptors is described. Effects on reproduction, teratogenicity, fetotoxicity and embryotoxicity are also summarized briefly.

Tests of genetic and related effects are described in view of the relevance of gene mutation and chromosomal damage to carcinogenesis (Vainio *et al.*, 1992; McGregor *et al.*, 1999). The adequacy of the reporting of sample characterization is considered and, where necessary, commented upon; with regard to complex mixtures, such comments are similar to those described for animal carcinogenicity tests on p. 18. The available data are interpreted critically by phylogenetic group according to the end-points detected, which may include DNA damage, gene mutation, sister chromatid exchange, micronucleus formation, chromosomal aberrations, aneuploidy and cell transformation. The concentrations employed are given, and mention is made of whether use of an exogenous metabolic system *in vitro* affected the test result. These data are given as listings of test systems, data and references. The data on genetic and related effects presented in the *Monographs* are also available in the form of genetic activity profiles (GAP) prepared in collaboration with the United States Environmental Protection Agency (EPA) (see also Waters *et al.*, 1987) using software for personal computers that are Microsoft Windows® compatible. The EPA/IARC GAP software and database may be downloaded free of charge from *www.epa.gov/gapdb*.

Positive results in tests using prokaryotes, lower eukaryotes, plants, insects and cultured mammalian cells suggest that genetic and related effects could occur in mammals. Results from such tests may also give information about the types of genetic effect produced and about the involvement of metabolic activation. Some end-points described are clearly genetic in nature (e.g., gene mutations and chromosomal aberrations), while others are to a greater or lesser degree associated with genetic effects (e.g. unscheduled DNA synthesis). In-vitro tests for tumour-promoting activity and for cell transformation may be sensitive to changes that are not necessarily the result of genetic alterations but that may have specific relevance to the process of carcinogenesis. A critical appraisal of these tests has been published (Montesano *et al.*, 1986).

Genetic or other activity detected in experimental mammals and humans is regarded as being of greater relevance than that in other organisms. The demonstration that an agent or mixture can induce gene and chromosomal mutations in whole mammals indicates that it may have carcinogenic activity, although this activity may not be detectably expressed in any or all species. Relative potency in tests for mutagenicity and related effects is not a reliable indicator of carcinogenic potency. Negative results in tests for mutagenicity in selected tissues from animals treated *in vivo* provide less weight, partly because they do not exclude the possibility of an effect in tissues other than those examined. Moreover, negative results in short-term tests with genetic end-points cannot be considered to provide evidence to rule out carcinogenicity of agents or mixtures that act through other mechanisms (e.g. receptor-mediated effects, cellular toxicity with regenerative proliferation, peroxisome proliferation) (Vainio *et al.*, 1992). Factors that

may lead to misleading results in short-term tests have been discussed in detail elsewhere (Montesano *et al.*, 1986).

When available, data relevant to mechanisms of carcinogenesis that do not involve structural changes at the level of the gene are also described.

The adequacy of epidemiological studies of reproductive outcome and genetic and related effects in humans is evaluated by the same criteria as are applied to epidemiological studies of cancer.

Structure–activity relationships that may be relevant to an evaluation of the carcinogenicity of an agent are also described.

For biological agents — viruses, bacteria and parasites — other data relevant to carcinogenicity include descriptions of the pathology of infection, molecular biology (integration and expression of viruses, and any genetic alterations seen in human tumours) and other observations, which might include cellular and tissue responses to infection, immune response and the presence of tumour markers.

11. SUMMARY OF DATA REPORTED

In this section, the relevant epidemiological and experimental data are summarized. Only reports, other than in abstract form, that meet the criteria outlined on p. 11 are considered for evaluating carcinogenicity. Inadequate studies are generally not summarized: such studies are usually identified by a square-bracketed comment in the preceding text.

(*a*) *Exposure*

Human exposure to chemicals and complex mixtures is summarized on the basis of elements such as production, use, occurrence in the environment and determinations in human tissues and body fluids. Quantitative data are given when available. Exposure to biological agents is described in terms of transmission and prevalence of infection.

(*b*) *Carcinogenicity in humans*

Results of epidemiological studies that are considered to be pertinent to an assessment of human carcinogenicity are summarized. When relevant, case reports and correlation studies are also summarized.

(*c*) *Carcinogenicity in experimental animals*

Data relevant to an evaluation of carcinogenicity in animals are summarized. For each animal species and route of administration, it is stated whether an increased incidence of neoplasms or preneoplastic lesions was observed, and the tumour sites are indicated. If the agent or mixture produced tumours after prenatal exposure or in single-dose experiments, this is also indicated. Negative findings are also summarized. Dose–response and other quantitative data may be given when available.

(*d*) *Other data relevant to an evaluation of carcinogenicity and its mechanisms*

Data on biological effects in humans that are of particular relevance are summarized. These may include toxicological, kinetic and metabolic considerations and evidence of DNA binding, persistence of DNA lesions or genetic damage in exposed humans. Toxicological information, such as that on cytotoxicity and regeneration, receptor binding and hormonal and immunological effects, and data on kinetics and metabolism in experimental animals are given when considered relevant to the possible mechanism of the carcinogenic action of the agent. The results of tests for genetic and related effects are summarized for whole mammals, cultured mammalian cells and nonmammalian systems.

When available, comparisons of such data for humans and for animals, and particularly animals that have developed cancer, are described.

Structure–activity relationships are mentioned when relevant.

For the agent, mixture or exposure circumstance being evaluated, the available data on end-points or other phenomena relevant to mechanisms of carcinogenesis from studies in humans, experimental animals and tissue and cell test systems are summarized within one or more of the following descriptive dimensions:

(i) Evidence of genotoxicity (structural changes at the level of the gene): for example, structure–activity considerations, adduct formation, mutagenicity (effect on specific genes), chromosomal mutation/aneuploidy

(ii) Evidence of effects on the expression of relevant genes (functional changes at the intracellular level): for example, alterations to the structure or quantity of the product of a proto-oncogene or tumour-suppressor gene, alterations to metabolic activation/inactivation/DNA repair

(iii) Evidence of relevant effects on cell behaviour (morphological or behavioural changes at the cellular or tissue level): for example, induction of mitogenesis, compensatory cell proliferation, preneoplasia and hyperplasia, survival of premalignant or malignant cells (immortalization, immunosuppression), effects on metastatic potential

(iv) Evidence from dose and time relationships of carcinogenic effects and interactions between agents: for example, early/late stage, as inferred from epidemiological studies; initiation/promotion/progression/malignant conversion, as defined in animal carcinogenicity experiments; toxicokinetics

These dimensions are not mutually exclusive, and an agent may fall within more than one of them. Thus, for example, the action of an agent on the expression of relevant genes could be summarized under both the first and second dimensions, even if it were known with reasonable certainty that those effects resulted from genotoxicity.

12. EVALUATION

Evaluations of the strength of the evidence for carcinogenicity arising from human and experimental animal data are made, using standard terms.

It is recognized that the criteria for these evaluations, described below, cannot encompass all of the factors that may be relevant to an evaluation of carcinogenicity. In considering all of the relevant scientific data, the Working Group may assign the agent, mixture or exposure circumstance to a higher or lower category than a strict interpretation of these criteria would indicate.

(*a*) *Degrees of evidence for carcinogenicity in humans and in experimental animals and supporting evidence*

These categories refer only to the strength of the evidence that an exposure is carcinogenic and not to the extent of its carcinogenic activity (potency) nor to the mechanisms involved. A classification may change as new information becomes available.

An evaluation of degree of evidence, whether for a single agent or a mixture, is limited to the materials tested, as defined physically, chemically or biologically. When the agents evaluated are considered by the Working Group to be sufficiently closely related, they may be grouped together for the purpose of a single evaluation of degree of evidence.

(i) *Carcinogenicity in humans*

The applicability of an evaluation of the carcinogenicity of a mixture, process, occupation or industry on the basis of evidence from epidemiological studies depends on the variability over time and place of the mixtures, processes, occupations and industries. The Working Group seeks to identify the specific exposure, process or activity which is considered most likely to be responsible for any excess risk. The evaluation is focused as narrowly as the available data on exposure and other aspects permit.

The evidence relevant to carcinogenicity from studies in humans is classified into one of the following categories:

Sufficient evidence of carcinogenicity: The Working Group considers that a causal relationship has been established between exposure to the agent, mixture or exposure circumstance and human cancer. That is, a positive relationship has been observed between the exposure and cancer in studies in which chance, bias and confounding could be ruled out with reasonable confidence.

Limited evidence of carcinogenicity: A positive association has been observed between exposure to the agent, mixture or exposure circumstance and cancer for which a causal interpretation is considered by the Working Group to be credible, but chance, bias or confounding could not be ruled out with reasonable confidence.

Inadequate evidence of carcinogenicity: The available studies are of insufficient quality, consistency or statistical power to permit a conclusion regarding the presence or absence of a causal association between exposure and cancer, or no data on cancer in humans are available.

Evidence suggesting lack of carcinogenicity: There are several adequate studies covering the full range of levels of exposure that human beings are known to encounter, which are mutually consistent in not showing a positive association between exposure to

the agent, mixture or exposure circumstance and any studied cancer at any observed level of exposure. A conclusion of 'evidence suggesting lack of carcinogenicity' is inevitably limited to the cancer sites, conditions and levels of exposure and length of observation covered by the available studies. In addition, the possibility of a very small risk at the levels of exposure studied can never be excluded.

In some instances, the above categories may be used to classify the degree of evidence related to carcinogenicity in specific organs or tissues.

(ii) *Carcinogenicity in experimental animals*

The evidence relevant to carcinogenicity in experimental animals is classified into one of the following categories:

Sufficient evidence of carcinogenicity: The Working Group considers that a causal relationship has been established between the agent or mixture and an increased incidence of malignant neoplasms or of an appropriate combination of benign and malignant neoplasms in (a) two or more species of animals or (b) in two or more independent studies in one species carried out at different times or in different laboratories or under different protocols.

Exceptionally, a single study in one species might be considered to provide sufficient evidence of carcinogenicity when malignant neoplasms occur to an unusual degree with regard to incidence, site, type of tumour or age at onset.

Limited evidence of carcinogenicity: The data suggest a carcinogenic effect but are limited for making a definitive evaluation because, e.g. (a) the evidence of carcinogenicity is restricted to a single experiment; or (b) there are unresolved questions regarding the adequacy of the design, conduct or interpretation of the study; or (c) the agent or mixture increases the incidence only of benign neoplasms or lesions of uncertain neoplastic potential, or of certain neoplasms which may occur spontaneously in high incidences in certain strains.

Inadequate evidence of carcinogenicity: The studies cannot be interpreted as showing either the presence or absence of a carcinogenic effect because of major qualitative or quantitative limitations, or no data on cancer in experimental animals are available.

Evidence suggesting lack of carcinogenicity: Adequate studies involving at least two species are available which show that, within the limits of the tests used, the agent or mixture is not carcinogenic. A conclusion of evidence suggesting lack of carcinogenicity is inevitably limited to the species, tumour sites and levels of exposure studied.

(*b*) *Other data relevant to the evaluation of carcinogenicity and its mechanisms*

Other evidence judged to be relevant to an evaluation of carcinogenicity and of sufficient importance to affect the overall evaluation is then described. This may include data on preneoplastic lesions, tumour pathology, genetic and related effects, structure–activity relationships, metabolism and pharmacokinetics, physicochemical parameters and analogous biological agents.

Data relevant to mechanisms of the carcinogenic action are also evaluated. The strength of the evidence that any carcinogenic effect observed is due to a particular mechanism is assessed, using terms such as weak, moderate or strong. Then, the Working Group assesses if that particular mechanism is likely to be operative in humans. The strongest indications that a particular mechanism operates in humans come from data on humans or biological specimens obtained from exposed humans. The data may be considered to be especially relevant if they show that the agent in question has caused changes in exposed humans that are on the causal pathway to carcinogenesis. Such data may, however, never become available, because it is at least conceivable that certain compounds may be kept from human use solely on the basis of evidence of their toxicity and/or carcinogenicity in experimental systems.

For complex exposures, including occupational and industrial exposures, the chemical composition and the potential contribution of carcinogens known to be present are considered by the Working Group in its overall evaluation of human carcinogenicity. The Working Group also determines the extent to which the materials tested in experimental systems are related to those to which humans are exposed.

(*c*) *Overall evaluation*

Finally, the body of evidence is considered as a whole, in order to reach an overall evaluation of the carcinogenicity to humans of an agent, mixture or circumstance of exposure.

An evaluation may be made for a group of chemical compounds that have been evaluated by the Working Group. In addition, when supporting data indicate that other, related compounds for which there is no direct evidence of capacity to induce cancer in humans or in animals may also be carcinogenic, a statement describing the rationale for this conclusion is added to the evaluation narrative; an additional evaluation may be made for this broader group of compounds if the strength of the evidence warrants it.

The agent, mixture or exposure circumstance is described according to the wording of one of the following categories, and the designated group is given. The categorization of an agent, mixture or exposure circumstance is a matter of scientific judgement, reflecting the strength of the evidence derived from studies in humans and in experimental animals and from other relevant data.

Group 1 — The agent (mixture) is carcinogenic to humans.
The exposure circumstance entails exposures that are carcinogenic to humans.

This category is used when there is *sufficient evidence* of carcinogenicity in humans. Exceptionally, an agent (mixture) may be placed in this category when evidence of carcinogenicity in humans is less than sufficient but there is *sufficient evidence* of carcinogenicity in experimental animals and strong evidence in exposed humans that the agent (mixture) acts through a relevant mechanism of carcinogenicity.

Group 2

This category includes agents, mixtures and exposure circumstances for which, at one extreme, the degree of evidence of carcinogenicity in humans is almost sufficient, as well as those for which, at the other extreme, there are no human data but for which there is evidence of carcinogenicity in experimental animals. Agents, mixtures and exposure circumstances are assigned to either group 2A (probably carcinogenic to humans) or group 2B (possibly carcinogenic to humans) on the basis of epidemiological and experimental evidence of carcinogenicity and other relevant data.

Group 2A — The agent (mixture) is probably carcinogenic to humans. The exposure circumstance entails exposures that are probably carcinogenic to humans.

This category is used when there is *limited evidence* of carcinogenicity in humans and *sufficient evidence* of carcinogenicity in experimental animals. In some cases, an agent (mixture) may be classified in this category when there is *inadequate evidence* of carcinogenicity in humans, *sufficient evidence* of carcinogenicity in experimental animals and strong evidence that the carcinogenesis is mediated by a mechanism that also operates in humans. Exceptionally, an agent, mixture or exposure circumstance may be classified in this category solely on the basis of *limited evidence* of carcinogenicity in humans.

Group 2B — The agent (mixture) is possibly carcinogenic to humans. The exposure circumstance entails exposures that are possibly carcinogenic to humans.

This category is used for agents, mixtures and exposure circumstances for which there is *limited evidence* of carcinogenicity in humans and less than *sufficient evidence* of carcinogenicity in experimental animals. It may also be used when there is *inadequate evidence* of carcinogenicity in humans but there is *sufficient evidence* of carcinogenicity in experimental animals. In some instances, an agent, mixture or exposure circumstance for which there is *inadequate evidence* of carcinogenicity in humans but *limited evidence* of carcinogenicity in experimental animals together with supporting evidence from other relevant data may be placed in this group.

Group 3 — The agent (mixture or exposure circumstance) is not classifiable as to its carcinogenicity to humans.

This category is used most commonly for agents, mixtures and exposure circumstances for which the *evidence of carcinogenicity* is *inadequate* in humans and *inadequate* or *limited* in experimental animals.

Exceptionally, agents (mixtures) for which the *evidence of carcinogenicity* is *inadequate* in humans but *sufficient* in experimental animals may be placed in this category

when there is strong evidence that the mechanism of carcinogenicity in experimental animals does not operate in humans.

Agents, mixtures and exposure circumstances that do not fall into any other group are also placed in this category.

Group 4 — The agent (mixture) is probably not carcinogenic to humans.

This category is used for agents or mixtures for which there is *evidence suggesting lack of carcinogenicity* in humans and in experimental animals. In some instances, agents or mixtures for which there is *inadequate evidence* of carcinogenicity in humans but *evidence suggesting lack of carcinogenicity* in experimental animals, consistently and strongly supported by a broad range of other relevant data, may be classified in this group.

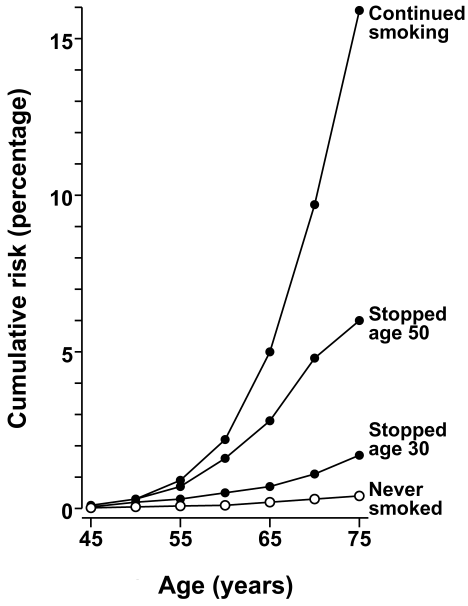
GENERAL REMARKS

Future worldwide health effects of current smoking patterns

As a cause of human cancer, tobacco smoke is uniquely important. In some populations it has, in recent decades, caused about half of all cancer deaths in men, plus a smaller, but increasing proportion of cancer deaths in women. Worldwide, it causes more cancer deaths than can be attributed to all other known causes of the disease and, in addition, it causes even more deaths from vascular and respiratory diseases than from cancer (US DHHS, 1989; Peto *et al*., 1994; Parkin *et al.*, 2000).

The fact that prolonged cigarette smoking is a cause — and the major cause — of lung cancer was reliably established during the 1950s, as was the fact that it can also cause several other types of cancer and various other diseases (for a historical review, see Doll, 1998). In the previous IARC *Monograph* on tobacco smoking (IARC, 1986), it was concluded that there was *sufficient evidence* that the habit could cause not only lung cancer, but also cancers of the upper aerodigestive tract, pancreas and lower urinary tract. Section 2 of the present monograph on tobacco smoke reviews and confirms these qualitative conclusions about particular types of cancer. It also reviews epidemiological studies on other types of cancer, which provide good evidence for some cancers (e.g. of the breast, endometrium and prostate) that smoking is of little or no causal relevance. Findings for other cancers (of the stomach, liver and cervix, renal-cell carcinoma and myeloid leukaemia) provide *sufficient evidence* that they can be caused by smoking, i.e. that smoking can increase their age-specific incidence rates. Other sections review the changing patterns of exposure, and the experimental evidence that tobacco smoke contains many chemicals that can, under certain circumstances, induce DNA damage or cancer in experimental animals. These qualitative conclusions about the many different chemicals in smoke and the many different types of cancer caused in humans do not, however, adequately reflect the real magnitude of the overall effects of smoking on mortality. This general introduction therefore summarizes the net effects of smoking on mortality from all cancers and overall mortality (for individuals and for populations), and indicates the extent to which individuals or populations who have already smoked for some years or decades can still limit these risks by cessation of the habit. Smoking lowers the risk for a few diseases and for one cancer (endometrial carcinoma), but this reduced risk is inconsequential, when compared with the net detriment of smoking to health.

Persistent cigarette smoking throughout adult life



Two observations are of particular relevance to assessing the current and future hazards of smoking. First, cigarettes, as commonly smoked during the twentieth century, have proved to be substantially more hazardous than other forms of tobacco that were commonly smoked in the nineteenth century. Second, the earlier in life that cigarette smoking is fully established, the greater are the hazards among persistent smokers in middle and old age. These differences in hazard can be substantial: for example, a difference of only a few years in the age at which smoking was established may lead to an approximately twofold difference in hazard many years later (Doll & Peto, 1981). Thus, national rates for lung cancer in people of around 70 years of age depend strongly on the intensity of pulmonary exposure to cigarette smoke half a century ago, when they were about 20 years of age. Retrospective assessment of smoking behaviour in previous decades, however, is subject to error; this limits the ability of epidemiological data to identify the ensuing consequences of earlier smoking. Current disease rates also depend strongly on current smoking patterns; even after a few decades of smoking, people who stop smoking before they develop lung cancer (or some other serious disease) decrease their risk of death from the habit: see Figure 1.

This dependence of current disease rates (not only on current smoking patterns but also on cigarette smoking patterns many decades earlier) implies a delay of about half a century between an upsurge in cigarette use by young adults in a particular population and the main upsurge in cases of lung cancer, and of some of the other smoking-related diseases, that eventually results. In contrast with this extremely long delay between increases in smoking and increases in risk, population-wide decreases in tobacco smoking can produce substantial benefits within just one or two decades.

Emerging hazards

Tobacco has been used for many centuries, originally in America, then in the sixteenth and seventeenth centuries in Europe, and subsequently throughout the world. The reasons for its widespread use are still imperfectly understood, but there are both psychosocial and pharmacological factors involved. Nicotine is addictive for many smokers, but other components of the smoke from tobacco, or from flavourants or other chemicals added to tobacco, may also be important. At first tobacco was smoked in pipes or as cigars: later, ‘bidis’, consisting of a small amount of tobacco wrapped in the leaf of another plant, began to be smoked in South Asia. Cigarettes, which would eventually cause much greater harm than did pipe or cigar smoking in the nineteenth century, only began to be manufactured in the second half of the nineteenth century; even in the early years of the twentieth century, cigarette consumption still remained low. Thereafter, however, cigarette consumption by men increased rapidly in the United Kingdom, the USA and several other industrialized countries, followed (decades later) by increased cigarette consumption by women in developed countries and also by men in developing countries.

Figure 1. Cumulative risk (%) of death from lung cancer (in the absence of other causes of death) in men at ages 45–75 years: in continuing cigarette smokers, ex-cigarette smokers who stopped at age 50 or at age 30 and lifelong nonsmokers, based on lung cancer death rates for men in the United Kingdom in 1990

From Peto *et al.* (2000)

[a] Nonsmoker risks are taken from a US prospective study of mortality

(For example, although the main increase in cigarette consumption by men was eventually about as great in China as in the United Kingdom or the USA, it took place about 50 years later, i.e. in the last quarter of the twentieth century, and its full effects on the mortality rates for Chinese men may take several more decades to emerge.) At present, cigarette consumption by women in developing countries is still relatively low.

In some countries, the spread of cigarette smoking during the twentieth century was driven or maintained by extensive advertising and promotion by tobacco companies. More recently, substantial efforts have been made in some countries to discourage smoking, and over the past few decades, cigarette consumption has been halved in a few countries such as the USA and the United Kingdom. Worldwide, however, about a thousand million men and a quarter of a thousand million women now smoke, consuming 5.5 million million cigarettes a year (plus many other tobacco products), and about 30 million young adults take up the habit each year (see Section 1). The emergence of increasingly large multinational tobacco companies with global reach could result in even more tobacco use in the future.

Because the main hazards of cigarette smoking in middle age (35–69 years) take several decades to become substantial, it was not until the 1950s (several decades after cigarette smoking became widespread) that clear medical evidence emerged, particularly from the USA and the United Kingdom, that smoking was a major cause of many fatal diseases, and was responsible for almost half of all male mortality in middle age. The main hazards in old age (≥ 70 years) take even longer — at least half a century — to become substantial, so only in recent decades has it become apparent that, for men in developed countries, about half of all persistent cigarette smokers would eventually be killed by the habit (a quarter in middle age plus a quarter in old age) (Doll *et al*., 1994). In addition, during the past quarter of a century, it has become increasingly clear that, although the main hazard is to the individual who smokes, there is some cancer hazard to nonsmokers (including former smokers) from exposure to secondhand tobacco smoke (see monograph on involuntary smoking, this volume).

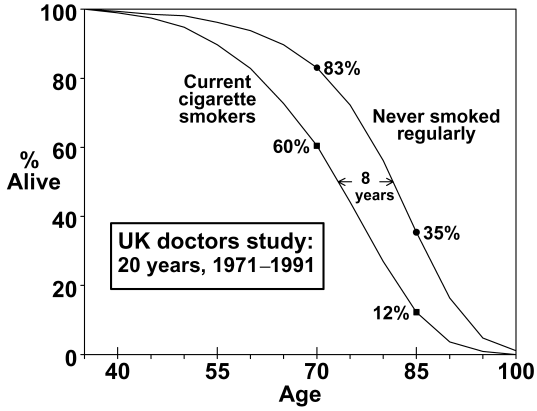


Figure 2 illustrates the effects of persistent cigarette smoking on mortality throughout adult life in male doctors in the United Kingdom: the difference in survival at age 70 years (i.e. 83% among nonsmokers versus 60% among smokers) reflects the fact that about one-quarter of the smokers had been killed by tobacco in middle age (35–69 years). Moreover, of those still alive at age 70 years, two-fifths of the nonsmokers and one-fifth of the smokers were still alive at 85 years of age. Among male doctors in the United Kingdom, many of those who had smoked substantial numbers of cigarettes for a long time gave up the habit permanently when clear evidence of its hazards emerged, and the extent to which cessation, even in middle age, eventually avoided hazard is illustrated in Figure 3.

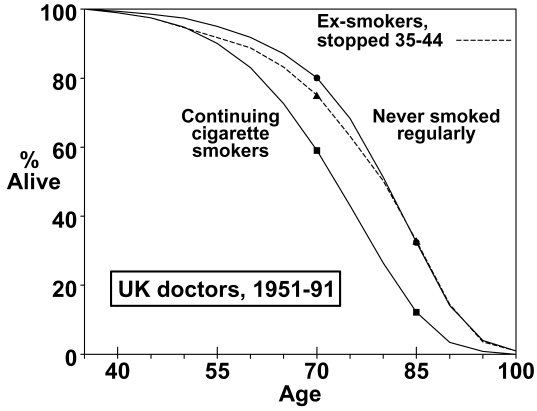
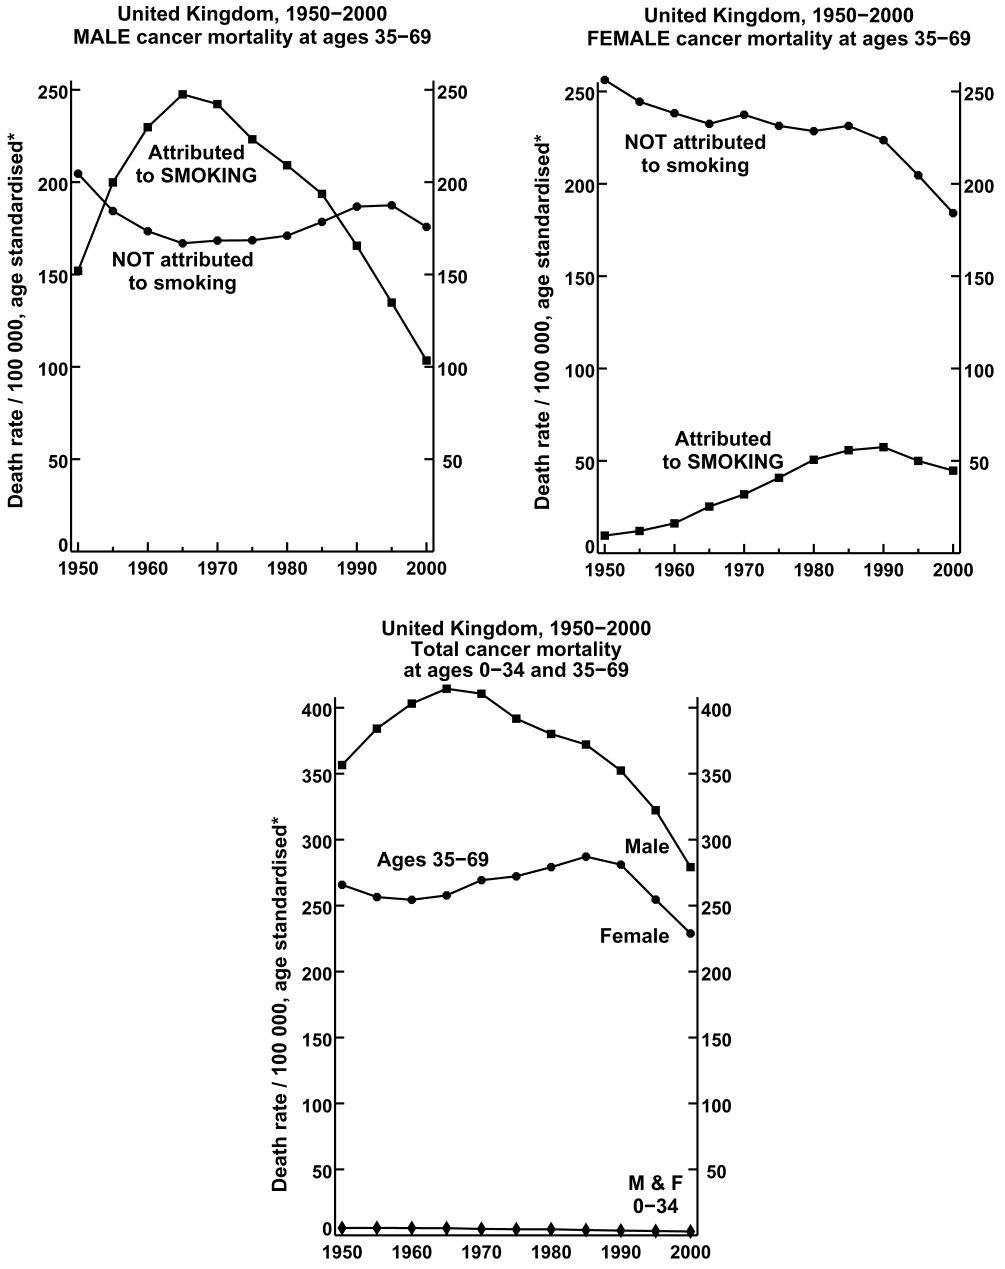
Trends in tobacco-attributed mortality in the United Kingdom and the USA, 1950–99

Cigarette smoking first became widespread among both men and women in the United Kingdom and the USA, and large epidemiological studies by the American Cancer Society yield indirect estimates of the overall cancer mortality attributed (and, by subtraction, that not attributed) to smoking over the past half century (1950–99) in those two countries (Figures 4 and 5). In the 1960s, men in the United Kingdom were probably the worst-affected major population in the world, but in recent decades male mortality from tobacco has declined substantially in the United Kingdom (Figure 4). In the USA, however, the mortality rate among men is only just beginning to decline substantially, whereas that among women in the USA has increased. In 1990, 34% of all cancer deaths in the USA were attributed to smoking (90% of the lung cancer deaths and 13% of the deaths from other, or unspecified, types of cancer; Table 1). Of the cancer deaths in the USA in 1990 that were attributed to smoking, three-quarters involved lung cancer (72% specified as such, plus one-third of the few deaths from cancer of an unspecified site). In people aged 35–69 years, the proportion of all cancer deaths in the USA in 1990 that were attributed to smoking was 40% (52% male, 27% female); at older ages, it was 31%. Relatively few deaths from cancer occur at younger ages. The rise in tobacco-attributed cancer



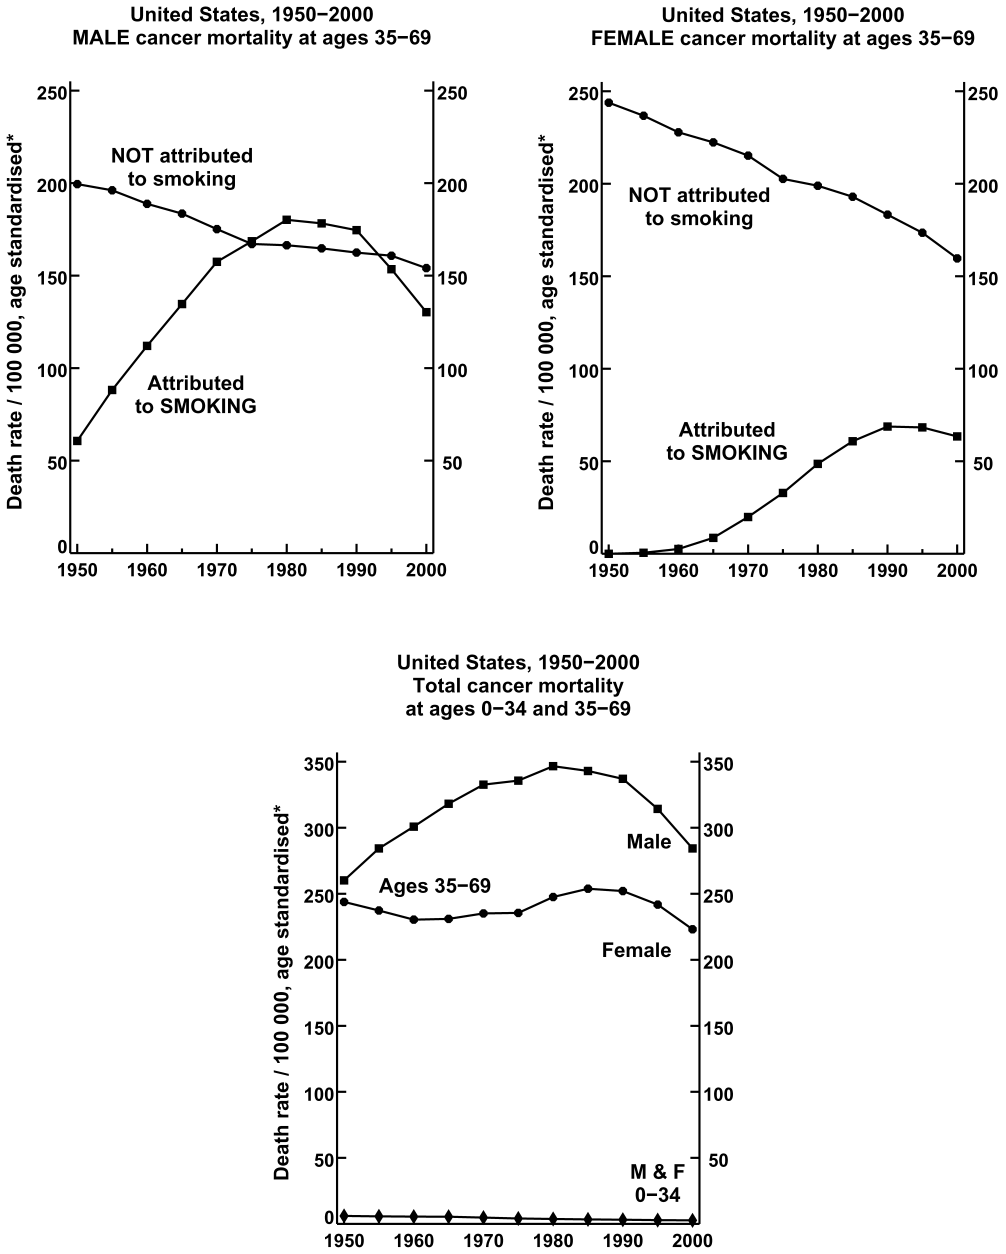
mortality in the USA during the second half of the twentieth century, first among men and then among women, is chiefly the inevitable but delayed effect of the rise in cigarette consumption during the first half of the twentieth century.

Figure 2. Effects of persistent cigarette smoking on the probability of surviving from 35 years to various ages



From Doll *et al.* (1994)

Figure 3. Effects of smoking cessation at ages 35–44 (broken line) on survival from age 35



From Doll *et al.* (1994)
Even in middle age, those who stop before they have incurable cancer, or some other serious disease, avoid most of their subsequent risk of death from tobacco; stopping earlier is even more effective.

Figure 4. Cancer mortality rates in the United Kingdom, 1950–2000, subdivided into the parts attributed, and not attributed to smoking

From Peto *et al.* (1994)
*Mean of annual rates per 100 000 in component 5-year age groups

Figure 5. Cancer mortality rates in the USA, 1950–2000, subdivided into the parts attributed, and not attributed to smoking

From Peto *et al.* (1994)

–, not available

Table 1 also indicates that tobacco smoking caused substantially more deaths from vascular, respiratory and other non-neoplastic causes than from cancer. The proportion of all deaths in the USA (neoplastic, vascular, respiratory or other causes) at ages 35–69 years that were attributed to tobacco was 33% in 1990, compared with only 12% in 1950.

Trends in tobacco-attributed mortality in developed and developing countries

In the aggregate of all developed countries, the epidemic of death from tobacco of men in middle age may have reached its peak by about 1990, and was by then almost as great as that in the USA (Table 2). In 1990, the epidemic in women, however, although still increasing, was less than half as great in the aggregate of all developed countries as it was in the USA. If current smoking patterns persist, the main increases in tobacco deaths over the next few decades are likely to be among women in developed countries and, in particular, among men in developing countries. In some of the developing countries, the populations are large and cigarette consumption by men in these countries has increased substantially in recent decades (Table 3).

Worldwide, the only major causes of mortality that are currently increasing rapidly are HIV, tobacco and, probably, obesity (Doll *et al*., 1994; Peto *et al*., 1994; Ad Hoc Committee on Health Research, 1996; Murray & Lopez, 1996; WHO, 1997; Peto *et al*., 1999). If current smoking patterns persist, there will be about one thousand million deaths from tobacco during the twenty-first century, as against ‘only’ about 0.1 thousand million

Table 2. All developed countries: deaths based on the Cancer Prevention Study II in 1990 attributed to smoking/total number of deaths (thousands)

		0–34	35–69	≥ 70	All ages

–, not available

(100 million) during the whole of the twentieth century (Table 4). About half of these deaths will be of people in middle age (35–69 years) rather than old age — and those killed by tobacco in middle age lose, on average, more than 20 years of life expectancy when compared with nonsmokers.

There are two main reasons for expecting this large increase in tobacco deaths. First, the population of middle-aged and old people worldwide is expected to increase. Second, the proportion of deaths in middle and old age that are caused by tobacco is expected to increase over the next few decades as a result of the delayed effects of the large increase in cigarette smoking among young adults over the past few decades (Doll *et al*., 1994; Peto *et al*., 1994; Ad Hoc Committee on Health Research, 1996; Murray & Lopez, 1996; WHO, 1997; Peto *et al*., 1999). Among persistent cigarette smokers, the risk of death from tobacco-related diseases in middle or old age is particularly great (about 1 in 2) only for those who start smoking in early adult life (Doll & Peto, 1981; Peto, 1986; Doll *et al*., 1994; Peto *et al*., 1994). Hence, the numbers of deaths from tobacco around the year 2000 were strongly influenced by the numbers of young adults who took up smoking around 1950, whereas the numbers of young adults who took up smoking around the year 2000 will strongly influence the numbers of deaths from tobacco around and beyond the year 2050.

In China, which is the largest and best studied of the developing countries (Liu *et al*., 1998; Niu *et al*., 1998; Peto *et al*., 1999), the increase in cigarette consumption by men and the increase in tobacco-related deaths both lag almost exactly 40 years behind the

Table 3. Forty-year delay between cigarette smoking and mortality from tobacco-related diseases in US adults and Chinese men

Cigarettes per day, by year			
US adults		Chinese men

1950	10	1992	10
Proportion of overall mortality at ages 35–69 years attributed to tobacco			
US adults		Chinese men	
1950	12%	1990	12%
1990	33%	2030	33%[a]

From Peto *et al*. (1999)

[a] Projection if current smoking patterns persist, i.e. two-thirds of the young men in mainland China start smoking cigarettes, and few give up the habit. In Hong Kong, where cigarette consumption by men reached its peak in the early 1970s, the proportion of deaths that was attributed to tobacco in men aged 35–69 years was one-third in 1998 (Lam *et al.*, 2001).

Table 4. Projected numbers of deaths from tobacco during the twenty-first century, if current smoking patterns persist[a]

Period	Tobacco deaths (millions)
2000–24	~150
2025–49	~300
2050–99	> 500
Total, twenty-first century	~1000
(Twentieth century: for comparison)	(~100)

[a] Of 100 million people per year now reaching adulthood, ~30 million become smokers. If most persist, and about half of those who do are eventually killed by smoking, then the annual number of tobacco-related deaths will eventually be 10–15 million.

USA (Table 3). At present, few young women in China become smokers (Liu *et al*., 1998). Cigarette consumption by Chinese men averaged 1, 4 and 10 per day in 1952, 1972 and 1992, respectively, with no further increase occurring during the past few years. The proportion of deaths attributed to tobacco in Chinese men at ages 35–69 years was measured to be 12% in 1990, and is projected to be about 33% in 2030 (Liu *et al*., 1998; Niu *et al*., 1998). Two-thirds of the young men become persistent smokers, and about half of those who do so will eventually be killed by the habit: therefore, about one-third of all the young men in China will eventually be killed by tobacco if current smoking patterns persist. China, which has 20% of the world's population, produces and consumes about 30% of the world's cigarettes, and a large nationwide study has shown that China already suffers almost a million deaths a year from tobacco-related diseases, a figure that is likely to double at least by 2025.

Worldwide, about 4 million deaths a year are currently caused by tobacco; 2 million of these occur in developed and 2 million in developing countries. However, these current numbers reflect smoking patterns decades ago, and worldwide cigarette consumption has increased substantially over the past half century (WHO, 1997). At present, about 30% of young adults become persistent smokers and relatively few quit (except in selected populations, such as educated adults living in parts of western Europe and North America). The main diseases by which smoking kills people differ substantially between different populations, but there is no good reason to expect the overall 50% risk of death from persistent cigarette smoking to differ greatly between different populations.

There are already well over one thousand million smokers, and by the 2030s about another thousand million young adults will, at current uptake rates, have started to smoke. Based on current smoking patterns, worldwide annual mortality from tobacco is likely to rise from about 4 million around the year 2000 to about 10 million around the year 2030 (i.e. 100 million per decade) (Peto *et al*., 1994), and will rise somewhat further in later decades. Tobacco is therefore expected to cause about 150 million deaths in the first quarter of the twenty-first century and 300 million in the second quarter. Predictions for the third and, particularly, the fourth quarter of the century are inevitably more speculative. However, if over the next few decades about 20–30 million young adults a year become persistent smokers and about half are eventually killed by their habit, then about 10–15% of adult mortality in the second half of the century will be due to tobacco smoking (probably implying more than 500 million deaths due to tobacco for 2050–99; Table 4).

The numbers of tobacco deaths predicted to occur before 2050 cannot be greatly reduced unless a substantial proportion of the adults who have already been smoking for some time give up the habit. A decrease over the next decade or two in the proportion of children who become smokers will not have its main effects on mortality until the third quarter of this century.

The effects on tobacco deaths of adult smokers quitting before 2050 and of young people not starting to smoke after 2050 will probably be as follows:

- *Quitting*: If many of the adults who now smoke were to give up over the next decade or two, thus halving global cigarette consumption per adult by the year 2020, this would prevent about one-third of tobacco-related deaths in 2020 and would almost halve tobacco-related deaths in the second quarter of the century. Such changes would avoid about 20 or 30 million tobacco-related deaths in the first quarter of the century and would avoid about 100 or 150 million in the second quarter.
- *Not starting*: If, by progressive reduction over the next decade or two in the global uptake rate of smoking by young people, the proportion of young adults who become smokers were to be halved by 2020, this would avoid hundreds of millions of deaths from tobacco after 2050. It would, however, avoid almost none of the 150 million deaths from tobacco in the first quarter of the century, and would probably avoid 'only' about 10 or 20 million of the 300 million deaths from tobacco in the second quarter of the century.

Thus, using widely practicable ways of helping large numbers of young people not to become smokers could avoid hundreds of millions of tobacco-related deaths in the middle and second half of the twenty-first century, but not before. In contrast, widely practicable ways of helping large numbers of adult smokers to quit (preferably before middle age, but also in middle age) might avoid one or two hundred million tobacco-related deaths in the first half of this century. Large numbers of deaths during the second half of the century could also be avoided if many of those who, despite warnings, still start to smoke in future years could be helped to stop before they are killed by the habit. Such calculations suggest that the effects of quitting could be more rapidly appreciated on a population scale than the effects of prevention of starting smoking. However, a more thorough evaluation of different strategies, in particular on a worldwide scale, and consideration of the specificities of developed and developing countries, respectively, is outside the scope of the present monograph.

Methodological considerations in interpreting epidemiological evidence on smoking and disease

The epidemiological evidence on smoking and risk for disease comes largely from observational studies that compare the risk for disease in smokers with that in people who have never smoked. Evidence from such studies may be affected by bias and confounding, and chance may also explain the observed associations of smoking with risk for disease. Most of the evidence comes from case–control and cohort studies; both types of study are potentially subject to particular forms of bias. For case–control studies, comparability of cases and controls and success in their recruitment are particularly critical. For cohort studies, the degree of success in recruiting and retaining participants are important considerations in interpreting data.

In studies of smoking, as for studies of any agent, information bias and confounding are of concern. Information bias may affect the classification of both active and involun-

tary smoking and extend to the classification of disease. The potential for error in classifying active and involuntary smoking is well recognized and the potential magnitude of any resulting bias has been considered both qualitatively and quantitatively. The Working Group does not regard information bias as an important consideration in interpreting the evidence on active smoking. For involuntary smoking, several analyses on information bias were considered by the Working Group. This is discussed in detail in the monograph on involuntary smoking.

Confounding arises when the effect of active or involuntary smoking is artificially increased or decreased by a factor that is associated with exposure to smoke in a particular data set and is a risk factor on its own. Confounding becomes more plausible as an alternative to causality as the magnitude of risk decreases. There are various causes, other than smoking, of the cancers considered in this monograph and hence there is potential for confounding. However, these other agents produce confounding only if associated with smoking in specific data sets. Control may be incomplete, leaving the possibility of residual confounding. The Working Group considered the potential for confounding and noted the approach used to control for such.

Active smoking and involuntary smoking have been reported to be associated with the development of many forms of cancer, with a wide range of relative risks ranging from about 1.2 to 20 and higher. When the apparent relative risk is high (for example 10), confounding is unlikely to explain all the excess risk; it has seldom been difficult to recognize such an association and, in most instances, to deduce that it is causal. However, if the apparent relative risk approaches unity, the data need to be interpreted more carefully and subtle sources of bias and confounding must be taken into account. Under these circumstances, the findings from case–control studies may be difficult to interpret, because they may be distorted by the inclusion of controls who are not truly representative of the population from which the cases are drawn. When controls are selected from hospital patients, care has to be taken to exclude those with tobacco-related diseases because the relative risk of the condition being studied will be underestimated. When controls are drawn from the general population, it is important to know what proportion of the selected controls responded. Even if the proportion is known and the compliance rate is reasonably high, ensuring that the results are not biased to some extent by the inclusion of a disproportionate number of people who are interested in questions of health and are therefore unusually health conscious may be difficult. Such people may be less likely to smoke, causing the relative risk to be overestimated.

Cohort studies have their own problems and their results also require careful interpretation. One problem is that the reports do not always cover the same types of cancers. The findings for common cancers (e.g. cancers of the lung, stomach and large bowel) are nearly always reported, but those for rare cancers (e.g. cancers of the nasal sinuses and testis and leukaemia) may be reported only when the numbers observed are unexpectedly high. It may be necessary to limit the data used to those from cohort studies that have reported on many types of cancer (say 20 or more), although selection bias in reporting may still not be excluded for some of the less common cancers.

A second problem, which particularly affects cancers that may grow slowly, such as prostate cancer, is that many patients may die with the disease and not necessarily because of it. This, however, may not be adequately reflected on death certificates because death may be attributed to the cancer when the patient had actually died of an independent broncho-pneumonia, myocardial infarction or another of the many conditions that are made more common by cigarette smoking, thus creating an artefactual positive relationship between smoking and the cancer (Adami *et al*., 1996).

A third problem is that observations may continue to be made for many years after the characteristics of the individual members of the cohort have been recorded and, during this period, these characteristics may have changed. Some smokers may have stopped smoking and, as benefit is commonly obtained within a few years of stopping, this may result in an underestimation of the harmful effects of smoking.

Although cohort studies allow repeated assessments of smoking behaviour to capture any changes, in some studies (e.g. CPS-II, US Veterans), smoking was assessed only at the start of follow-up and cessation after enrolment was not recorded.

During their evaluation of smoking and disease, the Working Group had substantial evidence available for many cancer sites. These data were summarized in tables for qualitative evaluation as to the consistency of findings, strength of association and dose–response. Such evaluation of large bodies of data can also be accomplished through a collaborative, combined analysis of the original data from multiple studies or by pooling the summary results of individual studies, an approach referred to as meta-analysis.

In a collaborative re-analysis, the relevant investigators contribute the raw data for a pooled analysis and give detailed accounts of their procedures for reconciliation of differences. It is often possible to check the results obtained in case–control studies by comparing them with those obtained in cohort studies. Under these circumstances, the data from all the different types of study may prove sufficiently comparable to allow them to be combined.

When collaborative re-analyses are not possible or feasible, the next best approach to interpreting the data from multiple studies is to perform a meta-analysis of the results reported in the published literature. However, aspects of study design and other issues that may affect the results may not be fully allowed for because only summary findings are used. Meta-analysis can be used to evaluate heterogeneity between study findings. It is particularly informative when the results of individual studies lack precision.

An example of a collaborative re-analysis of data is the one relating the risk for breast cancer and active smoking described in Section 2 of this monograph. This type of analysis has not been undertaken in the study of cancers weakly related to smoking and, under these circumstances, reliable estimates of risk are most likely to be obtained from the results of cohort studies. Consequently, in considering such diseases as prostate cancer and leukaemia, which are certainly not strongly related to smoking and for which many sets of data are available, the results of case–control studies are less important.

THE MONOGRAPHS

TOBACCO SMOKE

1. Production, Composition, Use and Regulations

1.1 Production and trade

1.1.1 *History*

The common tobacco plants of commerce had apparently been used for millenia by the peoples of the Western hemisphere before contact with Europeans began in 1492. The plants were cultivated by native Americans in Central and South America. Tobacco often had religious uses as depicted in Mayan temple carvings (Slade, 1997).

The start of the spread of tobacco from the Americas to the rest of the world invariably seems to date back to 11 October 1492, when Columbus was offered dried tobacco leaves at the House of the Arawaks, and took the plant back with him to Europe (IARC, 1986a). Presumably, the technique of smoking was picked up at the same time. The plant was named 'nicotiana' after the French ambassador to Portugal, who is said to have introduced it to the French court. The tobacco grown in France and Spain was *Nicotiana tabacum*, which came from seed that originated in Brazil and Mexico. The species first grown in Portugal and England was *Nicotiana rustica*, the seed coming from Florida and Virginia, respectively (IARC, 1986a).

Although claims were made that tobacco had been used earlier in China, no convincing documentation for this exists, but it is clear from Table 1.1 (IARC, 1986a) that tobacco was used widely and that a number of early societies discovered the effects of a self-administered dose of nicotine independently of each other, which implies that the plant was widely distributed, at least throughout the Americas.

Tobacco was grown, smoked and chewed by numerous peoples and eventually became ubiquitous; it certainly featured as an important tradeable source of income from the time of its discovery by Columbus until the present day.

The modern history of tobacco really starts with the design of the cigarette machine in the middle of the nineteenth century; a machine was patented in 1880 by James Bonsack (Bonsack, 1881). Another factor that contributed to the rise of cigarette smoking was concern over the spread of tuberculosis by spitting of smokeless tobacco (Glover & Glover, 1992). Since the 1920s, most tobacco has been smoked in cigarettes, with cigars, pipes and chewing tobacco declining to relatively small proportions of the global consumption. This does not mean that these other forms of use are trivial, as fashions have

Table 1.1. Chronicle of early tobacco cultivation and use

Date	Event
1492 (11 October)	Columbus sighted the home of the Arawaks and was offered 'dried' tobacco leaves.
1499	Amerigo Vespucci recorded the use of chewing tobacco on an island off Venezuela.
1545	Iroquois Indians near Montreal, Canada, were found to have smoking habits.
1556	Tobacco was first grown or became known in France.
1558	Tobacco was used in Brazil and Portugal.
1559	Tobacco was used in Spain.
1560	*Nicotiana rustica* was used in Central Africa.
1565	Tobacco was used in England.
1600	Tobacco was introduced to Italy, Germany, Norway, Sweden, Russia, Persia, India, Indochina, Japan, China and the west coast of Africa.
1612	John Rolfe, at Jamestown, Virginia, was the first man known to grow tobacco commercially for export.
1631	Tobacco production extended to Maryland and then gradually to other areas.
1650s	Portuguese took tobacco to South Africa and other countries. Spaniards distributed tobacco to the Philippines, Guatemala and other Central and South American countries and to the West Indies. Tobacco cultivation was begun in Indonesia. Tobacco cultivation was extended in Europe.

From IARC (1986a)

been started for the use of chewing tobacco and cigars as deliberate marketing ploys within the last two decades (Glover & Glover, 1992; Gupta, 1992; Gerlach *et al*., 1998).

1.1.2 *World production and trade*

World tobacco production is currently declining. It peaked in 1997 at 7 975 360 tonnes (US Department of Agriculture, 2001a) and by 2001 had fallen to 5 883 324 (US Department of Agriculture, 2002a; see Table 1.2). It is a little early to interpret the significance of these figures, and certainly too early to conclude that they reflect the beginning of a long-term downward trend.

The pattern of production has shifted significantly in recent decades. Whereas exports from the USA have fallen slightly, those from Brazil, China and Zimbabwe have increased substantially.

Table 1.2. World tobacco production

Crop year	Hectares	Tonnes
1976/77	4 127 740	5 892 000
1980	3 823 340	5 575 000
1985	4 519 600	6 433 300
1990	4 612 420	7 096 730
1996	4 544 060	7 349 480
1997	4 893 810	7 975 360

Turkey	–	74 014	42 174	155 058
USA	99 241	234 262	246 763	215 222
Zimbabwe	–	40 000	9 573	194 141

From Corrao *et al.* (2000)

Table 1.3 gives examples of some of the substantial shifts in tobacco production over the past three decades. Complex reasons lie behind the change in pattern. Economic pressures, often following political decisions, dictate who grows what and where. In developed areas, e.g. in the USA and the European Union, where farmers have, and still do, receive subsidies to grow tobacco, specific measures and programmes have also been initiated to pay farmers to stop growing tobacco or to switch to other crops (Council of the European Union, 2002; US Congress, 2002a,b; Womack, 2002). In developing countries, the cigarette manufacturers may provide seed and expertise as well as an assured market for the tobacco type they need (Time Asia, 2000). In other countries, cigarette manu-

facturers are compelled to purchase a proportion of their tobacco locally. Furthermore, consolidation of cigarette manufacturing followed the opening up of central and eastern Europe with the purchase by transnational corporations of antiquated tobacco monopolies (Griffin-Pustay, 1999, 2002). This affected the pattern of leaf production, import and export. The downward trend in tar and nicotine yields of cigarettes sold in developing countries during the 1990s meant that manufacturers' requirements were changed. The move towards tobacco with a low nitrosamine yield in the USA led to the export of substantial amounts of existing leaf.

The trend towards a smaller number of global brands was accompanied by the trend to global advertising. The complex trading situation is aggravated by the fact that a reported one-third (355 billion cigarettes) of annual global exports are smuggled (Joossens & Raw, 1998). Many smuggled cigarettes may be exported and imported several times.

1.1.3 *What is produced*

There is a wide variety of smoking tobacco products on the world market to chose from, including cigarettes, cigars, cigarillos, bidis, chuttas and kreteks (Table 1.4). Cigarettes and cigars use blended tobaccos and the type of tobacco used in these products has

Table 1.4. Smoking tobacco products

Cigarette	Any roll of tobacco wrapped in paper or other non-tobacco material; filter-tipped or untipped; approximately 8 mm in diameter, 70–120 mm in length
Cigar	Any roll of tobacco wrapped in leaf tobacco or in any other substance containing tobacco Types: little cigars, small cigars ('cigarillos'), regular cigars, premium cigars Some little cigars are filter tipped and are shaped like cigarettes. Regular cigars are up to 17 mm in diameter, 110–150 mm in length.
Bidi	Hand-rolled Indian cigarette; sun-dried temburni leaf rolled into a conical shape together with flaked tobacco and secured with a thread
Chutta[a]	Hand-rolled cigarette used for reverse smoking primarily by women in India
Kretek	Small cigar containing tobacco (approximately 60%[b]), cloves and cocoa. The burning blend gives a characteristic flavour and 'honey' taste to the smoke.

From Stratton *et al*. (2001)
[a] From Narayan *et al*. (1996)
[b] From Clark (1989)

a decisive influence on the physicochemical nature of the smoke they produce. The chemical composition of the tobacco leaf is determined by plant genetics, cultivation practices, weather conditions and curing methods (Tso, 1991). The classification of the leaf tobacco commonly used in cigarettes is primarily based on curing methods and tobacco types. For example, a standard system of classification by the US Department of Agriculture designates six major classes of US tobacco (Table 1.5). Each class comprises two or more different types. Individual types of flue-cured tobacco are no longer easily identified, and the type designation usually refers only to a marketing area. Different countries may use different classification terms, but the general principle is the same.

Table 1.5. Classification of US tobacco types

Tobacco type	Class	Characteristics	Main use	Growing regions
Flue-cured	1	Yellow, blond bright	95% in cigarettes	Alabama, Florida, Georgia, North Carolina, South Carolina, Virginia
Fire-cured	2	Light to dark brown; cured over open fires	'Roll-your-own' cigarettes, chewing tobacco, cigars and smoking tobacco	Kentucky, Tennessee, Virginia
Light air-cured	3A	Burley: cured without supplementary heat	> 90% in cigarettes	Indiana, Kentucky, Missouri, North Carolina, Ohio, Tennessee, Virginia, West Virginia
		Maryland	Almost all in cigarettes	Maryland
Dark air-cured	3B	Light to medium brown	For chewing tobacco and snuff	Kentucky, Tennessee, Virginia
Cigar filler	4	–	Tobacco types for use as cigar fillers, binders and wrappers; used for cigars	Indiana, Ohio, Pennsylvania, Puerto Rico
Cigar binder	5	–	Tobacco types for use as cigar fillers, binders and wrappers; used for cigars	Connecticut, Massachusetts, Minnesota, New York, Pennsylvania, Wisconsin
Cigar wrapper	6	–	Tobacco types for use as cigar fillers, binders and wrappers; used for cigars	Connecticut, Florida, Georgia, Massachusetts
Miscella-neous	7	–		Louisiana

From Tso (1991); US Department of Agriculture (2001c)

The major components of American blend cigarettes are flue-cured tobaccos (often called Virginia, blond or bright tobaccos), air-cured (burley) and Maryland tobaccos, sun-cured (Oriental) tobaccos and reconstituted or homogenized sheet tobacco which is made from tobacco dust, fines and particles, and leaf ribs and stems (Beauman *et al*., 1996; Hoffmann & Hoffmann, 1997). The American blend cigarette has been the predominant type in the USA, and the Virginia blend cigarette has been the most predominant type in Australia, Canada, China, Japan and the United Kingdom (Hoffmann & Hoffmann, 2001).

Blending is done to achieve specific pH, taste, burning characteristics and nicotine content and the type of tobacco blend significantly affects the pH, nicotine content and toxicity of the smoke. The pH strongly influences the concentration of free nicotine in tobacco smoke, whereas the nitrate content influences the carcinogenic potential of smoke. There is a choice of 60 *Nicotiana* species and 100 varieties of tobacco that can be blended. However, almost all commercial tobacco products use *Nicotiana tabacum* species and small amount of *N. rustica*. Cured tobacco lines can contain between 0.2 and 4.75% nicotine by weight, depending on plant genetics, growing conditions, degree of ripening, fertilizer treatment and position of leaf on the stalk (Tso, 1991; Stratton *et al*., 2001).

The actual recipes for blending are closely kept trade secrets and the consolidation of the manufacturing industry worldwide seems to be leading towards a relatively homogeneous cigarette with relatively modest differences in tar and nicotine yield, but considerable diversity in nitrosamine yield (Gray *et al*., 2000).

Roll-your-own (RYO) cigarettes are a cheaper substitute for commercially manufactured brands and are gaining in popularity worldwide. In Europe, two of the major markets for RYO are Germany and the Netherlands (Dymond, 1996). In Canada, they became so popular that, by the end of 1989, sales of RYO accounted for approximately 14% of the Canadian cigarette market (Kaiserman & Rickert, 1992a). In the United Kingdom in 1994, more than 20% of male smokers used RYO products as compared with less than 4% of female smokers (Darrall & Figgins, 1998). In the USA, 3.4 billion RYO cigarettes were smoked in 1994 (Maxwell Tobacco Fact Book, 2000).

A cigar is any roll of tobacco wrapped in leaf tobacco or any other substance containing tobacco. There are four main types of cigar: little cigars, small cigars (‘cigarillos’), regular cigars and premium cigars. Little cigars contain air-cured and fermented tobacco and are wrapped either in reconstituted tobacco or in cigarette paper that contains tobacco and/or tobacco extract. Some little cigars have cellulose acetate filter tips and are shaped like cigarettes. Cigarillos are small, narrow cigars with no cigarette paper or acetate filter. Regular and premium cigars are available in various shapes and sizes and are rolled to a tip at one end. The dimensions of regular cigars are from 110 to 150 mm in length and up to 17 mm in diameter. Regular cigars weigh between 5 and 17 g. Premium cigars (hand-made from natural, long filler tobacco) vary in size, ranging from 12 to 23 mm in diameter and 127 to 214 mm in length (Stratton *et al*., 2001). Although the use of cigarettes declined in the USA throughout the 1990s, consumption of large cigars and cigarillos

increased by 64% during the same period (from 2.34 billion to 3.85 billion pieces; US Department of Agriculture, 2002b).

In certain countries, considerable quantities of tobacco are consumed in forms other than cigarette smoking. Kreteks are a type of small cigarette that contain tobacco (approximately 60%), ground clove buds (40%) and cocoa, which gives a characteristic flavour and 'honey' taste to the smoke (Clark, 1989; Stratton *et al.*, 2001). Kreteks are indigenous to Indonesia, but are also available in the USA. In India, about seven times more bidis are consumed than cigarettes. Bidis are used extensively in India and in the rural areas of several south-east Asian countries (Stratton *et al*., 2001). They are also becoming increasingly popular among teenagers in the USA (Malson & Pickworth, 2002). A bidi is made by rolling a rectangular piece of a dried temburni leaf around approximately 0.2–0.3 g of sun-dried, oriental tobacco and securing the roll with a thread. These cigarettes are perceived by some as a better-tasting, cheaper, safer or more natural alternative to conventional cigarettes (Malson *et al*., 2001; Stanfill *et al.*, 2003). Chutta is an Indian home-made cigar, 5–9 cm long, prepared by rolling local tobacco inside a sun-dried tobacco leaf. Reverse smoking of chutta (with the burning end inside the mouth) is prevalent among women in the rural communities of Andhra Pradesh (van der Eb *et al*., 1993). Chutta is also smoked in the usual way. Additionally, about 40% of total tobacco consumption in India is in the form of smokeless or chewing tobacco (WHO, 1997). Two nicotine-delivery devices which mimic the cigarette, but heat the tobacco rather than burn it, have been developed and test-marketed under the names of Eclipse™ (deBethizy *et al*., 1990; Borgerding *et al*., 1998) and Accord™ (Buchhalter & Eissenberg, 2000).

Reliable figures for the proportion of tobacco that is used for pipes, hand-rolled cigarettes, chewing and snuff (including oral snuff) are not readily available for most countries. Nor is there any good record of the types and amounts of tobacco used as smokeless products.

Tobacco that is grown and used locally is not necessarily taxed or included in national statistics.

1.2 Composition

Both tobacco and tobacco smoke are very complex matrices consisting of thousands of compounds. A total of 3044 constituents have been isolated from tobacco and 3996 from the mainstream smoke of cigarettes (Roberts, 1988). Mainstream smoke is the smoke that is released at the mouth end of the cigarette during puffing whereas sidestream smoke is the smoke released from the burning cone and through the cigarette paper, mostly between puffs. Some 4000 mainstream smoke compounds have been identified to date, and account for more than 95% of the weight of mainstream smoke (Green & Rodgman, 1996; Jenkins *et al.*, 2000). A total of 1172 constituents are present both in tobacco and tobacco smoke (Roberts, 1988). 'Tobacco smoke constituents' refers to all substances present in smoke, regardless of their origin, i.e. whether they come from the

tobacco itself, or from the tobacco additives, the paper, the filter or from the air drawn into the cigarette.

The qualitative composition of smoke components is mainly identical in mainstream smoke, sidestream smoke and secondhand tobacco smoke, sometimes referred to as 'environmental' tobacco smoke (an air-diluted mixture of sidestream smoke and exhaled mainstream smoke). The quantitative composition of these different smoke matrices may, however, vary considerably.

Advances in chemical analytical techniques and an increased knowledge of the genotoxic environmental agents brought the number of carcinogens identified in tobacco smoke to 69 by the year 2000. These carcinogens include 10 species of polynuclear aromatic hydrocarbons (PAHs), six heterocyclic hydrocarbons, four volatile hydrocarbons, three nitrohydrocarbons, four aromatic amines, eight *N*-heterocyclic amines, 10 *N*-nitrosamines, two aldehydes, 10 miscellaneous organic compounds, nine inorganic compounds and three phenolic compounds (Hoffmann *et al.*, 2001).

Eleven compounds (2-naphthylamine, 4-aminobiphenyl, benzene, vinyl chloride, ethylene oxide, arsenic, beryllium, nickel compounds, chromium, cadmium and polonium-210) classified as IARC Group 1 human carcinogens have been reported as present in mainstream smoke (IARC, 1987, 1990, 1993a, 1994; Hoffmann *et al*., 2001; IARC, 2001).

Since the last *IARC Monograph* on tobacco smoking (IARC, 1986a), the focus of research on carcinogens in tobacco and tobacco smoke has predominantly been on benzo[*a*]pyrene (a surrogate for all PAHs), tobacco-specific *N*-nitrosamines (TSNA), especially *N*′-nitrosonornicotine (NNN) and 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK) and aromatic amines, especially 4-aminobiphenyl (4-ABP), because of their established carcinogenic potency (Vineis & Pirastu, 1997; Hecht, 1998, 1999; Castelao *et al*., 2001; Hecht, 2002).

1.2.1 *Cigarette tobacco*

The types of tobacco used in smoking products are listed in Table 1.5. The most common tobacco product in developed countries is the manufactured cigarette. A cigarette is defined as any roll of tobacco wrapped in paper or other non-tobacco material. Cigarettes can be either commercially manufactured or individually made (roll-your-own). Cigarettes are lit, and the burning process produces smoke that is inhaled through the unlit end. Cigarettes are approximately 8 mm in diameter and 70–120 mm in length (Borgerding *et al*., 2000; Stratton *et al*., 2001).

(*a*) *Occurrence of tobacco-specific carcinogens and their precursors in tobacco*

Unlike cigarette smoke, measurements of nicotine content and other constituents of tobacco have not been made or reported as a part of official tests of commercial cigarettes, although the smoke composition is directly dependent (both qualitatively and quantitatively) on the profile of tobacco smoke precursors.

Table 1.6 shows an international comparison of the concentrations of two carcinogenic tobacco-specific *N*-nitrosamines, NNN and NNK, and their putative precursors, nicotine and nitrate in the tobacco from commercial cigarettes. The assays of a large number of cigarette brands from Canada, the United Kingdom, the USA and other countries around the world, have demonstrated that there is a very wide variation in concentrations of nicotine (from 7.2 to 18.3 mg/cigarette) in the tobacco filler, of nitrate (from 0.3 to 20.6 mg/cigarette), NNN (from 45 to 58 000 ng/g tobacco) and NNK (from not detected to 10 745 ng/cigarette; detection limit < 50 ng/cigarette) (Fischer *et al*., 1989a; Nair *et al*., 1989; Djordjevic *et al*., 1990; Fischer *et al*., 1990b,c; Djordjevic *et al*., 1991b; Tricker *et al*., 1991; Atawodi *et al*., 1995; Kozlowski *et al*., 1998; Djordjevic *et al*., 2000b,c). The country of origin plays a profound role in the chemical composition of the product (e.g. cigarettes from India and Italy contained extremely high levels of tobacco-specific carcinogens, namely, up to 58 000 ng/g NNN and 10 745 ng/cigarette NNK).

The higher TSNA concentrations were usually measured in the tobacco from untipped cigarettes, especially those made of dark tobacco. Among the 55 brands sold in Germany in 1987, the lowest amounts of nitrate, NNN and NNK were measured in Oriental-type cigarettes, followed by Virginia and American blend cigarettes (Table 1.7). The highest levels were reported in the dark tobacco cigarettes (Djordjevic *et al*., 1989a; Fischer *et al*., 1989a,b; Tricker *et al*., 1991). Typically, the levels of NNK are lower than those of NNN in cigarettes except in those made from Virginia flue-cured tobacco, in which higher levels of NNK were reported (Fischer *et al*., 1989a,b, 1990b).

Despite the large variation in the amount of the components measured in various cigarettes by Fischer *et al.* (1989a), the correlations between TSNA and nitrate were high to moderate (NNN: $r^2 = 0.61$; NNK: $r^2 = 0.4$). NNN concentrations increased with increased nitrate concentrations and did not depend on the tobacco type. Oriental and Virginia type cigarettes were very low in nitrate and also had the lowest NNN concentrations. The highest NNN concentrations were found in cigarettes made of dark tobaccos, which also had the highest nitrate levels. The correlation between NNK and nitrate was not as strong as for NNN suggesting that other factors such as the tobacco type may have an influence on the formation of NNK. Although both nitrate and nicotine are precursors for NNN and NNK, only nitrate seems to play a predominant role in their formation. Table 1.7 also shows that NNN, NNK and nitrate levels in tobacco from unfiltered and filtered cigarettes in the same blend category were of the same order of magnitude, although somewhat higher values were reported for unfiltered brands (Tricker *et al*., 1991).

Different types of cigarette are manufactured to deliver different smoke yields under machine-smoking conditions. The terms ‘ultra low-’, ‘low-’, ‘medium-’ and ‘high-yield cigarettes’ are not official government-designated terms but are part of the trademarked names of products that provide information on the smoke yields obtained by machine-smoking using standardized protocols. In general, ultra low-yield products deliver less than 6 mg tar per cigarette, low-yield products between 6 and 15 mg tar and regular ‘full-flavoured’ cigarettes deliver more than 15 mg of tar, although different research groups have made their

[b] 23 Canadian cigarette brands; total nicotine (mg/cigarette)

[c] ng/g tobacco

[d] Cigarettes were designated into classes according to nicotine concentrations in mainstream smoke as follows: ultra-low, delivering < 0.5 mg FTC (Federal Trade Commission) nicotine/cigarette; low, delivering 0.5–< 0.85 mg FTC nicotine/cigarette; medium, delivering 0.85–1.2 mg FTC nicotine/cigarette; high, delivering > 1.2 mg FTC nicotine/cigarette. [In Djordjevic *et al.* (2000c), the authors only report the mean nicotine concentration in mainstream smoke of the six brands analysed, and do not specify which brand is unfiltered; the Working Group assumed that it corresponded to a high-yield brand.]

own classifications (Stratton *et al.*, 2001). Tobacco from ultra low-, low-, medium- and high-yield cigarettes contain similar amounts of preformed TSNA and their precursors (Table 1.7) within the brand type regardless the country of origin (Djordjevic *et al.*, 1990; Fischer *et al.*, 1990b; Kozlowski *et al.*, 1998; Djordjevic *et al.*, 2000c). The tobacco from Canadian brands had the least preformed NNN (up to 982 ng/cigarette) and brands in the USA the highest amounts (up to 3050 ng/cigarette). NNK content was of the same order of magnitude between countries (up to 884 ng/cigarette in Canadian cigarettes and up to 920 ng/cigarette in cigarettes in the USA). Japanese cigarettes contained the lowest concentrations of preformed NNK in tobacco (up to 330 ng/g tobacco).

The separate analysis of blend ingredients showed that pure Oriental and flue-cured, pure Virginia tobaccos contain the least nitrate (mean, 1.73 mg/g and 1.54 mg/g, respectively) and preformed tobacco-specific *N*-nitrosamines (mean, 34 ng/g tobacco and 216 ng/g tobacco NNK, respectively) (Table 1.8). The highest nitrate and NNK levels were measured in air-cured pure burley tobaccos (mean, 22.5 mg/g nitrate and 477 ng/g tobacco NNK) (Fischer *et al.*, 1989a). Similar data were reported for flue-cured and sun-dried tobaccos from the former USSR (Djordjevic *et al.*, 1991b).

Table 1.8. Nitrate and tobacco-specific *N*-nitrosamine concentrations in different cured tobaccos produced worldwide

Tobacco type	Nitrate (mg/g)	NNN (ng/g)	NNK (ng/g)
Oriental	0.2–6.0	20–460	ND–70
Virginia	< 0.05–16.0	10–600	30–1100
Burley	8.0–41.0	1300–8850	162–1400

From Fischer *et al*. (1989a); Djordjevic *et al*. (1991b)
ND, not detected (NNK < 50 ppb)

An international comparison of nicotine content in blended cigarettes (Kozlowski *et al.*, 1998) showed a similar spread across the whole range of smoke yields (0.1–1.3 mg nicotine and 1–17 mg tar per cigarette). Tobacco from American blended cigarettes ($n = 32$) contained an average of 10.2 mg nicotine/cigarette (range, 7.2–13.4 mg). The tobacco from Canadian Virginia blend cigarettes ($n = 23$) contained an average of 13.5 mg nicotine/cigarette (range, 8.0–18.3 mg), and that from British Virginia blend cigarettes ($n = 37$), 12.5 mg nicotine/cigarette (range, 9.0–17.5 mg).

(*b*) *The significance of the content of preformed TSNA precursors in tobacco*

The TSNA are formed predominantly during the curing process (Bush *et al*., 2001; Peele *et al*., 2001) although small quantities of TSNA have also been found in freshly harvested (green) leaves. The mean concentrations of NNN and NNK in green leaves

harvested from all stalk positions of the NC-95 flue-cured tobacco plant were 260 ppb and 280 ppb, respectively (Djordjevic *et al*., 1989b). These concentrations were six times higher in cured tobacco (1560 ppb and 1810 ppb, respectively). Bhide *et al*. (1987) reported on the presence of TSNA in green leaves of *N. tabacum* and *N. rustica* species grown in India in two different seasons. In one season, at one location, mature green leaves of *N. rustica* contained as much as 46 100 ppb NNN and 2340 ppb NNK. One year later, tobacco harvested at the same location contained 5730 ppb NNN and 352 ppb NNK. These levels were elevated to 15 000 ppb NNN and 25 800 ppb NNK in sun-cured tobacco. The extremely high potential of *N. rustica* to form carcinogenic TSNA is important because this tobacco species is still commercially grown in Russia, and several other former republics of the former USSR, and in Poland, South America and, to a limited extent, in India (Hoffmann & Hoffmann, 1997). The data shown in Table 1.6 suggest that *N. rustica* may have been used as a component of the blend in Indian (Nair *et al.*, 1989), but not in Polish cigarettes or those from the former USSR.

(*c*) *TSNA-reduced tobacco*

In recent years, it has been demonstrated that the use of new curing technologies can considerably reduce the levels of TSNA, especially NNK, or even completely eliminate them (Djordjevic *et al*., 1999; Wahlberg *et al*., 1999; Peele *et al*., 2001). Inhibition of the microbial reduction of nitrate to nitrite that reacts with tobacco alkaloids to form TSNA is one method to reduce the levels of these carcinogens in tobacco. The second method was described by Peele *et al.* (2001). It is common practice to flue-cure Virginia tobacco in bulk barns that have forced air ventilation and temperature control. Nitrogen oxides (NOx) are a combustion by-product of the liquid propane gas commonly used for curing; they react with naturally occurring tobacco alkaloids to form TSNA. The newly developed heat-exchange curing method precludes exposure of the tobacco to combustion gases and by-products, thereby eliminating this significant source of TSNA formation.

The flue-cured lamina that were used to produce test cigarettes for the evaluation of smoke composition contained from undetectable levels of NNK to 22 ng/g tobacco (detection limit for NNK, 0.11 ng/g tobacco; Djordjevic *et al.*, 1999). The concentration of nitrogen in the form of nitrite in 'TSNA-reduced' tobacco was similar, however, to that determined for a commercial American blend cigarette (1.8 versus 1.9 µg/g tobacco). The concentration of nitrogen in the form of nitrate was somewhat lower (1.5 versus 2.0 mg/g tobacco) and the nicotine content was higher (22.2 versus 15.9 mg/g tobacco). The levels of NNK in mainstream smoke as determined using the Federal Trade Commission (FTC) method in the test cigarette made with 'TSNA-reduced' tobacco were 6.5 ng/cigarette compared with 130 ng in a commercial American blend cigarette tested under the same experimental conditions (30% and 25% of the levels measured in tobacco, respectively).

(*d*) *The origin of TSNA in tobacco smoke*

The question of the origin of TSNA in the mainstream smoke has been also the subject of investigation since the previous *IARC Monograph* on tobacco smoking (IARC,

1986a). The studies have reported different results. In one study, the tobacco column was spiked with [carbonyl-^{14}C]NNK to determine the recovery of unchanged NNK in the smoke, and with [methyl-^{14}C]nicotine, to determine the extent of nicotine nitrosation during smoking. The researchers found that most of the NNK in cigarette smoke (63–74%) is pyrosynthesized from nicotine and nitric oxides during combustion and that the NNK yield in the smoke is independent of the nitrate content in the tobacco (Adams *et al*., 1983). Similarly, based on the 11.3% transfer rate of [^{14}C]-labelled NNN, it was concluded that 46% of NNN in the mainstream smoke of US blended cigarettes is due to the transfer from tobacco and that the remainder is synthesized during smoking (Hoffmann *et al*., 1977). More recent studies, however, have demonstrated that the levels of preformed TSNA in tobacco determine yields in smoke. The addition of the nitrosamine precursors nitrate and nicotine to the tobacco before the machine-smoking of cigarettes did not change the levels of NNN and NNK in mainstream smoke (Fischer *et al*., 1990a). The mainstream smoke/tobacco ratios for NNN and NNK for the commercial German cigarettes, even when corrected for the ventilation and cigarette length, remained constant and were dependent neither on the nicotine nor the nitrate content of the tobacco with the exception of NNK in the cigarettes made from nitrate-rich dark tobacco (Fischer *et al*., 1990a). The calculated transfer rates for NNN and NNK from tobacco in the mainstream smoke were 23% and 34%, respectively, for untipped cigarettes and 13% and 23%, respectively, for filter-tipped cigarettes. Based on these results, Fischer *et al*. (1990a) concluded that pyrosynthesis of NNN and NNK is not likely, at least for cigarettes containing Virginia, American blend and Oriental type tobacco.

The addition of increasing amounts of potassium nitrate (0.22%, 0.53%, 1.12% and 1.78% in the tobacco filler) in experimental blend cigarettes (50% Virginia, 15% Oriental, 10% Burley and 25% reconstituted tobacco sheets) resulted in a linear increase in the concentrations of oxides of nitrogen and *N*-nitrosopyrrolidine (NPYR), a volatile *N*-nitrosamine. NNK was not influenced by the nitrate concentrations in the tobacco filler whereas NNN and *N*′-nitrosoanatabine increased slightly with increased nitrate concentrations (Tricker *et al*., 1993a).

When an American blend unfiltered cigarette was spiked with 10 mg nicotine prior to machine-smoking, no detectable NNN or NNK was formed (Djordjevic *et al*., 1991a). The addition of 1 mg of the secondary tobacco alkaloid nornicotine, however, increased the concentration of NNN in mainstream smoke by 27%. The spiking of a French dark tobacco, untipped cigarette with 10 mg nicotine increased the NNK level in mainstream smoke by 40%. Brunnemann *et al*. (1996) concluded, based on the analysis of a variety of commercial Thai cigarettes, across a wide range of yields in smoke, that the concentration of TSNA in mainstream smoke, as well as the tar and nicotine yields, depend on tobacco composition.

The preformed TSNAs in tobacco appear to be determinants of the TSNA yields in the mainstream smoke of certain types of cigarette, although some formation may also occur under certain conditions during smoking.

However, there are other (qualitative) factors to be considered. Of particular note is the trend, at least in the USA, towards tobaccos higher in nitrate that lead to an increase in carcinogenic TSNAs in smoke and a reduction in carcinogenic PAHs (Hoffmann & Hoffmann, 1997). A major US cigarette manufacturer was awarded a patent in 1978 for developing a process that reduces the nitrate content of the reconstituted tobacco made from ribs and stems by more than 90%. It is unclear to what extent this patented method has been applied to the manufacture of cigarettes (Hoffmann & Hoffmann, 2001).

(*e*) *The occurrence of volatile* N-*nitrosamines and non-volatile* N-*nitrosamino acids and other toxic compounds in tobacco*

In addition to TSNA, the presence of several carcinogenic volatile *N*-nitrosamines, including *N*-nitrosodimethylamine (NDMA), *N*-nitrosoethylmethylamine (NEMA) and NPYR has been reported in cigarette tobacco (Tricker *et al*., 1991). The levels of volatile *N*-nitrosamines in tobaccos from 20 commercial German cigarettes were: NDMA, from 0.4 to 5.0 ng/cigarette; NEMA, from not detected (limit of detection, 0.1 ng/cigarette) to 1.5 ng; and NPYR, from 0.6 to 5.2 ng/cigarette. The levels of NEMA and NPYR were 87% and 53% higher in untipped than in filter-tipped cigarettes of the same blend type. The highest levels were measured in unfiltered brands made of dark tobacco.

The presence of several non-volatile *N*-nitrosamino acids, such as 4-(*N*-nitroso-*N*-methylamino)butyric acid (NMBA), *N*-nitrosopipecolic acid (NPIC), *N*-nitrososarcosine (NSAR), 3-(*N*-nitroso-*N*-methylamino)propionic acid (NMPA), *N*-nitrosoproline (NPRO), *N*-nitrosodiethanolamine (NDELA) and 4-(*N*-nitrosomethylamino)-4-(3-pyridyl)butyric acid (*iso*-NNAC), have also been reported in cigarette tobaccos (Djordjevic *et al*., 1989a, 1990; Tricker *et al*., 1991). Some of them, such as NSAR (IARC, 1978), NMPA and NMBA, are carcinogenic *per se* (Hoffmann *et al*., 1992), whereas others may undergo thermal decarboxylation during the pyrolysis of cigarette tobacco (Brunnemann *et al*., 1991) to yield their corresponding volatile *N*-nitroso analogues; for example, pyrolytic decarboxylation of NPRO gives rise to NPYR, whereas NMPA gives rise to NEMA. The levels of *N*-nitrososarcosine in cigarette tobacco range from 22 to 460 ng per cigarette, NMPA from 110 to 4990 ng/cigarette, and NMBA from not detected (limit of detection, 1.0 ng/cigarette) to 200 ng/cigarette. The upper values were usually found in untipped cigarettes made from dark tobacco (Tricker *et al*., 1991).

In 1989, the nicotine derived *N*-nitroso acid *iso*-NNAC was identified (Djordjevic *et al*., 1989a) and its concentration measured in both French dark tobacco and American blend cigarettes (Djordjevic *et al*., 1989a, 1990, 1991a). The *iso*-NNAC levels in tobacco ranged from not detected to 50 ppb, being higher in French dark tobacco cigarettes. *iso*-NNAC was not detected in the mainstream smoke of American blend cigarettes and was formed in minute amounts when the filler was spiked with the putative precursors cotinine and cotinine acid 4-(methylamino)-4-(3-pyridyl)butyric acid (COTAC) prior to machine smoking (Djordjevic *et al*., 1991a).

The minute amounts of preformed *iso*-NNAC in blended tobacco (other than dark tobacco), its very low transfer rate in mainstream smoke (1.1%), and the possibility that

this compound can also be formed endogenously, could make it a suitable candidate biomarker for the assessment of the levels of endogenously formed tobacco-derived *N*–nitrosamines. However, in one study, *iso*-NNAC was detected in the urine of four of 20 cigarette smokers (at levels of 44, 65, 74 and 163 ng/day) (Tricker *et al*., 1993b). The oral administration of nicotine and cotinine to abstaining smokers did not result in *iso*-NNAC excretion even after supplementation with 150 mg oral nitrate. The authors concluded that the occasional presence of *iso*-NNAC in smokers' urine resulted from exogenous exposure to the preformed compounds in mainstream smoke and not from the endogenous nitrosation of nicotine and its metabolites. It was not clear whether there were any smokers of dark tobacco cigarettes among the 20 volunteers in this study.

Stanfill and Ashley (1999) quantified 12 flavour-related compounds in cigarette tobacco: coumarin, pulegone, piperonal and nine alkenylbenzenes, including *trans*-anethole, safrole, methyleugenol and myristicin. In 62% of 68 brands analysed, one or more of these flavour-related compounds were detected (concentrations ranged from 0.0018 to 43 μg/g tobacco). The toxic properties and in some cases carcinogenic properties (e.g. of coumarin and safrole) (IARC, 1976) of these flavour-related compounds may constitute an additional health risk related to cigarette smoking.

1.2.2 *Mainstream cigarette smoke*

Cigarette mainstream smoke aerosol can be broadly categorized as consisting of CO, other vapour-phase components, particulate matter (tar) and nicotine. These four major components of smoke are simultaneously delivered to the active smoker as a complex and dynamic aerosol containing thousands of chemical constituents composed of several billion electrically-charged semi-liquid particles per cm^3 (aerodynamic diameter, 0.1–0.3 μm; 5×10^9 particles per cm^3) within the mixture of combustion gases (Smith & Fischer, 2001). The chemicals in the mainstream smoke aerosol are distributed between the particulate and vapour phase depending on their physical properties (e.g. volatility and stability) and their chemical properties as well as the characteristics of the environment (Jenkins *et al.*, 2000).

According to Hoffmann and Hoffmann (1997, 2001) and Kozlowski *et al*. (2001), the composition of cigarettes and of cigarette smoke has changed dramatically since the first large-scale epidemiological studies linking smoking and lung cancer were conducted in the 1950s (Doll & Hill, 1950; Wynder & Graham, 1950) and the subsequent reports of the Royal College of Physicians (1962), US Department of Health and Human Services (1964) and IARC (1986a). During that period, numerous carcinogens in tobacco smoke were identified and quantified and their biological activities and relevance to cancer have also been studied. The major focus, though, has been on PAHs such as benzo[*a*]pyrene and TSNAs such as NNK, which are considered to be major lung carcinogens (Hecht, 1998, 1999). 4-ABP and other aromatic amines have also been studied intensively because of their role in bladder carcinogenesis (Castelao *et al*., 2001). The carcinogenic heterocyclic amines such as 2-amino-1-methyl-6-phenylimidazo(4,5-*b*)pyridine (PhIP),

frequently found in cooked foods, and 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1) and 2-aminodipyridol[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2), the pyrolysis products of glutamic acid, have also been quantified in the smoke of filtered cigarettes from Japan, the United Kingdom and the USA (Kanai *et al*., 1990; Manabe *et al*., 1991).

(*a*) *Nicotine, tar and CO yields and other components in cigarette smoke*

(i) *Machine-smoking method — ISO/FTC parameters*

In 1998, there were 1294 brands of cigarette on the market in the USA for which the emissions of tar, nicotine and carbon monoxide (CO) had been measured (Federal Trade Commission, 2000). The reported emissions were based on a standardized machine-smoking procedure, introduced in 1936 by Bradford *et al*., and adopted with some modifications by the Federal Trade Commission (Federal Trade Commission, 1967; Pillsbury *et al*., 1969). This method sets up the smoking machine to draw 35-mL puffs of 2 sec duration once per minute until the predetermined butt length of 23 mm for unfiltered cigarettes — or the length of filter over wrapping paper plus 3 mm for filtered cigarettes — has been reached. Ventilation holes (when present) are not blocked during smoking.

The FTC machine-smoking method, which is used in the USA, is very similar to that of the International Organization for Standardization (ISO), which is used widely throughout the rest of the world (Eberhardt & Scherer, 1995). The key parameters of these and of the other machine-smoking protocols referred to in this monograph are summarized in Table 1.9.

Table 1.9. Machine-smoking protocols for measuring smoke yields of tobacco products

Protocol	Puff duration (sec)	Puff interval (sec)	Puff volume (mL)	Butt length (mm)	Filter ventilation holes
Tobacco Research Council	2	60	35	25	NA
Federal Trade Commission	2	60	35	23[a]	Open
International Standards Organization	2	60	35	23[a]	Open
Massachusetts	2	30	45	23[a]	50% blocked
Health Canada 1998–99	2	26	56	23[a]	Fully blocked
Health Canada 2000	2	30	55	23[a]	Fully blocked

[a] Cigarettes smoked to a 23-mm butt length or, if in excess of 23 mm, to the length of the filter and overwrap plus 3 mm

Tar yields in mainstream smoke are influenced primarily by filtration, ventilation (filter tip ventilation and paper porosity) and the choice of tobacco type and blending recipe. As with any agricultural product, there is natural variation in tobacco composition from year to year. In order to manufacture a consistent product, tobacco blends are made using the crops from previous years. The length of cigarettes and their burning rate also influence smoke yields. A faster rate of burning results in a lower tar yield in mainstream smoke per cigarette, because the burn time determines the number of puffs and the total tar delivery increases with each puff (Kozlowski *et al*., 1980; Darby *et al*., 1984; Kozlowski *et al*., 1998).

The tar and nicotine yields of cigarettes marketed in the USA have been systematically reported by the FTC since 1967, and the carbon monoxide (CO) ratings since 1980. The mainstream smoke of cigarettes currently marketed in the USA yields from < 0.05 mg to 2 mg nicotine, < 0.5 mg to 27 mg tar and < 0.5 mg to 22 mg CO per cigarette. The sales-weighted average yields of nicotine and 'tar' in smoke are now 0.9 mg and 12 mg per cigarette, compared with 1.4 mg and 21.6 mg, respectively, in 1968, a decrease of about 40% (Federal Trade Commission, 2000).

The reduction in tar has been achieved by several methods including reduced tobacco weight, improved filtration, dilution with air through ventilation holes on the filter wrapping paper, the use of reconstituted and expanded tobacco, the use of chemical additives to control the combustion rate and changes in agronomic practices. These modifications have also significantly reduced the yields of constituents associated with the vapour phase (Hoffmann & Hoffmann, 2001; Kozlowski *et al*., 2001). For example, in comparison with an untipped cigarette with a yield of vinyl chloride of 15.3 ng/cigarette, charcoal filtration reduced vinyl chloride in mainstream smoke to 5.1 ng/cigarette. The yield of benzene in mainstream smoke was correlated with the amount of tobacco burned and with the tar level. Agronomic factors such as production practices and soil characteristics, and environmental conditions such as rainfall, reportedly influence the accumulation of metals, including cadmium, beryllium, chromium, nickel and arsenic in the leaf. The use of fertilizers low in nitrates and heavy metals could reduce the yields of specific constituents in mainstream smoke (Smith *et al*., 1997).

In the USA, the FTC-rated yields of tar and nicotine in smoke decreased by at least 60% between 1950 and 1993 due largely to the introduction of filters (Stellman *et al*., 1997). However, smokers responded to low-yield cigarettes by changing their smoking behaviour so that they still obtained the desired amount of nicotine. Nicotine concentration in mainstream smoke is highly correlated with that of tar (r = 0.97 [0.93–0.99]; Kozlowski *et al*., 1998). The subject of changes in lung cancer mortality or incidence subsequent to changes in cigarette composition is discussed in Section 2.1.

In the United Kingdom, sales-weighted average tar yields have declined steadily. For example, in 1999, tar yield was 9.6 mg per cigarette, less than half the level in 1972. Over the same period, nicotine yields have decreased from 1.33 mg to 0.8 mg per cigarette; CO yields have shown smaller declines. At the same time as the absolute yields have declined, there have also been changes in tar to nicotine ratios. Smokers in the United Kingdom in

1999 were exposed to 22% less tar per unit of nicotine than in 1973. In the United Kingdom, cigarettes have been tested according to ISO standards since 1991. Before 1991, the Laboratory of the Government Chemist used a UK-specific definition of butt length, which resulted in slightly higher yields than the ISO method. There were also changes to the way nicotine was measured in 1991 which resulted in a decline of about 5% in values measured, or 0.05 mg/cigarette for a mean yield of 1 mg (Jarvis, 2001). During 1983–90, a series of special studies investigated the yields and range of additional analytes (e.g. hydrogen cyanide, aldehydes, acrolein, nitric oxide (NO), low-molecular weight phenols and PAHs) and their inter-relationship with the routinely monitored components. With the exception of NO, which is strongly dependent on tobacco type, and the delivery of some phenols and PAHs, the routinely monitored tar, nicotine and CO provided an adequate guide to the yields of other analytes in mainstream smoke of cigarettes available in the United Kingdom in the 1980s. Standard machine smoking conditions in terms of the duration (2 sec), volume (35 mL) and interval (58 sec) between puffs were applied (Phillips & Waller, 1991).

(ii) *ISO–FTC machine-smoking method — human smoking parameters*

When standard international smoking conditions (cigarettes were machine-smoked to a fixed butt length of 30 mm or filter-plus-overwrap plus 3 mm, when this length was greater than 27 mm; FTC puff volume, duration and frequency were applied) were compared with 26 different nonstandard conditions (variable puff volume, puff duration and interval between puffs), it was revealed that up to 95% of the variation in tar yield per cigarette could be explained by variation in the total volume of smoke produced per cigarette (Rickert *et al*., 1986).

When the influence of smoking parameters (puff profile including duration, volume and frequency of puffs) on the delivery of TSNAs into mainstream smoke was investigated, the total volume drawn through the cigarette was found to be the main factor responsible for the amount of TSNA delivery in mainstream smoke (Fischer *et al*., 1989c).

To obtain realistic estimates of smokers' exposure to components of cigarette smoke, the puffing characteristics of 133 adult smokers of cigarettes rated by the FTC as having yields of 1.2 mg of nicotine or less (56 smokers of low-yield cigarettes (≤ 0.8 mg nicotine/cigarette) and 77 smokers of medium-yield cigarettes (0.9–1.2 mg nicotine per cigarette)) were assessed by a pressure transducer system. The smoking profiles for a randomly chosen subset of 72 smokers were then programmed into a piston-type machine to generate smoke from each smoker's usual brand of cigarettes for assays of nicotine, tar, carbon monoxide, benzo[*a*]pyrene and NNK. The FTC protocol was used in parallel to assess levels of benzo[*a*]pyrene and NNK in the 11 brands most frequently smoked by study subjects. Comparison with the FTC protocol values showed that smokers of low- and medium-yield brands took statistically significantly larger puffs (48.6-mL and 44.1-mL puffs, respectively) at statistically significantly shorter intervals (21.3 and

18.5 sec, respectively) and they drew larger total smoke volumes than those specified in the FTC parameters. Consequently, smokers of low- and medium-yield brands received 2.5 and 2.2 times more nicotine and 2.6 and 1.9 times more tar, respectively, than FTC-derived amounts, as well as about approximately twice as much benzo[*a*]pyrene and NNK. Smokers of medium-yield cigarettes received higher doses of all components than did smokers of low-yield cigarettes. The major conclusion of this study was that the FTC protocol underestimates doses of nicotine and carcinogens received by smokers and overestimates the proportional benefit of low-yield cigarettes (Djordjevic *et al*., 2000a).

(iii) *Machine-smoking method — Massachusetts parameters*

The most comprehensive data on the profile of the biologically active mainstream and sidestream smoke constituents of contemporary cigarettes, based on standardized machine-smoking methods, were compiled in 'The 1999 Massachusetts Benchmark Study. Final Report' (Borgerding *et al*., 2000). Eighteen leading brands from the USA (26 brand styles with between 0.05 and 9% of market share by brand style), delivering from 1 to 26 mg tar per cigarette (by FTC parameters) were screened. All were American blend cigarettes made by mixing different tobacco types and grades, including reconstituted tobacco sheets, expanded tobacco and additives. Cigarette smoke was generated for the assay of 44 constituents (Table 1.10) both in vapour and particulate phase using both the FTC method and the Massachusetts machine-smoking method (45-mL puffs of 2 sec duration drawn twice a minute until the predetermined butt length of 23 mm for untipped cigarettes (or the length of filter over wrapping paper plus 3 mm) was reached: when applicable, the ventilation holes were 50% blocked) (Borgerding *et al*., 2000). The 'more intense' Massachusetts method was developed in response to the debate on the validity of the FTC method for the assessment of smokers' exposure (Shopland, 2001).

The yields of selected toxic and carcinogenic mainstream smoke constituents obtained by machine-smoking of the 26 brand styles of cigarettes using the Massachusetts method are shown in Table 1.10 (these data were also summarized by Gray & Boyle, 2002). The average nicotine yields of the 26 brands tested ranged from 0.50 mg to 3.32 mg/cigarette. The results are representative of the nature of mainstream smoke, as they illustrate the variety of constituents present and their variations in yield even within a narrow range of products. Relatively few constituents (e.g. tar, nicotine and CO) are delivered in milligram-per-cigarette quantities. Twenty-four of the 44 constituents assayed (including benzene, formaldehyde, 1,3-butadiene and acetaldehyde) are delivered in microgram-per-cigarette quantities and the remainder in nanogram-per-cigarette quantities. For some compounds, the data presented in Table 1.10 compare well with those published earlier by the National Research Council (1986). However the emission of others (e.g. acetone, acrolein and benzene) exceeds the levels reported in 1986. The explanation for these discrepancies is that the NRC values described the range of deliveries measured by the machine-smoking of commercial untipped cigarettes using the FTC method, whereas the data from the Massachusetts Benchmark Study describe the mainstream smoke emissions from filtered cigarettes measured using the more intense smoking method.

Table 1.10. Yields of 44 smoke constituents in the mainstream smoke of cigarettes assayed for the 1999 Massachusetts Benchmark Study

Constituent	Median yield/ cigarette	Range/cigarette	Unit
Tar	25.8	6.1–48.7	mg
Carbon monoxide	22.5	11.0–40.7	mg
Nicotine	1.70	0.50–3.32	mg
Acetaldehyde	1618.1	596.2–2133.4	µg
Isoprene	713.2	288.1–1192.8	µg
Acetone	627.9	258.5–828.9	µg
Nitric oxide	457.3	202.8–607.1	µg
Hydrogen cyanide	380.8	98.7–567.5	µg
Methyl ethyl ketone	170.3	72.5–230.2	µg
Acrolein	162.9	51.2–223.4	µg
Toluene	124.2	48.3–173.7	µg
Propionaldehyde	110.2	46.8–144.7	µg
Hydroquinone	103.9	27.7–203.4	µg
Catechol	92.1	28.1–222.8	µg
Benzene	75.9	28.0–105.9	µg
1,3-Butadiene	75.2	23.6–122.5	µg
Butyraldehyde	70.0	28.8–95.6	µg
Formaldehyde	49.5	12.2–105.8	µg
Crotonaldehyde	44.1	11.6–66.2	µg
Ammonia	36.6	9.8–87.7	µg
Phenol	25.1	7.0–142.2	µg
Acrylonitrile	23.2	7.8–39.1	µg
meta-Cresol + *para*-cresol	19.4	7.3–77.3	µg
Pyridine	14.9	2.8–27.7	µg
Styrene	11.7	4.5–19.3	µg
ortho-Cresol	8.0	ND–33.9	µg
Quinoline	1.0	0.3–2.7	µg
Resorcinol	NQ	NQ	µg
NNN	199.1	99.9–317.3	ng
N-Acetyltransferase	186.3	95.2–298.6	ng
NNK	147.3	53.5–220.7	ng
Cadmium	131.8	31.0–221.8	ng
Lead	52.1	11.0–92.1	ng
1-Aminonaphthalene	30.7	13.4–64.5	ng
N-Nitrosoanabasine	26.2	14.2–45.3	ng
Benzo[*a*]pyrene	22.5	5.6–41.5	ng
2-Aminonaphthalene	15.5	5.7–28.6	ng
Arsenic	10.7	1.6–24.9	ng
Mercury	4.8	2.5–14.2	ng

Table 1.10 (contd)

Constituent	Median yield/ cigarette	Range/cigarette	Unit
4-Aminobiphenyl	4.5	1.8–7.8	ng
3-Aminobiphenyl	2.9	1.3–4.8	ng
Nickel	NQ	ND	ng
Chromium	NQ	ND	ng
Selenium	NQ	ND	ng

From Borgerding *at al*. (2000)
ND, not detected (limit of detection for nickel, 8.4 ng/cigarette; for chromium, 3 ng/ cigarette; for selenium, 11.4 ng/cigarette; and for *ortho*-cresol, 1.3 μg/cigarette); NQ, not quantifiable (limit of quantification for resorcinol, 3 μg/cigarette); NNN, *N*′-nitrosonornicotine; NNK, 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone

The functional relationships established by the Massachusetts Benchmark Study can be used to predict the yields of certain individual mainstream smoke constituents for other brand styles that have not yet been tested, but for which data on nicotine, tar and CO yields measured using the FTC parameters are available. The example brand of cigarette illustrated in Table 1.11 is a full-flavour brand style that delivers 1.1 mg nicotine and 14.5 mg tar according to the FTC method. By using the data on nicotine obtained by the FTC method for the example brand, the yields of mainstream smoke constituents found in the particulate phase can be predicted (these values are shown in the 'mean' column). Similarly, the CO yield for the example brand provides the basis for predicting mainstream smoke vapour-phase constituents. The highlighted constituents in Table 1.11 are predicted based on the CO yield. In addition to the mean values interpolated from the mainstream smoke functional relationships, lower and upper prediction interval values are provided. For nicotine, the predicted upper yield for the example brand was 2.4 mg per cigarette and that for tar 34 mg per cigarette. Therefore, the established functional relationships provide both tentative predictions of the yields of some individual constituents, given standard nicotine and CO yields, and the expected range of yields of some constituents.

The drawback of this approach is that cigarettes with different tar and nicotine yields as measured by the FTC method are designed in ways that lead smokers to smoke them differently. Therefore, no single set of machine-smoking parameters will adequately reflect individual smoking behaviours and the resulting exposure to smoke carcinogens. Moreover, a very large inter-individual variation in smoking topography[1] for each brand needs to be taken into consideration during the exposure assessment. To demonstrate this,

[1]Smoking topography is a method of assessing exposure, e.g. how much smoke enters the lung as estimated by measuring puff volume, the number of puffs per cigarette, puff duration, total inhalation time, flow rate and interval between puffs.

Table 1.11. Application of mainstream functional relationships to estimate yield values for a hypothetical brand style: Massachusetts smoke constituent form

the smoke yields measured by the Massachusetts method for the two leading full flavour regular and mentholated cigarettes in the USA were compared with the values obtained by mimicking the puffing patterns of two individuals who smoked those particular cigarettes (Table 1.12). The smoker of the mentholated brand drew in 5.6 mg nicotine per cigarette and the smoker of the non-mentholated brand drew in 4.1 mg nicotine. These amounts were twice those estimated by the Massachusetts method. Moreover, the smoker of non-mentholated brand took in four times more carcinogenic TSNAs (Djordjevic *et al*., 2000a) than determined by the 'intense' Massachusetts method or by the FTC method.

When hand-rolled Thai cigarettes made with local-brand tobacco were machine-smoked at a rate of two puffs per minute, an average of 5.8 mg nicotine per cigarette was measured in the mainstream smoke by the FTC method (Mitacek *et al*., 1990). Indian cigarettes delivered up to 34 mg total particulate matter and up to 2.6 mg nicotine per cigarette when machine-smoked under the same conditions (Pakhale & Maru, 1998).

The delivered doses of some gaseous carcinogens could be higher than those shown in Table 1.10 if smokers completely blocked the filter air vents during puffing. Brunnemann *et al*. (1990) found that the levels of 1,3-butadiene, acrolein, isoprene, benzene and toluene were 3.3–8.8 times higher than the levels obtained by not blocking the ventilation holes. Stanfill and Ashley (2000) also reported that complete blocking of

ventilation holes in a cigarette's filter increased the percentage transfer of flavour-related alkenylbenzenes (eugenol, isoeugenol, methyleugenol, myristicin and elemicin) from tobacco to the particulate fraction of mainstream smoke by twofold to sevenfold.

(iv) *Machine-smoking method — Health Canada parameters*

The Tobacco Sales Act (1998) of British Columbia, Canada, mandates a machine-smoking method for cigarette testing that utilizes even more intense settings (puff volume, 55 mL; puff interval, 30 sec; puff duration, 2 sec; and 100% of the ventilation holes must be blocked during smoking). (For the reporting years 1998 and 1999, puff volume was 56 mL, puff interval 26 sec and the other parameters were the same as those currently in use).

The British Columbia Ministry of Health web site provides information on both in mainstream and sidestream smoke deliveries of 44 constituents in commercial leading Canadian cigarettes (the top 22 brands in British Columbia account for 70–80% of the market) under both standard (FTC/ISO methods) and modified, more intense smoking conditions, known as Health Canada smoking parameters (http://www.healthplanning.gov.bc.ca/ttdr/index.html). In 1999, 'regular', 'light', 'extra light' and 'ultra light' varieties of a leading Canadian cigarette brand sold in British Columbia were reported to deliver into mainstream smoke an average of 0.8–1.1 mg nicotine as measured by ISO smoking parameters and 2.5–2.9 mg nicotine per cigarette when measured by Health Canada

[b] Modified ISO test conditions: puff volume, 56 mL; puff interval, 26 sec; puff duration, 2 sec; ventilation holes full blocked

smoking parameters. The tar deliveries into mainstream smoke were 5.7–13.4 mg per cigarette under ISO, and 28.2–36.1 mg per cigarette, under the Health Canada smoking conditions (Table 1.13).

The yields of six IARC Group 1 carcinogens (benzene, cadmium, 2-aminonaphthalene, nickel, chromium and 4-aminobiphenyl) in the mainstream smoke from the above-mentioned Canadian cigarettes were an average of 2–4 times higher when measured by Health Canada than when measured by ISO smoking parameters. For example, using the ISO parameters, the mean yields of benzene were 27–56 µg/cigarette and using Health Canada parameters, 82–121 µg/cigarette. Similar 2–4-fold differences were seen in mainstream smoke

yields of 11 IARC Group 2 carcinogens (formaldehyde, 1,3-butadiene, benzo[*a*]pyrene, acetaldehyde, isoprene, catechol, acrylonitrile, styrene, NNN, NNK and lead) between the results obtained using the ISO and Health Canada methods. Whereas the yields of most of the 17 IARC carcinogens measured in mainstream smoke are significantly lower in the 'ultra light' cigarette than in the 'regular' cigarette, there was practically no difference in yields for most IARC carcinogens between the 'ultra light' cigarette and the 'regular' cigarette when measured by the Health Canada method. For example, in the 'regular' and 'ultra light' cigarettes, benzene yields were 56 and 27 µg/cigarette using ISO parameters compared with 82 and 92 µg/cigarette using the Health Canada parameters (Table 1.13).

(*b*) *The emissions of nicotine and carcinogens in mainstream smoke: international comparison*

Regardless of the designation of the cigarettes as low-yield and high-yield, the presence of a large pool of nicotine in tobacco enables the smoker, driven by a physiological need, to titrate his or her own dose by engaging in compensatory (more intense) smoking behaviours (i.e. more and longer puffs) (Henningfield *et al.*, 1994; Kozlowski *et al.*, 1998; Djordjevic *et al.*, 2000a). As a consequence, the more intense smoking will not only drive up the nicotine yield in smoke, but carcinogen yields as well. Therefore, both the qualitative and quantitative composition of a cigarette blend need to be considered when evaluating the addictive and carcinogenic potential of a specific product.

Table 1.14 lists the tobacco smoke carcinogens that have been evaluated previously in the *IARC Monographs* series and for which there is at least sufficient evidence of carcinogenicity in laboratory animals. Among these, there are 11 human carcinogens. The compounds listed here are those primarily responsible for the cancer-causing effects of tobacco smoke. There are also other compounds in tobacco smoke that may be carcinogenic, but have not been evaluated by IARC. Tobacco smoke also contains tumour promoters (phenolics), co-carcinogens (catechol and related compounds), toxic agents (acrolein and other aldehydes) and free radical species (nitric oxide and others). Most of the compounds listed in Table 1.14 are thought to exert their carcinogenic effects through classical genotoxic mechanisms, e.g. the formation and persistence of DNA adducts with consequent miscoding. Non-genotoxic (epigenetic) mechanisms such as cytotoxicity through means other than DNA damage, changes in gene expression via hypermethylation and genomic instability are other mechanisms of carcinogenesis that could operate after exposure to compounds in tobacco smoke.

Data on the carcinogenicity of the specific compounds in animals and humans in Table 1.14 are not discussed in this monograph, which focuses on the effects of tobacco smoke as a mixture. All the data on the carcinogenicity of these compounds are given in the appropriate *IARC Monographs*. The carcinogenic properties of some of these compounds are described briefly below.

PAHs are a diverse group of carcinogens formed during the incomplete combustion of organic material such as tobacco. They are found in tobacco smoke, broiled foods and polluted environments. Workers in iron and steel foundries and aluminium production plants are exposed to PAHs and these exposures are thought to be the cause of excess cancers in these settings (IARC, 1983a, 1984). Benzo[*a*]pyrene is the best known member of this class of compounds. PAHs are potent locally acting carcinogens in laboratory animals. They induce tumours of the upper respiratory tract and lung when administered by inhalation, instillation in the trachea or implantation in the lung (IARC, 1973, 1983a).

N-Nitrosamines are a large group of carcinogens that induce tumours in a wide variety of animal species and tissues. There is no reason to assume that humans might be resistant to the effects of these carcinogens. They are present in small amounts in foods and can be formed endogenously, but tobacco products are the most widespread and largest source of

Table 1.14. Carcinogens in cigarette smoke

Agent	Amount in mainstream cigarette smoke	*IARC Monographs* evaluation of carcinogenicity			Monograph volume, year
		In animals	In humans	IARC Group	
Polynuclear aromatic hydrocarbons					
Benz[*a*]anthracene	20–70 ng	Sufficient		2A	*32*, 1983a; *S7*, 1987

Table 1.14 (contd)

Agent	Amount in mainstream cigarette smoke	*IARC Monographs* evaluation of carcinogenicity			Monograph volume, year
		In animals	In humans	IARC Group	
Lead (inorganic)	34–85 ng	Sufficient	Limited	2A	*23*, 1980; *S7*, 1987; *87*, 2004b
Radio-isotope Polonium-210	0.03–1.0 pCi	Sufficient		1	*78*, 2001

This table (modified from Hoffmann *et al*., 2001) shows components of unfiltered mainstream cigarette smoke, with amounts given per cigarette. Virtually all these compounds are known carcinogens in experimental animals. In combination with data on cancer in humans and – in some cases – other relevant data (see *Preamble*), IARC Monographs classifications for these agents have been established as Group 2B (possibly carcinogenic to humans), Group 2A (probably carcinogenic to humans) or Group 1 (carcinogenic to humans). When IARC evaluations were made more than twice, only the two most recent Monographs are listed, with volume number and year of publication. No entry in the column 'humans' indicates inadequate evidence or no data.

Abbreviations: *S7*, Supplement 7 of the *IARC Monographs*; ND, not detected; A-α-C, 2-amino-9*H*-pyrido[2,3-*b*]indole; MeA-α-C, 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole; IQ, 2-amino-3-methylimidazo-[4,5-*b*]quinoline; Trp-P-1,3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole; Trp-P-2, 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole; Glu-P-1,2-amino-6-methyl[1,2-*a*:3′,2″-*d*]imidazole; Glu-P-2,2-aminodipyrido[1,2-*a*:3′,2″-*d*]imidazole; PhIP, 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine; pCi, picoCurie.

exposure to these carcinogens. Tobacco smoke contains volatile *N*-nitrosamines such as NDMA and NPYR as well as TSNAs such as NNN and NNK. TSNAs are chemically related to nicotine and other tobacco alkaloids and are therefore found only in tobacco products or related materials. Many *N*-nitrosamines are powerful carcinogens in laboratory animals, displaying striking organospecificity. For example, NNN causes tumours of the oesophagus and nasal cavity in rats, whereas the principal target of NNK in rodents is the lung. NNK is the only tobacco smoke carcinogen that induces lung tumours systemically in all three commonly used rodent models (i.e. rat, mouse and hamster) (IARC, 1978; Hecht, 1998).

Aromatic amines were first identified as carcinogens as a result of the exposure of workers in the dye industry. Of these, 4-aminobiphenyl and 2-naphthylamine are well-established human bladder carcinogens (IARC, 1972, 1974). Aromatic amines cause tumours at a variety of sites in laboratory animals. Some members of this class such as *ortho*-toluidine are only weakly carcinogenic. Heterocyclic aromatic amines are protein pyrolysate products found in broiled foods as well as in tobacco smoke. They are mode-

rately carcinogenic in various tissues including breast and colon (IARC, 1983b, 1986b, 1987, 1993b).

Formaldehyde and acetaldehyde induce respiratory tract tumours in rodents when administered by inhalation (IARC, 1987, 1995, 1999). They are weaker carcinogens than PAHs, *N*-nitrosamines and aromatic amines, but their concentrations in tobacco smoke are thousands of times higher. Butadiene and benzene are volatile hydrocarbons that also occur in considerable quantities in tobacco smoke. Butadiene is a multi-organ carcinogen, with particular potency in mice, whereas benzene causes leukaemia in humans (IARC, 1982, 1987, 1999). Metals such as nickel, chromium and cadmium are human carcinogens that are also present in tobacco smoke (IARC, 1987, 1990, 1993a).

Of the carcinogens discussed here, only NNK and NNN are specific to tobacco products. This is important when considering biomarkers of human carcinogen uptake. Carcinogen uptake in humans exposed to tobacco smoke can thus be specifically monitored by measurement of NNK metabolites (Hecht, 2003).

The total yields of carcinogens per cigarette are often several times higher than their yields in mainstream smoke. For example, total yields (mainstream smoke + sidestream smoke) of four popular Canadian cigarette brands including 'regular', 'light', 'extra light' and 'ultra light' cigarettes measured in nanograms per cigarette were: benzene, 278 000–548 000; cadmium, 115–592; arsenic, below detection level; nickel, 38–631; chromium, 64–78; 2-naphthylamine, 155–193; and 4-aminobiphenyl, 21–24 (Government of British Columbia, 2002).

The data presented in Table 1.15 on the composition of mainstream smoke generated by machine-smoking according to the FTC standard of cigarettes sold globally point to a wide range of emissions of nicotine, 'tar' and TSNA. The highest concentrations of TSNA were measured in unfiltered cigarettes sold in France and Italy (up to 1353 ng NNN and up to 1749 ng NNK per cigarette). The same brands contained the highest amounts of preformed TSNA (Fischer *et al*., 1990c). The lowest emissions were measured in blended cigarettes sold in Canada, Japan, the Netherlands, Sweden and the United Kingdom, with upper values of 66–103 ng NNK. Surprisingly, the NNN and NNK levels in the mainstream smoke of two cigarette brands from India were very low given the extremely high levels of preformed TSNA in the tobacco (Nair *et al*., 1989). The concentrations of benzo[*a*]pyrene in mainstream smoke ranged from 2.2 ng/cigarette to 28.4 ng/cigarette, except in Indian brands, in which the concentrations were 85–114 ng/cigarette (Table 1.15).

The comparative assessment of the composition of mainstream smoke of three popular brands of filter-tipped cigarette from the USA purchased on the open market in 29 countries worldwide showed little remarkable variation in the amounts of tar and nicotine, but substantial differences in the yields of NNN and NNK within each brand (Table 1.16). While the maximal variation in 'tar' levels in mainstream smoke ranged from 1.5- to twofold, the yields of NNK varied from three- to ninefold. NNK and NNN yields were highly correlated ($r = 0.88$; Gray *et al*., 2000).

To determine what governs the nitric oxide yields of cigarettes, 17 British, 14 American, eight French and one Turkish brand with a mean tar yield of 14.4 mg/cigarette in

mainstream smoke were analysed under standard machine-smoking conditions (Borland & Higenbottam, 1987). The country of origin appeared to be the major factor affecting NO yield. The mean values for American and French brands exceeded those for British brands by three- to fivefold. The NO yields in the mainstream smoke of British cigarettes ranged from 10 to 222 μg/cigarette, those in American cigarettes from 230 to 384 μg and those in French cigarettes from 320 to 409 μg/cigarette. These international differences in NO yields reflect differences in the nitrate content of tobaccos traditionally used in the manufacture of cigarettes in those countries. In 1996, the yields of tar and NO in the mainstream smoke of 33 cigarette brands from the British market were determined to ascertain if the formulations that reduced FTC tar yields when compared with those measured in the 1980s had an effect on NO yields. The mean tar yield was 10.8 mg/cigarette and the mean NO yield 141.4 μg/cigarette (range, 22–279 μg/cigarette). For the 11 cigarette brands for which samples manufactured in the 1980s were available for comparison, the median NO yields in 1996 were higher: 145 versus 110 μg/cigarette, with corresponding ranges of 70–279 and 40–450 μg/cigarette (Laboratory of the Government Chemist, 1998).

The yields of volatile *N*-nitrosamines in mainstream smoke are one or two orders of magnitude lower than those of TSNA. In Germany and the USA, NDMA yields ranged from 4.1 ng to 15.2 ng/cigarette in filter-tipped cigarettes and from 9.4 ng to 76 ng in untipped cigarettes. NPYR levels ranged from 3.9 to 32.7 and from 6.9 to 64.5 ng/cigarette for filter-tipped and untipped cigarettes, respectively (Adams *et al*., 1987; Tricker *et al*., 1991; Brunnemann *et al*., 1994). In Thai cigarettes, NDMA yields ranged from 8.5 to 31.9 ng/cigarette and NPYR from 8.8 to 49.6 ng/cigarette (Mitacek *et al.*, 1999).

The concentrations of benzene and associated volatile compounds were determined in the mainstream smoke of 26 cigarette brands on the British market by the ISO smoking parameters. The average benzene yield was 40 μg/cigarette (range from 3.2 to 61.7 μg per cigarette) in British brands, in comparison with an average yield of 55 μg/cigarette in the USA (Darrall *et al*., 1998).

In the six major brands of Thai filter-tipped and untipped cigarettes with tar yields of 4.98–34.8 mg, the levels of benzene were 25.5–40 μg/cigarette and the levels of 1,3-buta-

diene were 44.6–78.7 μg/cigarette. The amount of acrolein ranged from 79.9 to 181 μg/cigarette and that of isoprene from 313 to 694 μg/cigarette. The yields of these substances showed no correlation with tar deliveries in mainstream smoke (Mitacek *et al*., 2002).

Smoking fewer cigarettes may erroneously be expected to reduce exposure to toxins even if the smoker smokes more intensely to compensate for the reduced number of cigarettes. In a controlled experiment in which the average number of cigarettes smoked was reduced from an average of 37 to 5 cigarettes per day, the resulting urinary mutagenic activity per cigarette increased roughly threefold and daily exposure to nicotine and CO declined by only 60 and 50%, respectively (Benowitz *et al*., 1986). The reduction of the number of cigarettes smoked from 40 per day to 20 per day was not followed by a consistent reduction in the concentration of biomarkers of exposure to tobacco carcinogens (Hurt *et al*., 2000).

(*c*) *Other constituents of cigarette smoke*

Polychlorodibenzodioxins (PCDDs) and polychlorodibenzofurans (PCDFs) have been quantified in the 10 best-selling brands of German cigarettes. None of the cigarettes were found to contain 2,3,7,8-tetrachlorodibenzodioxin (TCDD). The total delivery of tetra-octachlorodibenzodioxins in mainstream smoke expressed as TCDD equivalents ranged from 0.05 to 0.17 pg/cigarette. The total PCDD deliveries were 4.4–10.3 pg/cigarette, and PCDF deliveries were 1.4–5.2 pg/cigarette (Ball *et al.*, 1990). 2,3,7,8-TCDD concentrations were also below the limit of detection (0.5 pg/g) in cigarettes and cigarette smoke analysed in Japan, but the toxic equivalent value for total PCDDs in smoke was 1.81 ng/m^3. Daily intake of PCDDs by smoking 20 cigarettes was estimated to be approximately 4.3 pg/kg bw per day (Muto & Takizawa, 1989).

The levels of organochlorinated pesticides were assessed in cigarettes from Japan, the USA and the former USSR. The major organochlorinated pesticides identified in tobacco and in the mainstream smoke of commercial cigarette brands in the USA that were manufactured between 1961 and 1979 were: *p*,*p*′-isomers of DDD (1540–20 220 ng/g tobacco), DDT (720–13 390 ng/g tobacco) and DDE (58–730 ng/tobacco). Since 1970, the concentrations of individual organochlorinated pesticides in tobacco have gradually decreased by over 98%. The transfer rates from tobacco into mainstream smoke were 22% for DDD, 19% for DDT and 27% for DDE. In 1995, the concentrations of organochlorinated pesticides in tobacco from the USA were below the maximum permissible limits set by the US Environmental Protection Agency. Until 1970, the organochlorinated pesticides in tobacco and mainstream tobacco smoke contributed significantly to the bioaccumulation of these pesticides in smokers. Currently, tobacco and mainstream cigarette smoke are minor sources of human exposure to organochlorinated pesticides (Djordjevic *et al.*, 1995).

During the smoking of cigarettes with charcoal filters, toxin-coated charcoal granules and other components of the filter are released in the mainstream smoke and inhaled or ingested by the smoker. An average of 3.3 charcoal granules per cigarette were observed on the filter tips of 80% of the 400 cigarettes examined. An increased health risk may

result from the inhalation of tar-coated particles (cellulose acetate fibres, paper and tobacco fibres, glass fibres and charcoal granules) released from the filter (Pauly *et al*., 1995, 1997, 1998).

The free radical and hydrophobicity-related toxicity of 203 of the 253 different substituted phenols present in cigarette smoke was considered. Of these, 162 that have electron-releasing groups may form potentially toxic phenoxyl-free radicals. In contrast, 41 substituted phenols with electron-withdrawing groups do not form phenoxyl-free radicals, but exert their toxic action primarily through lipophilicity. According to quantitative studies of the structure–activity relationship and evaluations of in-vitro cytotoxicity, the most toxic phenols in mainstream smoke included in descending order of toxicity: 2-(dimethylamino)-phenol, 2-ethyl-6-methyl-1,4-benzenediol, 2-methoxy-1,4-benzenediol and 4-ethyl-2-methoxy-6-methylphenol (Smith *et al.*, 2002).

1.2.3 *Roll-your-own cigarettes*

In a study by Darrall and Figgins (1998), 57% of cigarettes rolled by smokers for their own consumption produced higher levels of tar than the 15 mg/cigarette that was the maximum allowed for manufactured cigarettes in the United Kingdom until 1998. Seventy-seven per cent of smokers of roll-your-own (RYO) cigarettes made cigarettes with smoke nicotine yields greater than 1.1 mg/cigarette. Dutch consumers make RYO cigarettes that deliver, on average, 13.2 mg tar and 1.2 mg nicotine per cigarette (Dymond, 1996). These findings are comparable with the smoke yields for 31 brands of RYO tobaccos tested in Canada (15.5 mg tar and 1.1 mg nicotine per cigarette; Kaiserman & Rickert, 1992b). In another study, the same authors (1992a) reported even higher levels of tar and nicotine (19.4 mg and 1.6 mg per cigarette, respectively). Similar smoke yields were reported by Rickert *et al*. (1985) for fine-cut tobacco (21 mg tar and 1.3 mg nicotine per cigarette). Five of six brands handmade from fine-cut tobacco delivered significantly more tar, nicotine and CO both per cigarette and per litre of smoke than did the identically named manufactured brand. According to Kaiserman and Rickert (1992b), in addition to tobacco, it is the combination of the tube and filter that determines the delivery of toxic constituents to smokers. The mainstream smoke of three brands of hand-rolled cigarettes from Thailand was reported to yield 28.5–40.8 mg tar and 1.1–5.5 mg nicotine per cigarette (Mitacek *et al*., 1991).

The amount of benzo[*a*]pyrene in RYO cigarettes was reported to be 22.9–25.93 ng/cigarette in the particulate matter of the mainstream smoke of Canadian cigarettes (Kaiserman & Rickert, 1992a) and 48 ng/g tobacco for RYO cigarettes in the USA (Appel *et al*., 1990). Benzene and associated volatile components (toluene, ethylbenzene, xylene, styrene, isoprene and acrylonitrile) were measured in the vapour phase of the mainstream smoke of commercial and RYO cigarettes in the United Kingdom. The mean quantities of the above-mentioned compounds in the mainstream smoke of RYO cigarettes that had been made using 0.5 g of tobacco per cigarette were of the same order of magnitude or up to 2.6 times higher than the mean values reported for 26 commercial brands of

cigarette sold in the United Kingdom (Darrall *et al*., 1998). Based on a representative sample of 110 cigarette brands available on the United Kingdom market in 1999, the average weight of tobacco in a single cigarette was reported to be 0.76 g (Laboratory of the Government Chemist, 2001). The highest concentrations of benzene (an average of 68 μg/g tobacco) in the mainstream smoke of RYO cigarettes were reported by Appel *et al*. (1990). Appel *et al*. (1990) also tried to measure the lead content in the mainstream smoke of RYO cigarettes, but the concentrations were below the limit of reliable quantitation. No data are presently available on the levels of other carcinogens in the smoke of RYO cigarettes or on smoking topography and the true deliveries of smoke constituents as the result of specific smoking behaviours.

1.2.4 *De-nicotinized cigarettes*

Tobacco-based de-nicotinized cigarettes have been used in smoking research to distinguish the effects of smoking related to the delivery of nicotine or other components of tobacco smoke, from those related to the sensory process of smoking (Robinson *et al.*, 1992, 2000). For research purposes, four types of cigarettes were developed with FTC mainstream smoke yields ranging from 10 to 17.3 mg tar and from 0.07 mg to 1.0 mg nicotine per cigarette (Pickworth *et al*., 1999). The commercial de-nicotinized brand that was briefly test-marketed in the 1990s had similar mainstream smoke nicotine and tar yields as measured by the FTC criteria (0.04 and 10.2 mg, respectively) and detectable quantities of nicotine in tobacco (0.4 mg/g). However, despite being de-nicotinized, the commercial brand still contained amounts of preformed carcinogenic NNK in the tobacco comparable to five other commercial cigarettes (650 ng/g versus 500–890 ng/g tobacco; Djordjevic *et al*., 1990). This observation is very significant because it indicates that manipulation of tobacco composition, such as removing a single compound or group of compounds from tobacco, would not necessarily result in a reduction in the overall toxicity of the product.

1.2.5 *Cigars*

Concentrations of benzene, benzo[*a*]pyrene and lead were measured in the mainstream smoke of six brands of cigar following the Tobacco Research Council (TRC) recommended machine-smoking parameters (puff duration, 2 sec; puff volume, 35 mL; butt length, 25 mm), with the puff frequency altered to two per minute. The mean yields per gram of tobacco burned were 156 μg (range, 92–246 μg) for benzene and 42 ng (range, 35–49 ng) for benzo[*a*]pyrene. The quantities of lead were below the limit of reliable quantification (0.2 μg/cigar) (Appel *et al.*, 1990).

In 1997 in the USA, the leading brands of little, large and premium cigars (ranging in length from 7.3 to 17.6 cm and in weight from 1.24 to 8.1 g) were analysed and the levels of nicotine and selected carcinogens (e.g. benzo[*a*]pyrene, NNN and NNK) measured in the mainstream smoke (Table 1.17; Djordjevic *et al*., 1997). The results were obtained by

Table 1.17. Smoke yields of leading cigarette brands and little, large and premium cigars in the USA

	Medium-yield cigarettes (0.9–1.2 mg FTC nicotine)[a,b]	Cigars[c,d]		
		Little[e]	Large	Premium
Nicotine (mg/unit)	1.11	1.5	1.4	3.4
Tar (mg/unit)	15.4	24	37	44
Carbon monoxide (mg/unit)	14.6	38	98	133
Benzo[*a*]pyrene (ng/unit)	14.0	26.2	96	97.4
NNK (ng/unit)	146.2	290	805	2490

[a] From Djordjevic *et al*. (2000a)
[b] The cigarettes were smoked under FTC conditions: 1 puff/min, 35-mL volume, 2-sec puff duration, butt length; length of filter overwrap plus 3 mm (Pillsbury *et al*., 1969).
[c] From Djordjevic *et al*. (1997)
[d] The cigars were smoked under the ICCSS (International Committee for Cigar Smoke Study, 1974) conditions: 1 puff/40 sec, 20-mL volume, 1.5-sec puff duration, butt length 33 mm.
[e] Little cigars had filter tips
FTC, Federal Trade Commission; NNK, 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone

machine-smoking the cigars under standard smoking conditions as defined by the International Committee for Cigar Smoke Study (ICCSS 1974; i.e. 20-mL puffs of 1.5 sec duration drawn once every 40 sec to the predetermined butt length of 33 mm). The delivered dosages of nicotine, tar and CO were higher in premium cigars than in cigarettes. The levels of nicotine, benzo[*a*]pyrene and NNK were higher by three, seven and 17 times, respectively, in the mainstream smoke of premium cigars. The NNN levels were reported to be 22.4 times higher in cigar smoke (Rickert & Kaiserman, 1999). Another study compared mainstream smoke yields of tar, nicotine, CO and PAHs from 30 cigarette brands with those of 10 small cigar brands, using the ISO/FTC machine-smoking parameters. It was expected that the mainstream smoke yields of those cigars that were heavier than cigarettes would be significantly higher than the yields from cigarettes. However the yields from cigarette-size cigars (length, 74–99 mm; weight, 0.65–1.14 g) are also well above the corresponding cigarette yields: mean tar yield, 10.6 mg/cigarette versus 29 mg/cigar and mean benzo[*a*]pyrene yield, 11 ng/cigarette versus 21 ng/cigar. This is undoubtedly because cigars do not have the physical characteristics that are used to modify yields in cigarettes, such as filter retention, ventilation and paper porosity. It is evident, therefore, that yields of cigars are approximately proportional to the weight of tobacco burnt (Laboratory of the Government Chemist, 2002).

When little filter-tipped cigars were machine-smoked in a way that stimulated the puffing characteristics of smokers (larger puff volume, more frequent puffs), the emissions of total TSNA were twice as high (Djordjevic *et al*., 1997) as those determined using the standard ICCSS method. A similar 2.2-fold difference in the level of all smoke constituents due to more 'intense smoking' was reported by Rickert and Kaiserman (1999).

Under standard ISO conditions, the yields of certain mainstream smoke constituents generated from three brands of cigarette and one brand of cigar were substantially different (ammonia, 12.7 versus 327 μg/unit; nitric oxide, 48 μg versus 1.08 mg/unit; NNN, 41.5 versus 931 ng/unit) (Rickert & Kaiserman, 1999).

To control for variations in the total volumes of smoke delivered from cigarettes and cigars, standardized comparisons in milligrams of toxic substance per litre of smoke were made by Rickert *et al*. (1985). The mean deliveries of tar, nicotine and CO per litre of smoke were highest for small cigars, followed by hand-rolled and manufactured cigarettes. Large cigars had the lowest deliveries.

Henningfield *et al*. (1999) analysed 17 brands of cigar ranging in weight from 0.53 to 21.5 g. There was considerable variation in the total nicotine content of the tobacco, which ranged from 5.9 to 335.2 mg per cigar, as well as in the aqueous pH of the tobacco from the cigars (range, 5.7–7.8). The smoke pH values of the smallest cigars were generally acidic, changed little across the puffs and more closely resembled the profiles previously reported for typical cigarettes. The smoke pH of smaller cigars and cigarillos only became acidic after the first third of the rod had been smoked and remained acidic thereafter. The smoke pH of larger cigars was acidic during the smoking of the first third of the rod and became quite alkaline during the smoking of the last third. This phenomenon needs to be taken into consideration when the bio-availability and addictive potential of cigars is being evaluated.

Using the FTC smoking conditions, but with the puff frequency altered to two per minute, the average benzene and benzo[*a*]pyrene levels in the mainstream smoke of six brands of cigar sold on the US market reported by Appel *et al.* (1990) were 156 μg/g tobacco and 42 ng/g, respectively.

When tested in a similar manner, Thai cigars delivered 7.95–11.4 mg nicotine per cigar, 91–201 mg tar and 111–819 mg CO in mainstream smoke (Mitacek *et al*., 1991). The tobacco from an Indian cigar brand contained 25 000 ng preformed NNN and 8900 ng NNK per g tobacco (Nair *et al*., 1989).

It has been suggested that switching from smoking cigarettes to cigars, or smoking both products intermittently, may increase the exposure of smokers to toxic and carcinogenic compounds. In contrast with 'only cigar smokers' who relatively seldom inhale smoke into the lung, former cigarette smokers and concurrent cigar and cigarette smokers have a tendency to maintain their cigarette smoke inhalation pattern when they smoke cigars (Fant & Henningfield, 1998).

1.2.6 *Pipe tobacco*

Five brands of pipe tobacco were evaluated by machine-smoking in a pre-conditioned wooden pipe (bowl dimensions: 20 mm internal diameter, depth at centre 39 mm, stem length 60 mm from centre of bowl). The pipe required 3–4 g of tobacco for filling as follows: the pipe was filled loosely with tobacco to the top of the bowl, the tobacco was compressed by half, the bowl refilled and the tobacco compressed to fill about three-quarters of the bowl. The amount of tobacco consumed was approximated from the difference in weight of the pipe plus tobacco before and after smoking (Appel *et al*., 1990). The mean yield of benzene in mainstream smoke from smoking the pipe was 344 μg/g tobacco (range, 253–473 μg/g tobacco). (The FTC machine-smoking guidelines for puff duration and puff volume were applied, but puff frequency was increased to 12/min to keep the tobacco burning.)

1.2.7 *Other products*

Bidis: American versions of bidis were shown to have a lower percentage of tobacco by weight than US and Indian untipped commercial cigarettes (42.4% versus 94%, respectively) (Malson *et al.*, 2001).

The concentration of nicotine in the tobacco of bidi cigarettes (21.2 mg/g) is greater than that in the tobacco from commercial filter-tipped (mean: 16 mg/g; Malson *et al*., 2001; mean: 17.6 mg/g; Djordjevic *et al*., 1990; mean: 10.2 mg/g; Kozlowski *et al*., 1998) and untipped American and Indian commercial brands of cigarette (13.5 mg/g; Malson *et al*., 2001).

The levels of preformed NNN and NNK in bidi tobacco range from 6200 to 12 000 ng/g and from 400 to 1400 ng/g tobacco, respectively (Nair *et al*., 1989). When the concentrations of flavour-related compounds — nine alkenylbenzenes, coumarin, piperonal and pulegone — in Indian bidi cigarette tobacco sold in the USA were measured, two alkenylbenzene compounds, *trans*-anethole and eugenol, were found in more than 90% of the 23 brands analysed. Methyleugenol, pulegone and estragole were each detected in 30% or more of the brands, whereas safrole and elemicin were not detected in any of the brands. The flavour-related compounds with the highest concentrations in tobacco were eugenol (12 000 μg/g tobacco) and *trans*-anethole (2200 μg/g tobacco) — that is about 70 000 and 7500 times more, respectively, than the highest levels previously found in US cigarette brands (Stanfill *et al*., 2003).

Ten volunteers smoked longer and took more puffs to consume bidis (354–452 sec, 14 puffs) than to smoke their usual cigarette brand (297 sec, 10 puffs) (Malson *et al.*, 2002). In smokers who switched to Irie bidi (strawberry-flavoured) cigarettes, plasma nicotine levels increased above the levels recorded when they smoked regular filter-tipped cigarettes (26 ng/mL versus 18.5 ng/mL) (Malson *et al*., 2002).

The amount of nicotine in Indian bidi tobacco was higher than that in Indian filter-tipped cigarettes (38 mg/g versus 14 mg/g). The mainstream smoke of Indian bidis delivered less nicotine than Indian cigarettes (1.86 mg versus 2.58 mg/cigarette). The NNN

levels in the mainstream smoke of bidis ranged from 11.6 ng to 250 ng per cigarette and the NNK levels from not detected to 40 ng per cigarette. These concentrations were comparable with those measured in the mainstream smoke of Indian cigarettes (Pakhale & Maru, 1998).

In conclusion, because of their higher content of nicotine than in cigarette tobacco, and their similar or higher nicotine and TSNA deliveries in the mainstream smoke, bidis cannot be considered less harmful to health than regular cigarettes.

Kreteks: Eugenol, a natural compound found in high concentrations in clove buds, is the active ingredient that distinguishes kreteks from conventional cigarettes (Guidotti, 1989). In addition to eugenol, other constituents of clove and clove cigarette smoke include eugenol acetate, β-caryophyllene and α-humulene (LaVoie *et al*., 1986).

Chuttas: The nicotine content of chutta tobacco is comparable with that of bidi tobacco — 35 mg/g versus 38 mg/g. However, the nicotine level in mainstream smoke from chutta is higher (7 mg/product) than that from bidis (1.9 mg/product) (Pakhale & Maru, 1998). The quantities of NNN and NNK in chutta tobacco were reported to be extremely high (from 21 100 ng to 296 000 ng and from 12 600 ng to 210 000 ng/g, respectively). The reverse smoker inhales both the mainstream and sidestream smoke. The NNN and NNK levels in the mainstream smoke of chutta ranged from 289 ng to 1260 ng per chutta and from 150 ng to 2651 ng per chutta, respectively (Nair *et al*., 1989).

1.2.8 *Novel potentially reduced-exposure products*

There are currently two categories of potentially reduced-exposure smoking tobacco products that are being test-marketed worldwide:

- cigarettes made with modified tobacco containing reduced levels of carcinogens such as tobacco-specific nitrosamines (particularly NNK), or using technologies that reduce PAHs (particularly benzo[*a*]pyrene) and genetically modified tobacco containing no nicotine; and
- cigarette-like nicotine delivery devices (e.g. Eclipse™ and Accord™) engineered to reduce exposure to tobacco toxins using advanced technologies (Fisher, 2001; Stratton *et al*., 2001; Womack, 2002).

The cigarette test-marketed as a reduced-nitrosamine product is, according to the FTC ranking, a low-yield American blend cigarette. The chemical composition of the mainstream smoke as assessed by both the FTC and Massachusetts machine-smoking methods does not differ greatly from that of a normal cigarette except that there is a significant reduction in the amount of NNN and NNK in the smoke (Stratton *et al*., 2001).

No epidemiological data are available for these products and they are therefore not considered further in this monograph.

1.3 Use of tobacco

The forms of tobacco use are as diverse as the cultures and countries in which it is used and the people who use it. It is therefore difficult to compare different populations, as behaviours vary greatly. Although differences in smoking behaviour between one person and another within countries abound, there is some uniformity within national practices, e.g. almost all Japanese smokers use cigarettes. Figures for total consumption provide only a rough, albeit useful, measure of global dose and trends need to be observed over a reasonable period of time before acceptance of their significance (Table 1.18).

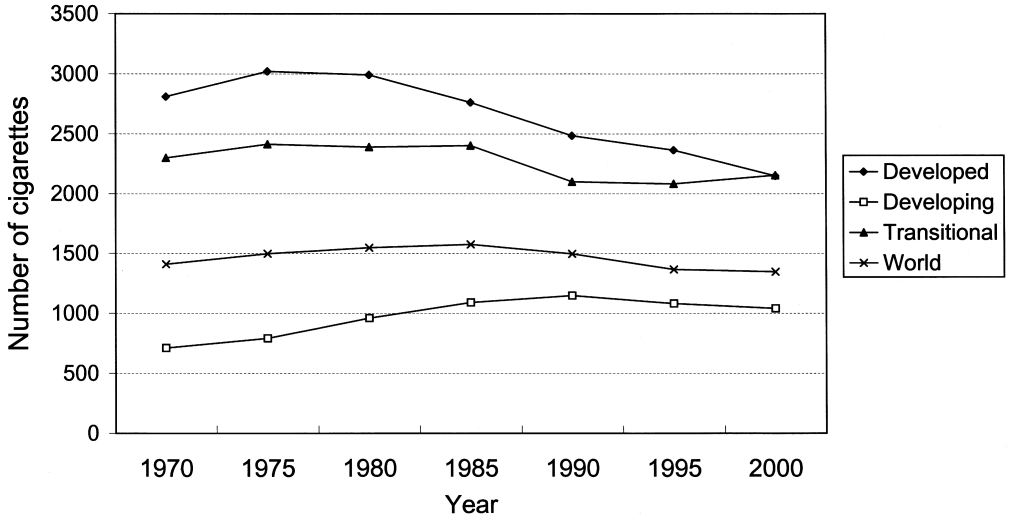
With regard to dose, using cigarettes as an example, the indices bearing on it are:

— numbers of cigarettes smoked;
— amount of carcinogen delivered per cigarette (discussed in detail in Section 1.2);
— duration of the behaviour and inhalation practice.

The components of dose are different and less measurable for other practices such as tobacco chewing and pipe smoking.

At present, exposure to tobacco components in most countries is almost entirely through smoke. The products used are mainly cigarettes, although pipes and cigars accounted for proportionally more of the exposure in earlier population cohorts. Several measures bear on the ways in which some populations are exposed to tobacco. These include estimates of national tobacco consumption and surveys of smoking behaviours (which are not always available in developing countries). This section mainly describes global patterns in adult cigarette smoking. Per-capita cigarette consumption appears to have risen in developing countries from 1970 to 2000 (Figure 1.1). The effects of tobacco on health are directly related to the dose consumed and the duration of use. In this context the trends in production and consumption might be expected to give an approximate indication of the trends in risk likely to be seen in the future.

Information on trends in per-capita consumption for most countries is collected by the World Health Organization and, in a general way, reflects actual consumption patterns, with the caveat that they are subject to many of the same economic factors that affect production estimates. The available world data on total cigarette consumption are shown in Table 1.18 (Mackay & Eriksen, 2002).



Selected comparative data from Australia, China, Japan, the United Kingdom and the USA (Corrao *et al*., 2000) offer a picture of the trend in cigarette consumption in those countries (Figure 1.2). The data from Australia show a persistent decline since 1980, those

Table 1.18. Global consumption of cigarettes (in thousand millions)

Year	1950	1960	1070	1980	1990	2000
Cigarettes consumed	1686	2150	3112	4388	5419	5500

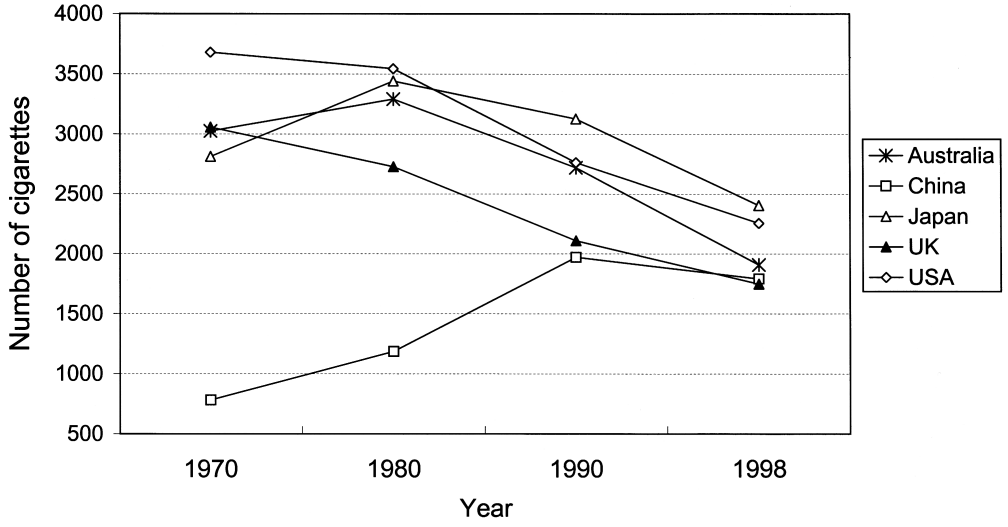

Figure 1.1. Trends in per-capita cigarette consumption by level of development of countries[a]

From Guindon & Boisclair (2003)

[a] Australia, Canada, Japan, New Zealand, USA and western Europe are considered 'developed countries'. Countries in transition from centrally planned to marked economies are labelled 'transitional'. All other countries fall into the 'developing category'.

Figure 1.2. Trends in per-capita cigarette consumption in selected countries

From Corrao *et al.* (2000)

from Japan show a less steep decline also since 1980 and in China, there has been a substantial increase up to the 1990s from a low base in the 1970s.

(*a*) *Surveys of smoking behaviour*

The only means by which it can be ascertained who is smoking, what is smoked, how much, for how long and (sometimes) in what way is through surveys. Regular surveys provide useful public health information, as they may identify populations at risk and some of the reasons they are at risk. Reliable random-sample surveys (using both telephone and in-person interviews) are carried out routinely in most developed countries and, if similar definitions are used, allow useful international comparisons. Table 1.19 shows smoking prevalence rates among adults in the WHO Regions. Since the methods used to collect information vary across these studies, small differences should be interpreted with caution. Nonetheless, smoking rates vary widely across regions. There is about a 1.5-fold difference in total smoking rates between the African or Eastern Mediterranean Regions and the Western Pacific Region. Similarly, smoking rates for women in the Western Pacific Region (5.8%) are much lower than in the European Region (23.4%). A nearly twofold difference in smoking rates is seen in men across the WHO Regions, with the lowest levels in the Eastern Mediterranean Region (34.2%) and the

Table 1.19. Prevalence of tobacco use and number of smokers by WHO Region and level of development in 2000

	Prevalence (% of the population ≥ 15 years of age)			No. of tobacco users (≥ 15 years) (millions)		
	Men	Women	Total	Men	Women	Total

World	57.4	10.3	28.9	1005.927	217.755	1223.682

From Guindon & Boisclair (2003)

highest in the Western Pacific Region (62.3%). Based on these weighted prevalence estimates, there are estimated to be over 1.2 billion smokers across the six WHO Regions.

Table 1.20 illustrates the variation in smoking prevalence rates by country (Corrao *et al.*, 2000). Even with the limitations in these data, some striking differences are evident. Women in China, Egypt, India, Republic of Korea, Singapore, Thailand and the United Arab Emirates smoke infrequently, whereas up to one-third of women smoke in other countries, such as Brazil, Denmark, Germany, Kenya, Norway and the United Kingdom.

Table 1.20. Smoking prevalence rates for men and women in selected countries[a]

Country	Year	Age group (years)	Men (%)	Women (%)
Argentina	1999	16–64	46.8	34
Australia	1995	≥ 16	27.1	23.2
Brazil	1995	≥ 15	38.2	29.3
Canada	1999	≥ 15	27	23
China	1996	15–69	63	3.8
Denmark	1998	≥ 14	32	30

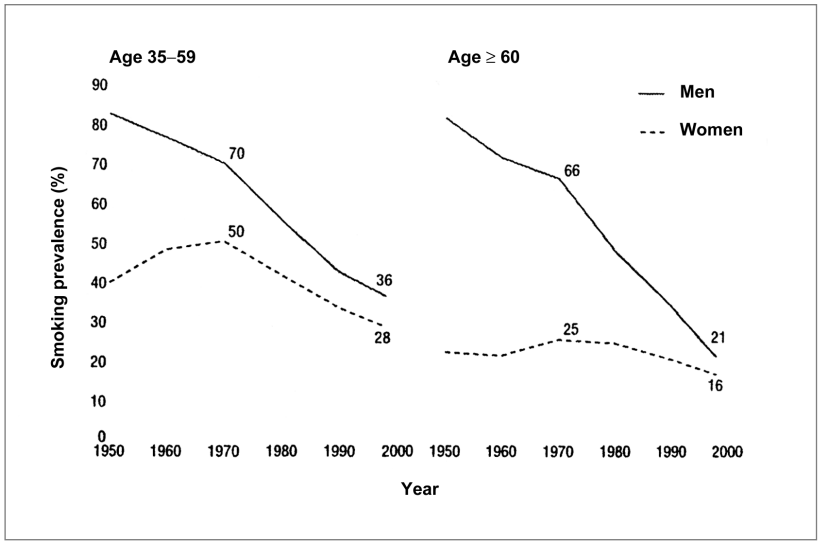
From Corrao *et al*. (2000)



[a] These data are not age-adjusted or weighted.

The highest prevalences of male smokers are found in Japan, Kenya, Republic of Korea and Russia. In general, more men tend to smoke than women, except in Sweden. The differences between the numbers of men and women smokers are also near zero in other countries such as Denmark, Norway and the United Kingdom.

The data in Tables 1.19 and 1.20 represent only a snapshot of current smoking at one point in time. A more comprehensive set of behavioural endpoints (e.g. time trends in current and former smoking rates) is needed to give a robust explanation of the causes of present and future morbidity and mortality attributable to smoking. As an example, Figure 1.3 illustrates current and former smoking rates since 1950 in the United Kingdom (Peto *et al.*, 2000). Between 1948 and 1952, the prevalence of smoking in men aged 25–34 years was 80% and for women of the same age, 53%. In 1998, however, the prevalence was 39% for men and 33% for women.

The prevalence of smoking in adolescents, although of considerable public health importance as an indication of future cancer trends and patterns, is extremely difficult to measure accurately and, consequently, to compare with other countries. It is usual for smoking habits to become established during adolescence, and smoking rates of young people in their late teens may approximate those of adults.

Figure 1.3. Trends in prevalence of smoking at ages 35–59 (left) and ≥ 60 (right) in men and women in the United Kingdom, 1950–98

From Peto *et al.* (2000)

(*b*) *Other indices of dose in developing countries and future surveillance needs*

Although the relationship between tobacco smoke and lung cancer in developed countries may be the most researched subject in epidemiological history, there remains a paucity of precise information concerning smoking behaviours in developing countries.

It is already clear that there is a worldwide trend towards the sale of machine-made cigarettes. On one hand, the manufacture of bidis and the various other home-grown, home-made products cannot be quantified readily because it is based on village cultivation or small industry. These products are generally cheap, vary widely in size and composition from district to district, and may or may not be subject to taxation. Conversely, cigarettes are mass produced or imported, easy to count and are almost invariably taxed before sale. For this reason, increases in sales can be measured, and taxation figures can be used to monitor sales trends. What cannot be seen is the effect of the market expansion of manufactured cigarettes on the use of other tobacco products. In addition, cigarette smuggling is a significant problem in several regions, e.g. southern Europe, North America and South America (Pagano *et al*., 1996; Galbraith & Kaiserman, 1997; Square, 1998; Yurekli & Zhang, 2000; Shafey *et al*., 2002) and a high rate of smuggling will make taxation figures inaccurate. Almost a third of global cigarette exports are estimated to go to the contraband market (Joossens & Raw, 1998).

In some areas (e.g. South-east Asia and India), it is not clear how far the behaviour of cigarette smoking is becoming a substitute for bidi smoking or for chewing, or whether cigarette smoking is becoming an additional behaviour. Mixed tobacco habits are also common. There is no way of estimating precisely the lifetime exposure to smoking products such as bidis or chuttas.

The detailed patterns and trends in national smoking behaviours can be identified only by regular measures of smoking rates operating within surveillance systems. There are considerable limitations to the current measures of prevalence. Data are expensive to collect and are incomplete or non-existent in many regions. In many cases, prevalence rates are underestimated because of the limitations in surveillance systems (e.g. fewer members of the lower income groups who tend to smoke more have telephones). Data on smoking by young people are incomplete and inaccurate for most countries. To address these issues, information is needed on initiation, prevalence and cessation. Routine surveillance data are needed to track smoking behaviours over time. In the future, much better methods for systematic reporting of smoking rates need to be applied worldwide.

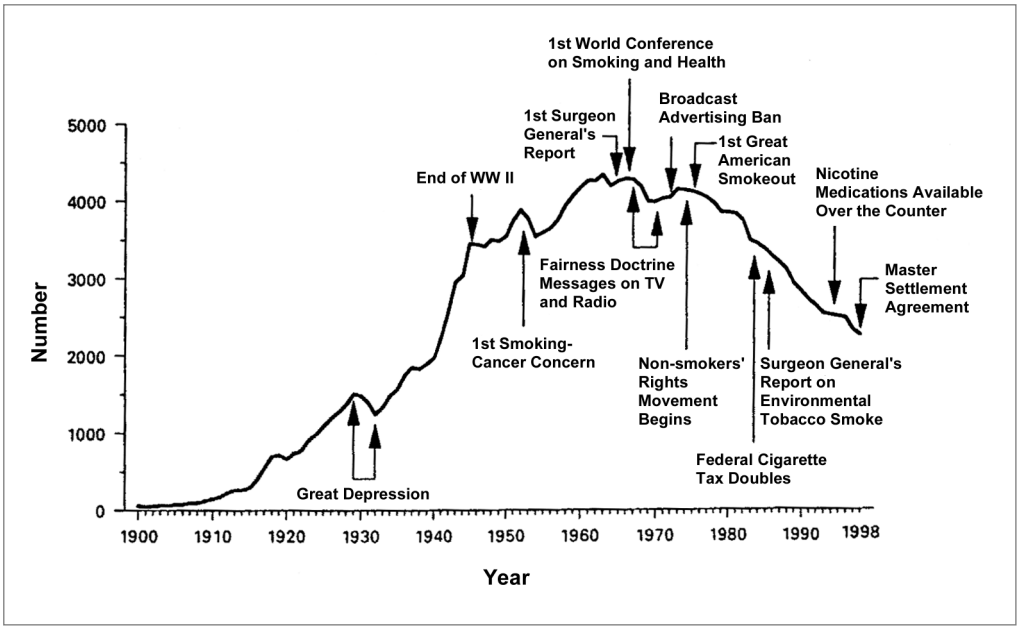
1.4 Regulations

This section reviews the scope and potential impacts of tobacco control regulations. Because the focus of this monograph is on the risks of tobacco smoking, the preventive implications of regulation are covered only briefly with references to the literature for key studies and reviews of regulatory effects and effectiveness. Increasing the cost of ciga-

rettes through taxation and restrictions on smoking in the workplace are two public policy changes for which substantial bodies of information exist to define their effectiveness (Burns, 2000).

In recent years, researchers have increasingly recognized the role of regulation in influencing the use of tobacco. Policy or regulatory measures alter or control the legal, social, economic and physical environment (Brownson *et al*., 1995). Policies are 'those laws, regulations, formal, and informal rules and understandings that are adopted on a collective basis to guide individual and collective behaviour' (Schmid *et al*., 1995). Smokers frequently respond to environmental cues, such as a work break or entering a restaurant, when deciding whether or not to smoke. Regulatory interventions are based on the knowledge that individuals are strongly influenced by the sociopolitical and cultural environment in which they act (US Department of Health and Human Services, 2000).

Roemer (1988) clearly listed a set of purposes for tobacco regulation:



- to set forth governmental policy on the production, promotion and use of tobacco, and to protect the right of nonsmokers to breathe clean air;
- to reduce to some extent the harmful substances in cigarettes;
- to contribute to the development of a social climate in which smoking is unacceptable;
- to provide the basis of allocating resources to support effective programmes to combat smoking; and
- to encourage smokers to stop smoking and to dissuade potential smokers, particularly young persons, from starting to smoke.

The place of legislation in tobacco control was very clearly defined by a World Health Organization Expert Committee in 1983. It stated: 'It may be tempting to try to introduce smoking control programmes without a legislative component, in the hope that relatively inoffensive activity of this nature will placate those concerned with public health, while generating no real opposition from cigarette manufacturers. This approach, however, is not likely to succeed. A genuine broadly defined education programme, aimed at reducing smoking must be complemented by legislation and restrictive measures' (WHO, 1983).

In 2003, the 192 Member States of the World Health Organization unanimously adopted the Global Framework Convention on Tobacco Control (FCTC, 2003), the world's first international tobacco control treaty [added in print after the meeting]. The FCTC was prepared over four years by participants from a wide range of sectors and included representatives of WHO Member States representing 95% of the world's population. The FCTC is intended to provide a comprehensive regulatory structure, which when ratified and enacted as proposed, will lay the legal foundations for the regulation of tobacco and tobacco smoking in a range of situations (e.g. protecting children from tobacco use and exposure, promoting smoke-free environments and promoting healthy tobacco-free lifestyles).

As one example from a developed country, Figure 1.4 shows the correlation between per capita consumption of cigarettes in the USA and historical events since 1900. These events, such as the first US Surgeon General's report, the ban on tobacco advertising in

Figure 1.4. Annual adult per-capita consumption of cigarettes and major smoking and health events, USA, 1900–1998

From US Department of Agriculture; US Department of Health and Human Services (1986)
WWII, Second World War

the broadcast media and increases in the federal cigarette tax were followed by a decrease in tobacco consumption. Similar tracking of regulatory events, such as restrictions on tobacco advertising, may be used by any country wishing to monitor changes in tobacco consumption.

Although most of the regulatory interventions discussed below focus on the passage of a law or ordinance, many others can be implemented through an executive order or regulatory action. An example of an executive order is a ban on tobacco advertising on all city-owned buses. An example of a regulatory action is the adoption of an accrediting standard prohibiting smoking in hospital buildings (Longo *et al*., 1995).

Regulations regarding clean indoor air are described in detail in the monograph on involuntary smoking (Section 1.3). There has been a dramatic increase in the fraction of the working population protected by total bans on smoking in the workplace, which increased from 3% in 1986 to 64% in 1996. The implementation of these restrictions has had two effects on smokers: they have increased the rate at which smokers attempt to quit, and have reduced the number of cigarettes smoked per day (Burns *et al.*, 2000). To estimate the impact of smoking bans on cigarette use, Chapman *et al*. (1999) estimated the contributions of smoke-free workplaces to the recent declines in cigarette consumption noted in Australia and the USA. In Australia, smoke-free workplaces are considered to be

responsible for 22.3% of the 2.7 thousand million decrease in the number of cigarettes smoked between 1988 and 1995. Similarly in the USA, it was estimated that workplace bans are responsible for 12.7% of the 76.5 thousand million decrease in the number of cigarettes smoked between 1988 and 1994.

(*a*) *Price/excise taxes*

A substantial increase in tobacco excise taxes may be the single most effective measure at the national, state and local level for decreasing tobacco consumption (Sweanor *et al.*, 1992; Jha & Chaloupka, 2000). Youths and young adults may be more sensitive to increases in tobacco price than adults (Chaloupka & Warner, 2000). Excise taxes on tobacco products vary widely between the developed countries and in many cases the increases in taxes have been much smaller than the price increases imposed by cigarette manufacturers. The 'earmarking' (allocation of a portion) of tobacco price increases for prevention efforts has proved to be an effective strategy in California, USA (Elder *et al*., 1996; Fichtenberg & Glantz, 2000), Victoria, Australia (Chapman & Wakefield, 2001) and other places.

Numerous studies have quantified the effects of increases in excise tax on smoking rates. A recent systematic review that looked at the median estimates from a number of studies found that a 10% increase in the price of tobacco products resulted in a 3.7% decrease in the number of adolescents and young adults who used tobacco and 4.1% decrease in the amount of tobacco used by the general population (Hopkins *et al*., 2001).

One of the main arguments raised against increases in tobacco tax involves the regressivity of such taxes — that is, a tax where the proportion of an individual's income consumed by the tax is inversely related to income. Health advocates argue that the concern over regressivity is outweighed by the lives saved from unnecessary cancer and heart disease due to the reduced prevalence of smoking (Jacobs, 2001). Smoking and mortality rates from these diseases are disproportionately higher among individuals in lower income groups. Therefore, greater decreases in smoking-related disease and death rates in these groups would be expected to follow a tax increase.

(*b*) *Restricting tobacco advertising and promotion*

Cigarettes are possibly the most heavily advertised and promoted consumer product in the world (Mackay & Eriksen, 2002). In 2000, the six major US tobacco companies spent US$ 9.57 thousand million on cigarette advertising and promotion in the USA — more than US$ 26 million each day (Federal Trade Commission, 2002). The advertising and promotion of tobacco products leads to increased use of tobacco products, particularly by youths (Pierce *et al*., 1991). Advertising and promotion affect cigarette consumption by conveying to children and young adults that smoking has social benefits and that it is far more common than it really is; by creating attitudes and images that reinforce the desirability of smoking, and by suppressing full disclosure by the media of the health hazards of smoking. Numerous institutions involved in cultural events, minority causes and sports are financed by contributions from the tobacco industry. This

situation undermines an institution's ability to enact policies and practices to reduce tobacco use (Kaufman & Nichter, 2001).

Numerous governments have enacted laws banning tobacco advertising by cinemas, posters, press, radio, television and at points of sale. Giving samples and sponsorship are also banned in some countries (European Union, 2000). Governmental entities have banned advertising on public transport, in sports stadiums or on property owned by local government. These actions are based upon the conclusion reached by many localities that national laws do not preempt them from restricting advertising on their own property or within their jurisdiction.

Governments also can support legislative, regulatory and non-legislative policies to reduce tax deductions for tobacco advertising, to restrict tobacco promotions like the Marlboro Adventure Team incentives, to prohibit the exhibition of a cigarette brand name, to restrict product placement and ultimately to eliminate tobacco advertising. Recent evidence has also demonstrated that most of the current warning labels on cigarette packets are neither effective in transferring knowledge regarding the health hazards associated with tobacco use, nor likely to have a positive impact on the health behaviour of people using these products. The experiences in countries such as Canada and Poland where the warning labels and package inserts are larger, more visible and simpler should be examined in detail to determine their effects on public health (Canada ASH; Health Promotion Foundation, 2002). Despite mixed findings on the effectiveness of these warning labels, they are viewed as a cost-effecive anti-smoking measure by their mere presence and are considered to be an important part of larger anti-smoking efforts (Guttman & Peleg, 2003).

(*c*) *Restricting the uptake of tobacco use by young people*

In most countries, adult smokers began their smoking behaviour as young teenagers (National Cancer Institute, 2001). In several developed countries, there has been virtually no decline in smoking rates among all teenagers over the past decade. Because smoking begins at a young age, the most important potential actions for affecting the overall rates of tobacco use should emphasize prevention of tobacco use in youth. As yet, the effects of many of the regulatory actions intended to prevent smoking by young people have not been established by research studies.

For example, in most parts of the world, there are laws prohibiting the sale of cigarettes to persons under 18 years of age. Many researchers and public health practitioners have concluded that the only way to limit minors' access to cigarettes is to ban vending machines, raise tobacco prices and excise taxes and enforce laws governing the access of young people to tobacco. Yet the enforcement of comprehensive laws on the access of minors to tobacco has been the subject of considerable debate and the existing literature on the effectiveness of specific types of enforcement efforts is limited and inconsistent (Forster & Wolfson, 1998; Stead & Lancaster, 2000).

Other approaches that may be used to protect young people from becoming smokers include educational programmes, which in some countries have been made compulsory

by law, and specific prohibitions against smoking in places where young people congregate, such as schools and recreational facilities.

(*d*) *Regulation and litigation*

Litigation efforts include four main categories: individual cases, class actions, public interest lawsuits and health care cost recovery actions. Within the final category, several cases have been brought by several states of the USA to attempt to recover the costs of medical care attributable to cigarette smoking as product liability suits. In general, these actions are based on the fact that taxpayers pay for medical care for smoking-related illnesses through Medicaid and other state-supported systems. The states had no choice as to whether the taxpayers should pay for damages caused by a dangerous product; therefore, the suits claim a need for the recovery of costs on behalf of all state taxpayers. As data on state-specific costs became available, specific damages were calculated that permitted substantial cost recovery from the tobacco companies. As an example, state attorneys general in the USA agreed to a US$ 206 thousand million settlement with the tobacco industry in November 1998, the so-called 'Master Settlement Agreement' (National Association of Attorneys General, 1998). Results to date from this settlement have been less successful than anticipated because much of the funding from the Master Settlement that was originally intended for smoking prevention activities is being diverted to other governmental programmes. Of particular relevance to this monograph, is that one important outcome of the recent tobacco litigation has been the public release of numerous tobacco industry documents (CDC, 2002) (close to 40 million pages) showing what the industry knew about the carcinogenic potential of tobacco and when they knew it.

(*e*) *Regulation of tobacco smoke constituents*

Worldwide, only minimal regulation applies to the constituents of cigarettes and tobacco smoke, as for example in Europe. The maximum tar yield of cigarettes marketed in the European Union was set at 15 mg/cigarette in 1992, 12 mg/cigarette in 1997 (European Commission, 1999) and 10 mg/cigarette in 2001. In addition to tar, the new Directive lays down the maximum permitted nicotine and CO yields for cigarettes released for free circulation, marketed or manufactured in the Member States, i.e. 1 mg/cigarette for nicotine and 10 mg/cigarette for CO. In 2003, it was prohibited to describe one product as less harmful than another (by using names, symbols). Moreover, manufacturers and importers are now required to submit to the Member States, on a yearly basis since 2002, a list of all ingredients used in the manufacture of tobacco products and their quantities, together with toxicological data on their effects on health and any addictive effects. This list must be accompanied by a statement setting out the reasons for the inclusion of the ingredients. It must also be made public and be submitted to the Commission (European Parliament, 2001). For example, currently over 600 additives to tobacco products are permitted in the United Kingdom (Department of Health, 2000).

In the future, it is likely that upper limits for carcinogens and toxins will be set for cigarette smoke as they have already been for car exhausts and other ambient pollutants. This is dependent on the acquisition of appropriate legal powers by regulatory agencies.

2. Studies of Cancer in Humans

The available knowledge on the relationship between tobacco usage and a variety of human cancers is based primarily on epidemiological evidence. An immense amount of such evidence has been obtained, and, of necessity, only a small proportion can be referred to here. The cancers considered to be causally related to tobacco smoking in the previous *IARC Monograph* on tobacco smoking (IARC, 1986) included those of the lung, upper aerodigestive tract (oral cancer and cancer of the oropharynx, hypopharynx, larynx and oesophagus), urinary bladder and renal pelvis and pancreas. Since 1986, there have been numerous additional cohort and case–control studies on the relationship of cigarette smoking and other forms of tobacco use to these and other cancers in many different countries. The most comprehensive evidence, although often not the first or most detailed, has been obtained from several large cohort studies that are referred to repeatedly in this monograph with respect to different cancer sites and types of tobacco product. These cohort studies are described briefly below and in Table 2.1, listed by country. The case–control studies are described in the sections pertaining to particular cancer sites.

Description of cohort studies

(*a*) *Europe*

(i) *United Kingdom*

British Doctors' Study

In 1951, a questionnaire on smoking habits was sent to all British doctors included in the Medical Register; 34 440 men and 6194 women responded, representing 69% and 60%, respectively, of those doctors not known to have died at the time of the inquiry. [The exact number of men and women included in the study varies between publications as a number of women were misclassified as men in early reports.] Further questionnaires about changes in smoking habits were sent in 1957, 1966, 1972, 1978 and 1990 to men and in 1961 and 1973 to women; on each occasion, at least 94% of those alive responded. Reports were published on cause-specific deaths after 10, 20 and 40 years for men and after 10 and 22 years for women; more than 99% of the subjects had been traced. Information on causes of death was obtained principally from the Registrars General of the United Kingdom and, otherwise, from the records of the general Medical Council, the

Bristish Medical Association, relatives or friends. Because the subjects in the study were themselves physicians, they were a reasonably uniform socioeconomic group and the causes of death were certified more accurately than might have been the case among a sample of the general population. For the first 20 years of the study, confirmation of all deaths attributed to lung cancer was obtained from a chest physician who was unaware of the patient's smoking history (Doll & Hill, 1964a,b; Doll & Peto, 1976; Doll *et al*., 1980, 1994).

Whitehall Study

A total of 19 018 men aged 40–69 years from the British Civil Service were clinically examined between 1967 and 1969, and followed up for vital status until 1987 through the National Health Service Central Registry. Information on exposure was collected only at baseline. The study concentrated on residual risk after smoking cessation as well as comparing risk associated with different tobacco products (Ben-Shlomo *et al.*, 1994).

British United Provident Association (BUPA) Study

Wald and Watt (1997) studied a cohort of 21 520 professional and businessmen with a National Health Service identification number who attended a routine health examination between 1975 and 1982 at a British United Provident Association (BUPA) Medical Centre in London. At this examination, a detailed smoking history was obtained, including self-reported level of inhalation (rated as nil, slight, moderate or deep). In addition, a blood sample was collected and carboxyhaemoglobin saturation and cholesterol levels were measured. Causes of death of cohort members were obtained from records of the National Health Service and the Office of Population Censuses and Surveys records. The risks of mortality from three causes (i.e. ischaemic heart disease, lung cancer and chronic obstructive lung disease) were computed using Cox's proportional hazard analysis.

(ii) *Sweden*

Swedish Twin Registry Study

A cohort of 10 945 twin pairs of the same sex, identified using the Swedish Twin registry, was asked to complete a questionnaire in 1961. Zygosity was based on questions of childhood similarity. Mortality in twins was followed up by record linkage with the central registry of causes of death through 1997. The information from death certificates, hospital records and other data was collected for the period up until 1981 and was reviewed without prior knowledge of smoking status; the underlying cause of death was determined according to the ICD 8th revision. For the period after 1981, the underlying cause of death as stated in the death certificate was used (Floderus *et al.*, 1988; Steineck *et al.*, 1988; Grönberg *et al.*, 1996; Terry *et al.*, 1998, 1999, 2001).

Swedish Census Study

A sample of the Swedish population drawn from the 1960 census was stratified by sex, year of birth and residence (urban or rural). The objective was to determine the smoking

habits of the Swedish population by means of postal questionnaires, telephone interviews and home visits. A questionnaire was posted in 1963, and, of 55 074 eligible subjects, 89% responded. Information was collected by telephone or personal interview for another 5.3%. A sub-sample of 20% was sent a second questionnaire in 1969, with the aim of validating the accuracy of the replies and collecting information about changes in smoking patterns. Mortality in the cohort was ascertained through death certificates. In addition, cancer incidence was ascertained through the nationwide Swedish Cancer Registry, which recorded an estimated 95.5% of all cancers. The follow-up period extended from 1964 until 1989. Cancer outcomes were reported after 10 and 26 years for men and women combined (Cederlöf *et al.*, 1975; Nordlund *et al.*, 1999) and after 16 years for men only (Carstensen *et al.*, 1987) and after 26 years for women only (Nordlund *et al.*, 1997). Cox proportional hazards regression models were used to compute odds ratios stratified by age and place of residence.

Swedish Construction Workers' Study

A cohort of male Swedish construction workers was identified in 1971, when workers filled out a questionnaire, the answers to which included a detailed smoking history. The cohort included about 135 000 men recruited between 1971 and 1975 or 350 000 men recruited between 1971 and 1992. Each cohort member contributed person–years of observation from the date of first registration visit until the date of diagnosis, death, migration or end of follow-up (Adami *et al.*, 1996; Nyrén *et al.*, 1996; Adami *et al.*, 1998; Chow *et al.*, 2000). Data on cancer incidence were obtained through linkage with the population-based national cancer registry established in 1958. Each cohort member was identified by his national registration number, a unique personal identifier assigned to all residents in Sweden.

(iii) *Norway*

Norwegian Cohort Study

Heuch *et al.* (1983), Engeland *et al.* (1996a,b) and Kjaerheim *et al.* (1998) reported the cancer incidence of a cohort of 26 000 Norwegians who completed a self-administered questionnaire in 1964–1965. The target population was drawn from three sources: approximately 19 000 persons were randomly drawn from lists of residents of Norway from the 1960 population census, approximately 5200 were drawn from four selected counties, and approximately 13 000 were drawn from a cohort of Norwegians living in Norway who had siblings living in the USA. The final study population comprised 26 126 persons, contributing approximately 540 000 person–years for analysis (230 000 for men and 310 000 for women). At the initial assessment, 17% of the men reported never having been a smoker, whereas 68% of the women had never smoked. Information on cancer incidence was obtained through the population-based Norwegian Cancer Registry, which has been operational through the mandatory reporting of cancer cases by physicians since 1953. All cohort members were followed up from 1966 to the date of the first diagnosis of the cancer being considered, the date of emigration, the date of death, or until 31 December 1993. The

only exception was for cancers of the upper aerodigestive tract, where more than one diagnosis per person was allowed. Questionnaire data were not updated during the follow-up period. Analyses were performed using the Cox proportional hazards regression models.

Norwegian Screening Study

The Norwegian Screening study followed the cancer incidence in a random sample of adults from two cities and three counties in Norway who were screened for coronary heart disease between different time periods (see Table 2.1). Participants were followed until death or emigration up to 1988. The officially coded underlying cause of death was used as the end-point. Mortality rates were adjusted for age and area of residence and analysed with Cox proportional hazards models (Vatten & Kvinnsland, 1990; Tverdal *et al.*, 1993; Thune & Lund, 1994; Veierød *et al.*, 1997).

(iv) *Finland*

Finnish Men's Study

A cohort of 4604 Finnish–Norwegian men was interviewed in 1962 about their smoking habits and cardiorespiratory symptoms. The study subjects were selected from three urban areas in western and central Finland, and three rural areas in western and eastern Finland (Pedersen *et al.*, 1969). One hundred and thirty-two men who died or were diagnosed with lung cancer before 1964, and 20 who had not given details of their smoking habits at the interview, were excluded, leaving an effective cohort size of 4452 men. The follow-up period for analysis covered 1964–80. Lung cancer cases were identified through the population-based cancer registry in Finland, by use of the Finnish personal identification number. The effect of smoking and different respiratory symptoms on lung cancer incidence was assessed by a log-linear modelling technique (Tenkanen *et al.*, 1987; Hakulinen *et al.*, 1997).

Finnish Mobile Clinic Health Examination Study

Between 1966 and 1972, the Finnish Mobile Clinic Health Examination Survey performed multiphasic health examinations in rural, semiurban and industrial municipalities in different parts of Finland. A total of 62 440 white adults aged ≥ 15 years were invited to participate, and the participation rate was 83%. All participants completed a questionnaire that had been sent in advance and checked at baseline examination. Participants were followed up until 1991 (Knekt *et al.*, 1998; Heikkilä *et al.*, 1999).

(v) *Iceland*

Reykjavík Study

Tulinius *et al.* (1997) assembled a cohort of 22 946 adult Icelanders in five stages for a study on risk factors for cardiovascular disease. The first stage took place from 1967 to 1969, the second from 1970 to 1972, the third from 1974 to 1979, the fourth from 1979 to 1984 and the fifth from 1985 to 1991. The initial enrolment interview took place at a clinic visit at which the completion of a comprehensive questionnaire concerning various

risk factors was followed by a series of anthropometric and biochemical measurements. Although interviews were conducted at each stage, this study used only data from each subject's first interview. Overall, 73% of the initial target population was successfully recruited into the study. The cohort was linked with the Icelandic Cancer Registry, a population-based registry of the entire country that was begun in 1954. Linking to the registry was facilitated by the unique identification number assigned to all residents in Iceland. Cox's regression was used to analyse the predictive power of a number of variables on the incidence of first cancer after enrolment into the study.

(vi) *Netherlands*

Dutch Study

A cohort of 26 697 women from the city of Utrecht in the Netherlands answered a questionnaire and provided a 12-h urine sample at the beginning of the follow-up period. Follow-up continued from entry to the study for up to 15 years. The full cohort was drawn from two previously established screening programmes. The first was a population-based screening programme for the early detection of breast cancer in women aged 40–64 years, called the DOM project. This portion of the cohort had 14 697 women who were enrolled from early 1975 until mid-1977, 72% of whom participated. One year later, 81% of this group participated in a follow-up effort in which a second 12-h urine sample was collected. The second breast cancer screening programme (Lutine study) was undertaken in 1982–83 and included more than 12 000 women 40–49 years of age [exact number not stated by the author]. For this second screening programme, 12-h urine samples were taken on days 21–23 of three consecutive menstrual cycles. Participation in the second screening programme was only 44%, probably because of the demanding study protocol. An all-cause-of-death register was established for this study to which all medical practitioners in the city of Utrecht who saw cohort members in their practices reported. In 1987, a regional cancer register was established, making it possible to follow the entire study cohort for cancer incidence. There were three distinct follow-up periods (Ellard *et al.*, 1995; de Waard *et al.*, 1995; van Wayenburg *et al.*, 2000).

(vii) *Denmark*

Copenhagen City Heart Study

In 1976, a prospective epidemiological study was initiated in which participants were selected from 90 000 persons living in a defined area around the University Hospital of Copenhagen. An age-stratified sample of subjects aged 20 years or more was selected at random. Seventy-four per cent of those invited to participate (14 223 subjects) attended. The subjects were followed up until 1989. Notification of deaths and causes of death were obtained from the Central Death Registry of the National Board of Health (Lange *et al.*, 1992).

(*b*) *North America*

(i) *USA*

Framingham Heart Study

The Framingham Heart Study included 5209 subjects who were first examined between 1948 and 1952, and were aged 45–84 years at baseline examination. Participants were routinely examined every two years for 24 or 34 years. At these examinations, information on smoking status and other risk factors was updated. A tumour registry was set up for this cohort (Williams *et al.*, 1981; Freund *et al.*, 1993).

American Cancer Society (nine-state) Study

In 1952, more than 22 000 volunteers for the American Cancer Society each distributed a questionnaire to 10 white men aged 50–69 years whom the volunteer knew well. Smoking histories were collected from 204 547 men in nine states. After exclusion of unsuitable subjects, a cohort of 187 783 men was followed by the volunteers from 1952 through 1955 (average duration, 44 months). A total of 11 870 deaths (6.2%) and 1.1% losses to follow-up were recorded. Death certificates were obtained for all reported deaths and further information was sought from the physician, hospital or tumour registry whenever cancer was mentioned in the certificate (Hammond & Horn, 1958a,b). The distribution of smoking habits in the study population was in close agreement with that reported in a large survey on smoking habits in a sample of the US population (Haenszel *et al*., 1956).

US Veterans' Study

Beginning in January 1954, 293 958 holders of US government Life Insurance policies who had served in the armed forces at any time between 1917 and 1940 were sent a questionnaire on smoking habits; 198 834 (68%) responded and 49 361 additional replies were obtained by a subsequent mailing in 1957 (total response rate, 85%). Policy holders were almost exclusively white men of the middle and upper social classes. Subjects were followed up from 1954 until 1980 during which time there were 192 756 deaths. Whenever a claim was filed for payment of a policy, a copy of the death certificate was sent by the Veterans' Administration to the National Institutes of Health study office. 'Terminated' policies were also checked annually to ascertain if termination was due to death or to other reasons. Additional information on policy holders who had died was requested from a certifying physician or hospital. The 26-year follow-up was considered to be almost complete by Chow *et al.* (1995), with 95% of the death certificates of cohort members who had died having been obtained (Kahn, 1966; Rogot & Murray, 1980; Kinlen & Rogot, 1988; McLaughlin *et al.*, 1989; Hsing *et al*., 1990a; McLaughlin *et al.*, 1990a,b; Hsing *et al*., 1991; Heineman *et al.*, 1992; Zahm *et al.*, 1992; Chow *et al*., 1993; Heineman *et al.*, 1994; Chow *et al.*, 1995; McLaughlin *et al.*, 1995; Chow *et al.*, 1996).

Californian Study

Information on occupational exposures and smoking history was collected from self-administered questionnaires in 1954–57 from 68 153 male labour union members, aged 35–64 years, in California. Subjects were followed up for mortality up to December 1962 (average follow-up time, 7.1 years) through California death records. A total of 4706 deaths occurred in the cohort, 936 of which were from cancer (Weir & Dunn, 1970). [The Working Group noted that the data available on smoking habits were less extensive than those obtained in other studies.]

Cancer Prevention Study I (CPS-I)

Between October 1959 and February 1960, volunteers for the American Cancer Society in 25 states recruited more than one million subjects from among their friends, neighbours and acquaintances. Families were enrolled, with the condition that there be at least one person aged over 45 years in the family. All family members over 30 years of age were requested to fill out a detailed four-page questionnaire. Participants were predominantly white (97%), married (82%) and college-educated. For the 1 051 038 subjects enrolled, vital status was monitored by the volunteers, originally to September 1965 (Thun & Heath, 1997). Each subject was traced annually and every 2 years was requested to fill out a brief follow-up questionnaire. Of the subjects originally enrolled, 1% could not be traced in the follow-up, and 2% of the questionnaires were unusable. Death certificates were obtained from state or local authorities and, when cancer was mentioned, further information was sought from physicians. The underlying cause of death was coded according to the ICD 7th revision. During the first 6 years of follow-up, 76 888 subjects died and 14 029 (1.4%) were lost to follow-up; 483 519 white women and 358 422 white men alive at the end of 1966 were further followed up for mortality until 1972 with a success rate for follow-up of 99%. This is the largest of the early cohort studies on tobacco and mortality (Hammond & Garfinkel, 1961; Hammond, 1966; Garfinkel, 1980; Hammond & Seidman, 1980; Garfinkel, 1985; Stellman & Garfinkel, 1986, 1989a,b; Garfinkel & Boffetta, 1990; Thun *et al.*, 1995; Thun & Heath, 1997; Thun *et al.*, 1997a; Shanks & Burns, 1998).

Harvard Alumni Study

A cohort of undergraduates who had entered the University of Harvard between the years of 1916 and 1950 was identified when they responded to a health questionnaire sent out in 1962 or 1966. Updated information was obtained from 13 905 cohort members from periodic surveys that assessed lifestyle habits and medical history. The questions asked for information on daily amount of cigarette smoking, age at start and cessation of cigarette smoking, weight, height and physical activity. In surveys conducted in 1988 and 1993, participants were asked whether a cancer had been diagnosed by a physician. Deaths that occurred up to 1992 were traced using information from the alumni office to obtain death certificates. The authors claimed that mortality follow-up was virtually complete (Paffenbarger *et al.*, 1977, 1978).

Tecumseh Community Health Study

The Tecumseh Community Health Study involved subjects who participated in one or more rounds of physical examinations offered to 9794 persons from a semi-rural community in 1959–60, 1962–65 and 1967–69. Cigarette smoking history was taken at each examination cycle. A retrospective cohort was created from those participants aged 25 years and older and who were free of cancer (except for non-melanoma skin cancer) at baseline or within 1 year of entering the study. These criteria resulted in a fixed cohort of 3956 subjects, for whom complete follow-up data were available. In 1986–87, a comprehensive cancer incidence survey was conducted by means of a questionnaire sent to the participants or their next-of-kin. An estimated completeness of 95% was achieved. The reported cancer cases were verified, with the permission of the participant, by requesting abstracts of hospital records. A Cox proportional hazards model was used to examine lung cancer incidence in relation to smoking habits (Islam & Schottenfeld, 1994).

Kaiser Permanente Medical Care Program Study

The first cohort included approximately 175 000 subjects aged 15–94 years who underwent at least one multi-phasic health check-up between 1964 and 1973 within the Kaiser Permanente Medical Care Program. Cancer incidence was ascertained from the first health examination until 1988 through the San Francisco-Oakland Surveillance, Epidemiology and End Result (SEER) programme and the Northern California Kaiser Permanente Medical Care Program. Approximately 4.4% of the cohort were lost to the study (Hiatt & Bawol, 1984; Hiatt & Fireman, 1986; Friedman, 1993; Friedman & van den Eeden, 1993; Herrinton & Friedman, 1998; Iribarren *et al.*, 2001). Between 1978 and 1985, a similar cohort was established, which included a maximum of 120 000 subjects aged 30–89 years. In one study, the cohort was further followed up until 1987 (Sidney *et al.*, 1993). Cancer cases were ascertained as for the first cohort (Hiatt *et al.*, 1988; Klatsky *et al.*, 1988; Sidney *et al.*, 1993; Hiatt *et al.*, 1994; Herrinton & Friedman, 1998).

American Men of Japanese Ancestry Study

A cohort of 8006 American men of Japanese ancestry, born during the years 1900–19 and who resided on the Hawaiian island of Oahu, were interviewed and examined clinically from 1965 to 1968. Information obtained at the interview included age, smoking history, usual occupation, type of housing, education and religion. A 24-h dietary recall questionnaire was also administered. Newly diagnosed cases of cancer were identified through continuous surveillance of Oahu hospitals and linkage with the Hawaii Tumor Registry (Stemmermann *et al.*, 1988; Severson *et al.*, 1989; Nomura *et al.*, 1990a,b; Chyou *et al.*, 1992, 1993a,b, 1995; Nomura *et al.*, 1995; Chyou *et al.*, 1996).

Lutheran Brotherhood Insurance Study

A cohort of 17 633 white male life insurance policy holders of the Lutheran Brotherhood Insurance Society was identified in 1966. A response rate of 68.5% was achieved and little difference was observed between responders and non-responders to the ques-

tionnaire with regard to age, urban or rural residence, policy status and cancer mortality at 11.5 years of follow-up. The questionnaire included questions on tobacco use in the form of cigarettes, cigars, pipes and smokeless tobacco. Other questions asked for details of the longest held occupation, frequency of consumption of 35 food items and the consumption of coffee, beer and spirits. Death certificates were coded for underlying and contributory causes of death. Person–years were accumulated up to death, loss to follow-up or the end of the study in 1986. The age-adjusted relative risks for cancer mortality resulting from exposure to tobacco, occupation and dietary variables were computed using Poisson regression. Statistical interaction between smoking and other risk factors was also examined. About 23% of the cohort members were lost to follow-up (Hsing *et al.*, 1990b; Kneller *et al.*, 1991; Linet *et al.*, 1991; Chow *et al.*, 1992; Linet *et al.*, 1992; Zheng *et al.*, 1993; Hsing *et al.*, 1998).

MRFIT Study

The MRFIT study was conducted on a cohort of 361 662 men who were seen at an initial screening visit at 22 clinical centres throughout the USA and were thereby enrolled into the cohort in 1975. At the initial visit, 37% ($n = 133\ 117$) were current smokers, consuming an average of 26 cigarettes per day. A total of 12 866 participants were selected for an intervention trial based on a high risk score for coronary heart disease assigned at the baseline physical examination. High risk for coronary heart disease was determined by a combination of factors, using a logistic regression function derived from men in the same age group in the Framingham Heart Study, including cigarette smoking habits, diastolic blood pressure and serum cholesterol at the first screening visit (Kuller *et al.*, 1991).

Nurses' Health Study

In 1976, a cohort of 121 700 female registered nurses was assembled in the USA. At enrolment, the nurses completed a mailed questionnaire on risk factors for cancer and heart disease. Responses to food-frequency questionnaires were also collected in 1980, 1984, 1986 and 1990. The response rate to follow-up questionnaires was almost 96% through to 1990. Family members were the main source of vital status information for non-respondents but the National Death Index was also used. Multiple logistic regression models were used to compute odds ratios, after controlling for age, total energy intake and other potentially confounding variables (Willett *et al.*, 1987; Hunter *et al.*, 1990; Chute *et al.*, 1991; Giovannucci *et al.*, 1994a; Grodstein *et al.*, 1995; Kearney *et al.*, 1995; Fuchs *et al.*, 1996; Egan *et al.*, 2002).

Using the same cohort, Speizer *et al*. (1999) collected and updated information on smoking status and health status by means of a follow-up questionnaire distributed every 2 years from baseline until 1992.

Adventists' Health Study

A cohort of 34 198 non-Hispanic white Seventh-day Adventists in California (mean age, 55.4 years) was formed in 1976 when they completed a questionnaire concerning

lifestyle. During the period of follow-up from enrolment until December 1982, newly diagnosed cancers were ascertained by various means. First, a record linkage of the cohort members was made with two population-based cancer registries, the Cancer Surveillance Program in Los Angeles and the Resource for Cancer Epidemiology in San Francisco. Second, annual contact was maintained with every member of the cohort by means of a mailed questionnaire in which the study subject was asked to report whether he or she had been hospitalized in the previous 12 months. Study staff reviewed all medical records for evidence of cancer diagnoses. The authors stated that follow-up was 99% complete. Relative risks adjusted for permanent covariates were computed by use of the Cox proportional hazards model (Mills *et al.*, 1988, 1989a,b, 1990, 1991; Singh & Fraser, 1998).

Leisure World Study

A detailed health questionnaire was sent to all residents of a retirement community in California in 1981, and to new residents in 1982, 1983 and 1985. A response rate of 61% was achieved overall. Almost all of the residents were Caucasians of the upper-middle class; about two-thirds were women; and 80% were aged 65–86 years. Histological diagnosis of cancer was obtained from local hospitals. All participants were sent a follow-up questionnaire every 2 years (Wu *et al.*, 1987; Ross *et al.*, 1990; Shibata *et al.*, 1994).

Cancer Prevention Study II (CPS-II)

The Cancer Prevention Study II (CPS-II) is a nationwide prospective mortality cohort study of nearly 1.2 million adults enrolled by volunteers of the American Cancer Society in 1982. As in CPS-I, enrolment was based on families and excluded persons in institutions and military service and others who would be difficult to trace (Garfinkel, 1985). Each participant completed a confidential four-page postal questionnaire on tobacco and alcohol use, diet and other factors potentially related to cancer. Deaths were ascertained from month of enrolment until 31 December 1996 through personal enquiries made by the volunteers in 1984, 1986 and 1988 and later through linkage with the National Death Index. Most of the smoking-related analyses were based on follow-up through 1986, 1988 or 1989 to minimize misclassification of exposure of those smokers who quit during follow-up. By 1988, 1.8% of the cohort were lost to follow-up and 79 802 (6.7%) had died (Thun & Heath, 1997). The ninth revision (ICD-9) of the International Classification of Diseases was used to code the underlying cause of death. Participants in CPS-II were more likely to be white (93%), married (81%) and educated (high school graduates or above, 85.6%) than the general population of the USA. The analyses excluded former cigarette smokers and persons with incomplete or unclassifiable data on smoking status or on the frequency or duration of cigarette smoking; men who ever smoked a pipe or a cigar or for whom pipe or cigar smoking status was unclear, were also excluded (Garfinkel, 1985; Stellman & Garfinkel, 1986; Garfinkel & Stellman, 1988; Stellman & Garfinkel, 1989a; Garfinkel & Boffetta, 1990; Calle *et al.*, 1994; Thun *et al.*, 1995; Heath *et al.*, 1997; Thun & Heath, 1997; Thun *et al.*, 1997a,b; Kahn *et al.*, 1998; Chao *et al.*, 2000; Shapiro *et al.*, 2000; Chao *et al.*, 2002).

Iowa Women's Health Study

The Iowa Women's Health Study was conducted on a cohort of 41 837 women who completed a postal questionnaire (response rate, 42.7%) sent in 1986 to a random sample of women from the Iowa driver's licence list (Potter *et al*., 1992). The questionnaire covered information on age, smoking history, physical activity, level of education and alcohol consumption. Cigarette consumption was analysed as pack–years for both current and former smokers. Physical activity was ascertained by questionnaire and translated into a three-level physical activity score (low, medium and high). Incident cases of cancer were ascertained by the Health Registry of Iowa, which is a population-based cancer registry in the SEER Program of the National Cancer Institute (Bostick *et al.*, 1994; Harnack *et al.*, 1997; Parker *et al.*, 2000).

Health Professionals' Follow-up Study

In 1986, a cohort of 51 529 male dentists, optometrists, osteopaths, podiatrists, pharmacists and veterinarians in the USA were asked to respond to a postal questionnaire. The questionnaire included questions on age, current and past tobacco use, marital status, height and weight, ancestry, medications, disease history, physical activity and diet. Only men who completed the diet questionnaire adequately at baseline and who reported no cancer other than non-melanoma skin cancer were included in the analysis. After all baseline exclusions, 47 781 men comprised the analysis cohort. Follow-up questionnaires were sent in 1988, 1990, 1992 and 1994 to ascertain new cancer cases and to update smoking status. Family members and the National Death Index were the main source of information on vital status of non-respondents. After repeated mailings, the follow-up response rate was 94% up to 1994 and ascertainment of death was estimated to be 98%. Pooled logistic regression was used in analysis, which accounts for varying time to the outcome event and which is asymptotically equivalent to a Cox regression model with time-dependent covariate, given the short intervals and low probability of outcomes (Giovannuci *et al.*, 1994b; Kearney *et al.*, 1995; Fuchs *et al.*, 1996; van Dam *et al.*, 1999; Giovannuci *et al.*, 1999).

(ii) *Canada*

Canadian War Veterans' Study

After a pilot study to validate the questionnaire in 1955–56, 207 397 war veterans listed by the Canadian Pension Commission were sent a questionnaire on smoking habits, principal occupations and residence history. Approximately 118 000 forms (57%) were returned; after removal of duplicates and unusable forms some 92 000 (44%) (78 000 men and 14 000 women) remained. Follow-up was conducted from 1956 to 1962 through quarterly lists of deaths made available by the Department of Veterans Affairs. There were 9491 deaths among men and 1794 deaths among women; in most cases the cause of death was confirmed by autopsy (Best *et al*., 1961; Lossing *et al*., 1966).

National Breast Screening Study

The National Breast Screening Study is a multicentre, randomized controlled trial of mammography screening for breast cancer. Between 1980 and 1985, 89 835 women aged 40–59 years were recruited. In 1982, a second questionnaire was distributed to new attendees and previously enrolled women returning to the screening centres for further screening. A total of 56 837 women returned the questionnaires. Analyses are based mainly on respondents to the second questionnaire (Friedenreich *et al.*, 1993; Terry *et al.*, 2002).

(*c*) *Asia*

(i) *China*

Shanghai Factory Study

Chen *et al*. (1997) studied a cohort of 9351 adults from 11 factories in urban Shanghai. This cohort was identified in two stages: one during 1972–73 and the other during 1977–78, when members completed an interview based on a structured questionnaire. The questionnaire included questions on smoking, alcohol consumption, occupation, medical history and physical exercise. Vital status of the cohort members was monitored using factory records until 1 January 1993, with only 4% of subjects lost to follow-up. Cause of death was ascertained by examination of death certificates and the underlying cause of death was determined by two nosologists blinded to the smoking status of the individual. The Cox proportional hazards model was used for comparing a gradient of smoking categories with nonsmokers, while simultaneously adjusting for relevant covariates. At baseline, 61% of men and 7% of women smoked. Of the men, 46% consumed more than 20 cigarettes per day whereas only 11% of the female smokers consumed this number. Thirty-eight per cent of male smokers had started smoking prior to their twenty-fifth birthday, whereas among women, this figure was 25%.

Xi'an Factory Study

A cohort of 1696 persons was identified for a cross-sectional survey of coronary heart disease among employees of a machinery factory in Xi'an in May 1976. Employees were monitored for cause-specific mortality until 1996. Approximately 7% of the cohort members were subjected to occupationally hazardous exposures according to factory physicians. Vital status was ascertained from personnel and union records and confirmed through interviews of co-workers or relatives. The Cox regression model was used, adjusting for potential confounding factors including age, marital status, occupation, education, diastolic blood pressure and triglycerides and total cholesterol levels. During the 20 years of follow-up, 173 men and 45 women died (Lam *et al.*, 1997).

Shanghai Residential Study

A cohort of 213 800 residents from urban, suburban and surrounding rural areas of Shanghai were surveyed for smoking status. Subjects in urban areas were followed up annually for 12 years (January 1983 to December 1994) and subjects in suburban areas

and rural counties for 11 years (January 1984 to December 1994). The cause of deaths during the follow-up period was ascertained by medical professionals. Only data on subjects aged 40 years and over at enrolment were analysed. Because the prevalence of smoking among women aged 40 years and over in suburban and rural areas was very low (3.1% and 1.5%, respectively), data on women in these areas were excluded from the analysis. Person–years observed were calculated by sex, age, smoking status and area of residence. A Poisson regression model was used to estimate age-adjusted relative risks with 95% confidence limits for each cause of death (Gao *et al.*, 1999).

Linxian Intervention Trial Study

In the frame of an intervention trial for micronutrients, approximately 30 000 residents of the Linxian region were interviewed to obtain information on usual dietary intake, tobacco use, alcohol drinking, family history of cancer and other factors. The cohort was followed up from 1986 until 1991, with little loss to follow-up. Information on cause of death and incidence of cancer was collected from local hospitals or a study medical team. Relative risks were adjusted for potential confounders as well as the vitamin/mineral intervention group (Guo *et al.*, 1994).

Shanghai Men's Study

Ross *et al.* (1992) and Yuan *et al*. (1996) studied a cohort of 18 244 male residents of Shanghai, enrolled between 1986 and 1989 (80% of eligible subjects). A structured questionnaire was completed at a face-to-face interview. The information obtained included level of education, history of tobacco and alcohol use, current diet and medical history. At recruitment, 50% of study subjects were current smokers, half of whom smoked 20 or more cigarettes per day. Former smokers represented 7% of the cohort while 43% of cohort members had never smoked cigarettes regularly. Cancer incidence was ascertained through the population-based Shanghai Cancer Registry and vital status was ascertained by inspection of the Shanghai death certificate records. Only 50 subjects were lost to follow-up which continued until 1993.

Taiwanese Study

A cohort of 14 397 residents of metropolitan, urban and rural areas in Taiwan, China were recruited between 1982 and 1986. Information on sociodemographic characteristics, smoking status, alcohol drinking and food habits was collected at interview using a structured questionnaire. The cohort was followed up until 1994 by linkage with the death certification system in Taiwan. Causes of death were classified according to ICD-9. Cox proportional hazards regression models were used to derive relative risks for mortality and to examine dose–responses (Liaw & Chen, 1998).

(ii) *Japan*

Life Span Study

The Life Span Study cohort originally consisted of 100 000 survivors [sex distribution not reported] of the atomic bomb blasts in Hiroshima and Nagasaki. The cohort was expanded in 1968 and 1985 by adding approximately 10 000 survivors each time. The total cohort included approximately 120 000 individuals, of whom approximately 27 000 were non-exposed controls. Information on smoking was obtained from three interview surveys conducted on a subgroup of the entire cohort in 1963–64, 1964–68 and 1968–70, and four postal surveys conducted on various subgroups in 1965, 1969, 1979 and 1980. The cancer incidence in 61 505 survivors for whom smoking data were available was reported. For 42% of this group, information on smoking was available from at least two surveys. Information on cancer incidence and mortality was obtained from the Radiation Effects Research Foundation tumour registry and mortality database. Poisson regression models were used to fit log-linear relative risk and linear excess relative risk models (Akiba, 1994; Land *et al.*, 1994; Goodman *et al.*, 1995).

Japanese Physicians' Study

A survey of smoking and drinking habits among physicians in western Japan was carried out using self-administered questionnaires in 1965. From 6815 male respondents in nine prefectures (51% response rate), a cohort of 5477 male physicians was established. Vital status was followed until 1983 and confirmed by various medical associations. Copies of death certificates were obtained from the District Legal Affairs Bureau and the cause of death coded with the ICD-8. After exclusions, the analysis was done on 5130 men. Statistical analysis was performed using the Cox proportional hazards model (Kono *et al.*, 1987).

Six-prefecture Study

In 1965, 122 261 men and 142 857 women aged ≥ 40 years (95% of the census population) in 29 health centre districts from six prefectures in Japan were interviewed. The six prefectures were selected as being representative of the entire country. The questionnaire included questions on smoking, alcohol consumption and dietary habits, occupation, and marital status. A record linkage system was established for the annual follow-up. During the 16-year follow-up period, 8% of the cohort migrated from the original health districts. Deaths among cohort members were monitored by linkage to vital statistics kept at each public health centre. Cause of death was coded using the 7th revision of the International Classification of Diseases (Hirayama, 1967, 1975a,b, 1977a,b, 1978, 1981, 1982, 1985, 1989a,b,c; Mizuno *et al.*, 1989; Akiba & Hirayama, 1990; Hirayama, 1990; Kinjo *et al.*, 1998).

Regular male smokers who had started smoking between 18 and 22 years of age, and who were, at that time, between the ages of 40 and 79 years, were selected from the cohort for further analysis, resulting in a subcohort of 49 013 men (Mizuno *et al.*, 1989). [This

study was large and unique in that it involved a non-Caucasian population and was based on interviews rather than self-completed questionnaires.]

Chiba Center Association Study

The Chiba Center Association Study was a nested case–control study based on a cohort population of 17 200 male participants in a mass screening for gastric cancer by the Chiba Cancer Association in Japan in 1984. Cancer cases in cohort members were detected by record linkage to the Chiba Cancer Registry. The participants were followed from 1984 until 1993. For each cancer case, two controls were selected from the cohort population by matching on sex, birth year and area of residence (Murata *et al.*, 1996).

Fukuoka Study

A baseline survey was conducted from 1986 until 1989 among the general population of Fukuoka, the region with the highest liver cancer mortality in Japan. All inhabitants aged > 30 years were asked to answer a questionnaire, to which the response rate was 84.3%. A follow-up survey was conducted annually to verify the vital status of participants. For study subjects who had died, the cause of death was determined from the health certificate and classified according to ICD-9. The participants were followed up until 1996.

Women were excluded from this survey because of the small numbers of deaths and current smokers. After exclusions, 4050 men were included in the analysis. Cox proportional hazards regression analysis was employed to estimate relative risks and 95% confidence intervals (Mizoue *et al.*, 2000).

(*d*) *Others*

Seven-country Study

Jacobs *et al*. (1999) studied a cohort of 12 763 men in seven countries between 1957 and 1964, after administration of a standardized questionnaire. The questionnaire included questions about daily cigarette consumption at entry, years of smoking cessation for former smokers, age, weight and height. A physical examination at baseline included a comprehensive history of cardiovascular and cerebral vascular health. Information on vital status and cause of death was obtained during the 25 years of follow-up, by examining death certificates, collecting medical records from hospitals and from interviews with physicians and relatives. A Cox proportional hazards model was used to compute relative risk.

Israel Civil Service Centre Study

In 1963, Kark *et al*. (1995) studied a cohort of 9975 male civil servants between the ages of 40 and 69 years living in Haifa, Jerusalem and Tel Aviv, Israel. The initial examination included a physical examination, measurement of blood pressure, weight and height, electrocardiography and venipuncture. A questionnaire, which included questions on sociodemography, health behaviour, diet and psychosocial factors, was administered

by a trained interviewer. Further examinations were carried out in 1965 and 1968. The follow-up period ended on 31 December 1986 and included 198 298 person–years of cancer surveillance by linking the cohort list to both the National Cancer Registry and the National Death Registry. A total of 153 cases of lung cancer were identified. The Cox proportional hazards model was used to compute relative risk by including age as a continuous variable, and city of employment, cigarette smoking and body-mass index as dummy variables. The reference categories were never-smokers, resident in Haifa and Tel Aviv, and the upper fifth of the body-mass index frequency distribution.

Table 2.1. Cohort studies of cancer and cigarette smoking

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
United Kingdom								
British Doctors' Study	1951	Doll & Hill (1964a,b); Doll & Peto (1976); Doll *et al.* (1980, 1994)	1951–91	40 634 (34 440 men, 6194 women) British doctors [age not reported]	Postal questionnaire	Deaths	Lung, urinary bladder, kidney, upper aerodigestive tract (oesophagus, mixed), pancreas, stomach, colon, rectum, liver, leukaemia, ovary, non-Hodgkin lymphoma, multiple myelomas	Information on pipe and cigars
Whitehall Study	1967–69	Ben-Shlomo *et al.* (1994)	1967–87	19 018 men from the British Civil Service, clinically examined, aged 40–69 years	Interview	Deaths	Lung	Information on pipe and cigars
British United Provident Association (BUPA) Study	1975–82	Wald & Watt (1997)	1975–93	21 520 professional and businessmen, aged 35–64 years	Interview	Deaths	Lung	Information on pipe and cigars
Sweden								
Swedish Twin Registry Study	1961	Floderus *et al.* (1988); Steineck *et al.* (1988); Grönberg *et al.* (1996); Terry *et al.* (1998, 1999, 2001)	1961–97	10 942 same-sex twin pairs, born 1886–1925	Postal questionnaire	Deaths	Lung, urinary bladder, stomach, colon, rectum, endometrium, prostate	Information on pipe and cigars Floderus *et al.* mentioned 10 945 pairs.

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Swedish Census Study	1963	I: Cederlöf *et al.* (1975); Carstensen *et al.* (1987)	1963–72	Adults selected from the 1960 census population, aged 18–69 years I: 51 911 (25 444 men, 26 467 women)	Postal questionnaire (94%), telephone, interview	Deaths	Lung, urinary bladder, pancreas, colon, rectum, liver, endometrium, cervix	Information on pipe and cigars Stratified by urban-rural residence
		II: Nordlund *et al.* (1997, 1999)	1964–89	II: 41 710 (15 881 men, 25 829 women)	Postal questionnaire (87%), telephone, home visits	Cases	Lung, urinary bladder, kidney, upper aerodigestive tract (oral cavity, pharynx, oesophagus, mixed), pancreas, stomach, colon/ rectum, liver, breast, endometrium, cervix, leukaemia	Stratified by place of residence
Swedish Construction Workers' Study	1971–75 (I) 1971–91 (II) 1971–92 (III)	I: Adami *et al.* (1996); Nyrén *et al.* (1996) II: Adami *et al.* (1998) III: Chow *et al.* (2000)	1971–92	Male construction workers, aged ≥ 35 years I: 143 998 II: 334 957 III: 363 992	Self-administered questionnaire/ interview	Cases	Kidney, colon, rectum, prostate, leukaemia, non-Hodgkin lymphoma, Hodgkin lymphoma, multiple myelomas	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Norway								
Norwegian Cohort Study	1964–65	Heuch *et al.* (1983); Engeland *et al.* (1996a,b); Kjaerheim *et al.* (1998)	1966–93	26 132 subjects (11 863 men, 14 269 women) including a sample of the 1960 census population, a random sample from 4 selected counties and a sample of siblings living in Norway with a sibling living in the USA, aged 33–72 years	Postal questionnaire	Cases	Lung, urinary bladder, kidney, upper aerodigestive tract (mixed), pancreas, stomach, colon, rectum, breast, endometrium, cervix, prostate, leukaemia, ovary	
Norwegian Screening Study	1974–78 (I) 1972–78 (II) 1977–83 (III)	I: Vatten & Kvinnsland (1990) II: Tverdal *et al.* (1993); Thune & Lund (1994) III: Veierød *et al.* (1997)	1972–88	Participants in a health screening programme, aged 35–49 years I: 24 329 women II: 44 290 men, 24 535 women; 53 242 men III: 26 119 men	Interview	Deaths	Lung, pancreas, stomach, colon, rectum, breast, cervix, prostate	Information on pipe and cigars
Finland								
Finnish Men's Study	1962	Pedersen *et al.* (1969); Tenkanen *et al.* (1987); Hakulinen *et al.* (1997)	1964–80	4452 men from 3 urban and 3 rural areas, born 1898–1917	Interview	Cases	Lung, prostate	Hakulinen *et al.* (1997) also included subjects from another survey in 1972–77

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Finnish Mobile Clinic Health Examination Study	1966–72	Knekt *et al.* (1998); Heikkilä *et al.* (1999)	1966–91	56 973 subjects having received multiphasic health examination from the Mobile Clinic [sex distribution not reported]	Postal questionnaire, checked by interview	Cases	Colon, rectum, prostate	
Iceland								
Reykjavík Study	1967–91	Tulinius *et al.* (1997)	1968–95	22 946 (11 366 men, 11 580 women) residents of Reykjavík, born 1907–1954, aged 31–61 years	Self-administered questionnaire	Cases	Lung, urinary bladder, oesophagus, pancreas, stomach, colon, endometrium, cervix, prostate, leukaemia	
The Netherlands								
Dutch Study	1975–77, 1982–83	Ellard *et al.* (1995); de Waard *et al.* (1995); van Wayenburg *et al.* (2000)	1975–90	26 697 women from 2 breast cancer screening programmes (DOM project and Lutine Study) in Utrecht, aged 40–64 years	Self-administered questionnaire	Cases	Lung, colon/rectum	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Denmark								
Copenhagen City Heart Study	1976–78, 1981–83	Lange *et al.* (1992); Prescott *et al.* (1999)	1976–89	14 223 subjects (6511 men, 7703 women) randomly selected among 90 000 persons living in a defined area of Copenhagen, aged ≥ 20 years	Self-administered questionnaire	Deaths	Lung	The study by Prescott *et al.* (1999) was based on data from three cohorts, including the Copenhagen City Heart Study, the Centre of Preventive Medicine and the Copenhagen Male Study.
USA								
Framingham Heart Study	1948–52	Williams *et al.* (1981); Freund *et al.* (1993)	1948–82	5209 subjects receiving routine examinations at the Framingham Heart Study Clinic, MA	Interview	Cases	Lung, colon	
American Cancer Society (nine-state) Study	1952	Hammond & Horn (1958a,b)	1952–55	187 783 men from 9 states, aged 50–69 years	Self-administered questionnaire	Deaths	Lung, urinary bladder, upper aerodigestive tract (mixed), pancreas, colon, rectum	Information on pipe and cigars

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
US Veterans' Study	1954, 1957	Kahn (1966); Rogot & Murray (1980); Kinlen & Rogot (1988); McLaughlin *et al.* (1989); Hsing *et al.* (1990a); McLaughlin *et al.* (1990a,b); Hsing *et al.* (1991); Heineman *et al.* (1992); Zahm *et al.* (1992); Chow *et al.* (1993); Heineman *et al.* (1994); Chow *et al.* (1995); Heineman *et al.* (1995); McLaughlin *et al.* (1995); Chow *et al.* (1996)	1954–80	293 958 male holders of a US Government Life Insurance, aged 31–84 years	Postal questionnaire	Deaths	Lung, urinary bladder, kidney, upper aerodigestive tract (oral cavity, nasopharynx, larynx, pharynx, oesophagus), pancreas, stomach, colon, rectum, liver, leukaemia, soft-tissue sarcoma, brain, biliary ducts, adrenals, non-Hodgkin lymphoma, Hodgkin's lymphoma, multiple myelomas	Information on pipe and cigars
Californian Study	1954–57	Weir & Dunn (1970)	1954–62	68 153 male labour union members, aged 35–64 years	Postal questionnaire	Deaths	Lung, urinary bladder, upper aerodigestive tract (oral cavity, larynx, pharynx, oesophagus), pancreas	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Cancer Prevention Study I (CPS-I)	1959–60	Hammond & Garfinkel (1961); Hammond (1966); Garfinkel (1980); Hammond & Seidman (1980); Garfinkel (1985); Stellman & Garfinkel (1986, 1989a,b); Garfinkel & Boffetta (1990); Thun *et al.* (1995); Thun & Heath (1997); Thun *et al.* (1997a); Shanks & Burns (1998)	1959–72	1 051 038 adults from 25 states, aged > 30 years	Postal questionnaire	Deaths	Lung, urinary bladder, upper aerodigestive tract (oesophagus, mixed), pancreas, stomach, colon/rectum, liver, endometrium, cervix, leukaemia, biliary ducts	Information on pipe and cigars For women, all sites of the aerodigestive tract and all cancers of the haematopoietic system were grouped.
Harvard Alumni Study	1962, 1966	Paffenbarger *et al.* (1977, 1978)	1962–92	13 905 male Harvard alumni; mean age, 58.3 years	Postal questionnaire	Cases/ deaths	Leukaemia, Hodgkin lymphoma	
Tecumseh Community Health Study (I/II/III)	1962–69	Islam & Schottenfeld, 1994	1962–87	3956 residents (1857 men, 2099 women) of Tecumseh, MI, aged > 25 years	Interview	Cases	Lung	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Kaiser Permanente Medical Care Program Study	1964–73 (I) 1978–85 (II) 1964–91 (I+II)	I: Hiatt & Bawol (1984); Hiatt & Fireman (1986); Friedman (1993); Friedman & van den Eeden (1993); Iribarren *et al.* (1999, 2001) II: Hiatt *et al.* (1988); Klatsky *et al.* (1988); Sidney *et al.* (1993); Hiatt *et al.* (1994) I+II: Herrinton & Friedman (1998)	I: 1964–97 II: 1978–87 I + II: 1973–93	Members of the Kaiser Permanente Medical Care Program I: approx. 175 000 members aged 15–94 years II: approx. 80 000 members aged 30–89 years I+II: 252 836 members aged 16–84 years	Interview	Cases	Lung, pancreas, colon, rectum, breast, prostate, leukaemia, thyroid, non-Hodgkin lymphoma, multiple myelomas	Information on pipe and cigars Period of collection and age range of participants at baseline vary slightly between studies, leading to different cohort sizes
American Men of Japanese Ancestry Study	1965–68	Stemmermann *et al.* (1988); Severson *et al.* (1989); Nomura *et al.* (1990a,b); Chyou *et al.* (1992, 1993a,b, 1995); Nomura *et al.* (1995); Chyou *et al.* (1996)	1965–95	8 006 American men of Japanese ancestry residing in Hawaii, born 1900–19	Interview	Cases	Lung, urinary bladder, upper aerodigestive tract (mixed), stomach, colon, rectum, colorectal polyps, prostate	
Lutheran Brotherhood Insurance Study	1966	Hsing *et al.* (1990b); Kneller *et al.* (1991); Linet *et al.* (1991); Chow *et al.* (1992); Linet *et al.* (1992); Zheng *et al.* (1993); Hsing *et al.* (1998)	1966–86	17 633 male holders of a Lutheran Brotherhood Insurance policy, largely of Swedish, Norwegian or German descent, aged ≥ 35 years	Postal questionnaire	Deaths	Lung, pancreas, stomach, colon/rectum, leukaemia, non-Hodgkin lymphoma, multiple myelomas	Information on pipe and cigars
MRFIT Study	1975	Kuller *et al.* (1991)	1975–85	12 866 randomized participants initially selected for the MRFIT, aged 35–57 years	Interview	Deaths	Lung, urinary bladder, kidney, upper aerodigestive tract (oesophagus, mixed), pancreas	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Nurses' Health Study	1976	Willett *et al.* (1987); Hunter *et al.* (1990); Chute *et al.* (1991); Giovannucci *et al.* (1994a); Kearney *et al.* (1995); Grodstein *et al.* (1995); Fuchs *et al.* (1996); Speizer *et al.* (1999); Egan *et al.* (2002)	1976–92	121 700 female nurses from 11 states, aged 30–55 years	Postal questionnaire	Cases	Lung, colon, rectum, colorectal polyps, pancreas, breast, skin	
Adventists' Health Study	1976	Mills *et al.* (1988, 1989a,b, 1990, 1991); Singh & Fraser (1998)	1976–82	34 198 male and female Adventists, aged > 25 years	Postal questionnaire	Cases	Urinary bladder, breast, pancreas, colon, prostate, leukaemia, multiple myeloma	
Leisure World Study	1981–82 (I) 1981–85 (II)	I: Wu *et al*. (1987) II: Ross *et al.* (1990); Shibata *et al.* (1994)	1981–85	Retirees living in a retirement community I: 11888 II: 13 976 [sex distribution not reported]	Postal questionnaire	Cases	Pancreas, colon/rectum, prostate	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Cancer Prevention Study II (CPS-II)	1982	Garfinkel (1985); Stellman & Garfinkel (1986); Garfinkel & Stellman (1988); Stellman & Garfinkel (1989a); Garfinkel & Boffetta (1990); Calle *et al.* (1994); Thun *et al.* (1995); Heath *et al.* (1997); Thun & Heath (1997); Thun *et al.* (1997a,b); Kahn *et al.* (1998); Chao *et al.* (2000); Shapiro *et al.* (2000); Chao *et al.* (2002)	1982–96	1 185 106 adults from 25 states, aged > 30 years	Postal questionnaire	Deaths	Lung, kidney, stomach, colon/rectum, colorectal polyps, breast, leukaemia	Information on pipe and cigars
Iowa Women's Health Study	1986	Potter *et al.* (1992); Gapstur *et al.* (1992); Bostick *et al.* (1994); Harnack *et al.* (1997); Parker *et al.* (2000)	1986–98	41 837 women randomly selected from the Iowa driver's licence list, aged 55–69 years	Postal questionnaire	Cases	Lung, pancreas, colon, breast, non-Hodgkin lymphoma	
Health Professionals' Follow-up Study	1986	Giovannucci *et al.* (1994b); Kearney *et al.* (1995); Fuchs *et al.* (1996); van Dam *et al.* (1999); Giovannucci *et al.* (1999)	1986–94	47 781 male health professionals, aged 40–75 years	Postal questionnaire	Cases	Pancreas, colon/rectum, colorectal polyps, prostate, skin	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Canada								
Canadian War Veterans' Study	1956	Best *et al.* (1961); Lossing *et al.* (1966)	1956–62	92 000 war veterans (78 000 men, 14 000 women), aged 55–79 years	Postal questionnaire	Deaths	Lung, urinary bladder, pancreas	
National Breast Screening Study (NBSS)	1980–85	Friedenreich *et al.* (1993); Terry *et al.* (2002)	1980–93	Multicentre randomized controlled trial of mammography screening for breast cancer in almost 90 000 women, aged 40–59 years	Self-administered questionnaire	Cases	Breast, endometrium	Friedenreich *et al.* (1993) conducted a nested case–control study.
China								
Shanghai Factory Study	1972–73, 1977–78	Chen *et al.* (1997)	1972–93	9351 factory employees (6494 men, 2857 women) aged 35–64 years	Interview	Deaths	Lung, upper aerodigestive tract (oesophagus), stomach, colon/rectum, liver	Site-specific analyses conducted for men only
Xi'an Factory Study	1976	Lam *et al.* (1997	1976–96	1696 factory employees (1124 men, 572 women) aged ≥ 35 years	Interview	Deaths	Lung, upper aerodigestive tract (oesophagus), liver	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Shanghai Residential Study	1983–84	Gao *et al.* (1999)	1983–94	213 800 residents of urban, suburban and rural areas of Shanghai, aged > 20 years [sex distribution not reported]	Interview	Deaths	Lung, upper aerodigestive tract (oesophagus), stomach, liver	
Linxian Intervention Trial Study	1985	Guo *et al.* (1994)	1985–91	Approx. 30 000 residents of 4 communes in Linxian, aged 40–69 years [sex distribution not reported]	Interview	Cases	Upper aerodigestive tract (oesophagus), stomach	Nested case–control study
Shanghai Men's Study	1986–89	Ross *et al.* (1992); Yuan *et al.* (1996)	1986–93	18 244 male residents of 4 communities in Shanghai, aged 45–64 years	Interview	Cases	Lung, urinary bladder, upper aerodigestive tract (oesophagus, mixed), pancreas, stomach, colon, rectum, liver	Ross *et al.* (1992) conducted a nested case–control study on smoking and risk of colorectal adenomatous polyps.
China, Province of Taiwan								
Taiwanese Study	1982–86	Liaw & Chen (1998)	1982–94	14 397 residents (11 096 men, 3301 women) of Taiwan, aged > 41 years	Interview	Deaths	Lung, urinary bladder, upper aerodigestive tract (nasopharynx, oesophagus, mixed), stomach, colon/rectum, liver, pancreas, cervix	

Table 2.1 (contd)

Country Name of study	Date of cohort sampling	References	Maximum years of follow-up	Cohort sample and age at beginning of follow-up	Collection of information	Cases/ deaths	Neoplasms analysed	Comments
Japan								
Life Span Study	1963, 1968, 1985	Akiba (1994); Land *et al.* (1994); Goodman *et al.* (1995)	1963–87	93 000 exposed survivors of the atomic blasts and 27 000 non-exposed controls [sex distribution not reported]	Postal questionnaire, interview	Cases	Lung, upper aerodigestive tract (nasal cavity and sinuses, larynx, oesophagus, mixed), colon, rectum, liver, breast	
Japanese Physicians' Study	1965	Kono *et al.* (1987	1965–83	5477 male physicians, aged 27–89 years	Self-administered questionnaire	Deaths	Lung, upper aerodigestive tract (oesophagus, mixed), stomach, colon/rectum, liver	
Six-prefecture Study	1965	Hirayama (1967, 1975a,b, 1977a,b, 1978, 1981, 1982, 1985, 1989a,b,c); Mizuno *et al.* (1989); Akiba & Hirayama (1990); Hirayama (1990); Kinjo *et al.* (1998)	1965–81	265 118 subjects (122 261 men, 142 857 women) covering > 90% of the census population from 29 districts, aged > 40 years	Interview	Deaths	Lung, urinary bladder, upper aerodigestive tract (larynx, oesophagus, mixed), pancreas, stomach, colon, rectum, liver, cervix	
Chiba Center Association Study	1984	Murata *et al.* (1996)	1984–93	17 200 male participants in a mass screening for gastric cancer	Self-administered questionnaire	Cases	Lung, urinary bladder, upper aerodigestive tract (mixed), pancreas, stomach, colon, rectum, liver	
Fukuoka Study	1986–89	Mizoue *et al.* (2000)	1986–96	13 270 residents of 4 towns in Fukuoka, aged ≥ 30 years [sex distribution not reported]	Self-administered questionnaire	Deaths	Stomach, liver	Results reported include only men because of the low prevalence of site-specific cancer deaths in women.

Table 2.1 (contd)

2.1 Cigarette smoking

2.1.1 *Lung cancer*

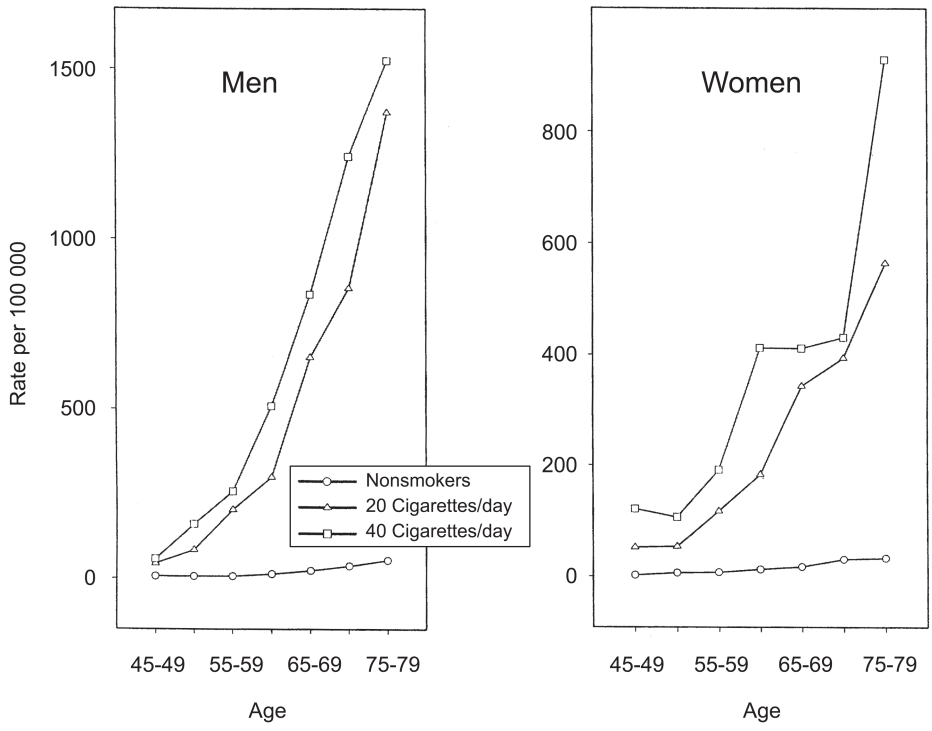
Lung cancer is now the most common type of cancer in the world, and the total number of cases that occur annually is estimated to be 1.2 million (Parkin *et al.*, 2000).

The causal relationship between tobacco smoking and lung cancer was established during the 1950s (Medical Research Council, 1957; Doll, 1998).

Tobacco smoking was considered to be causally related to cancer of the lung in the *IARC Monograph* on tobacco smoking based on the findings of the studies available at that time (IARC, 1986). Since 1986, much further evidence has accumulated on the magnitude of the increase in lung cancer risk associated with prolonged smoking, the progressive increase in smoking rates in women as well as in men, the decrease in risk that occurs among smokers after cessation compared with smokers who continue smoking, and the increase in the risk for adenocarcinoma of the lung in smokers in recent years. The current epidemiological evidence comes from many more countries and geographical regions than were considered in 1986. The following section summarizes the epidemiological evidence on how the relationship between smoking and lung cancer varies with duration and intensity of smoking, cessation of smoking, type of cigarette, histological type of lung cancer and population characteristics. The main characteristics and the results of the cohort studies are presented in Tables 2.1 and Tables 2.1.1.1–2.1.1.3, respectively. For the case–control studies, the study designs are summarized in Table 2.1.1.4 while results are presented in Tables 2.1.1.5–2.1.1.13.

(*a*) *Factors affecting risk*

(i) *Duration and intensity of smoking*



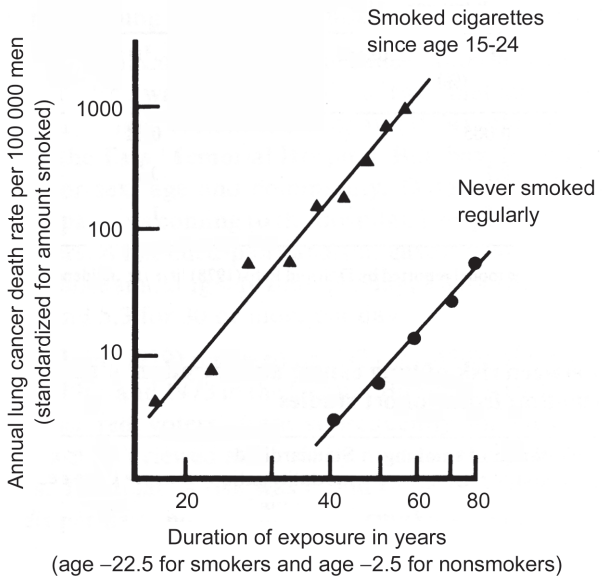
The results of cohort and case–control studies that reported on duration and intensity of smoking in association with lung cancer risk are presented in Tables 2.1.1.1 and Tables 2.1.1.5–2.1.1.7, respectively. In smokers, the most important parameter of smoking that affects lung cancer risk is the duration of regular smoking, although risk also increases with the number of cigarettes smoked per day. The stronger association of lung cancer risk with the duration than with the intensity of smoking may in part reflect the accuracy with which these two parameters are measured. Duration is determined by the age at initiation and attained age in current smokers or by age at smoking cessation. These parameters can be estimated reasonably accurately in epidemiological studies. The intensity of smoking is influenced not only by the number of cigarettes smoked per day, which can be estimated from self-reporting, but also by depth of inhalation, number of puffs taken per cigarette and retention time in the lung. Misclassification of smoking intensity may occur because of the necessity for a smoker to maintain his or her accustomed level of nicotine intake. Smokers therefore compensate for reductions in the number of cigarettes smoked per day by smoking each cigarette more intensively. The studies that are most informative about the relative importance of duration of smoking versus number of cigarettes smoked per

day are large cohort studies where age-specific lung cancer rates can be compared across a broad range of ages and durations of smoking within narrow strata of numbers of cigarettes smoked per day.

For example, Figure 2.1.1.1 presents the annual death rate from lung cancer (per 100 000) among men and women enrolled in the American Cancer Society cohort (CPS-II) during the first 6 years of follow-up (1982–88) (see Table 2.1 for cohort description). Age-specific death rates are presented for lifelong nonsmokers and for participants who reported that they smoked 20 cigarettes per day or 40 cigarettes per day at the time of enrolment in the study. For men and women, the death rate from lung cancer increased approximately 30-fold from age 45–49 years to age 75–79 years among those who reported currently smoking either 20 cigarettes per day or 40 cigarettes per day at enrolment. This age interval corresponds to an average increase in the duration of smoking from 22–26 years to 62–66 years among current smokers in this population. There is a much smaller increase in the age-specific death rates between participants who smoked 40 cigarettes per day and those who smoked 20 cigarettes per day.

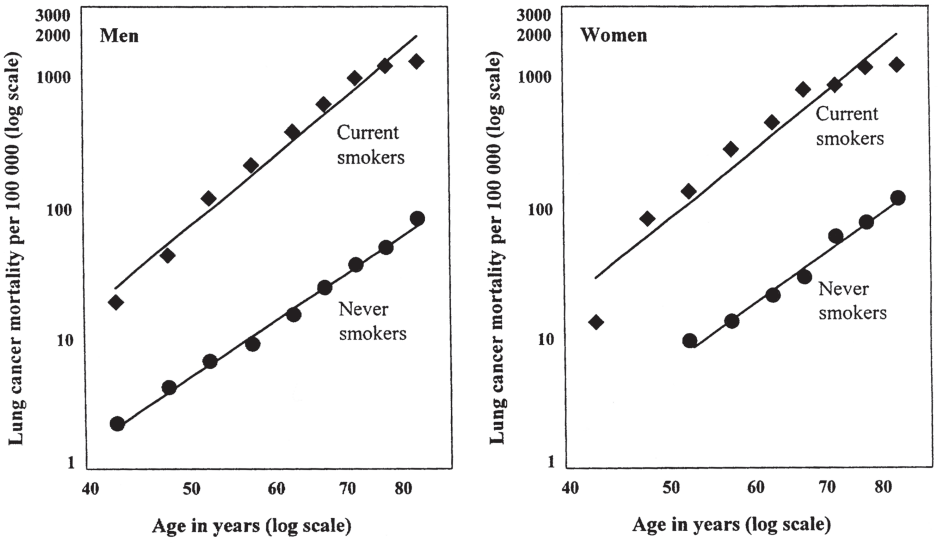
The critical relationship between the duration of smoking and risk for lung cancer was demonstrated by Peto and Doll (1984) based on a 20-year follow-up of the British Doctors' Study (Doll & Peto, 1976). Using a statistical model fitted to data from the men

Figure 2.1.1.1. Lung cancer mortality rates by age and amount currently smoked



in the British Doctors' Study, Doll and Peto (1978) estimated that the annual excess incidence of lung cancer increased approximately 100-fold when men who had smoked for 45 years were compared with those who had smoked for 15 years (see Table 2.1.1.14). This 100-fold increase with duration of smoking is seen for both moderate and heavy smokers. Case–control studies that have examined risk in relation to both duration of smoking and number of cigarettes smoked per day have demonstrated a stronger association with duration (see Table 2.1.1.7).

The effects of duration of smoking are so strong, and so closely correlated with age, that it is difficult to determine whether ageing itself has any independent effect on excess lung cancer rates among people of different ages who have similar smoking histories. Lung cancer risk was found to increase exponentially with age among male current smokers in both the British Doctors' Study (Figure 2.1.1.2) and in CPS-II (Figure 2.1.1.3). Death rates from lung cancer also increased exponentially with age among female current smokers in CPS-II during the 1982–88 follow-up, except in women aged ≥ 80, who represented birth cohorts of women who started smoking 4–15 years later than the average age of starting smoking among women aged 40 in 1982 (Thun *et al.*, 1997a).



The close correspondence between the age of starting smoking and the duration of cigarette smoking among current smokers results in higher age-specific cancer death rates in smokers who began smoking at earlier ages. This is illustrated in Figure 2.1.1.4, based on 8.5 years of follow-up of the US Veterans cohort (Kahn, 1966). In both 'moderate'

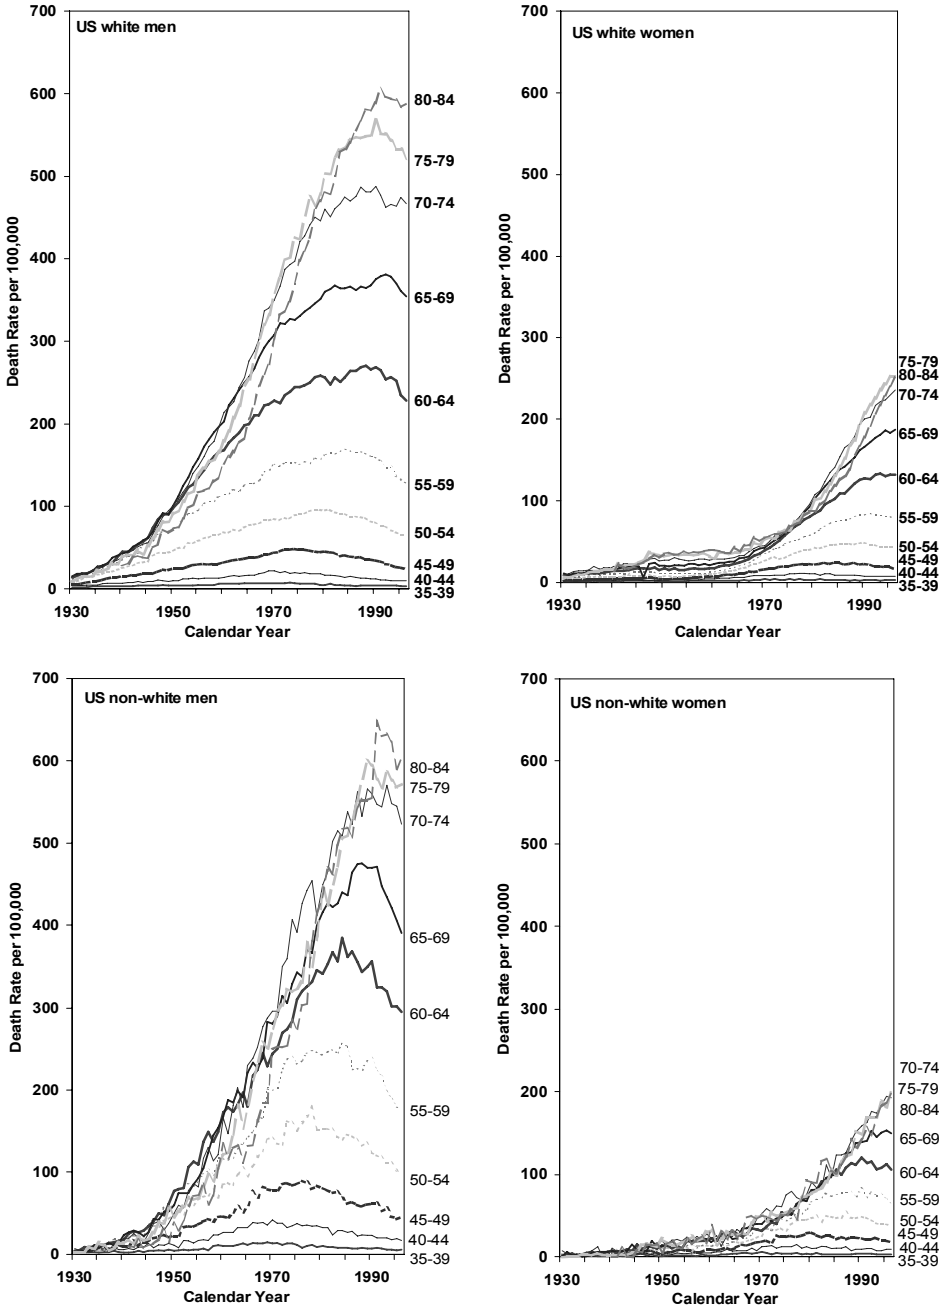
Figure 2.1.1.3. Lung cancer mortality rates by cigarette smoking status and age in men and women from the CPS-II cohort, 1982–88

Adapted from Thun *et al.* (1997a)

Figure 2.1.1.4. Relationship between age at starting regular cigarette smoking and lung cancer death rates at age 55–64 years in US men

From Doll and Peto (1981)

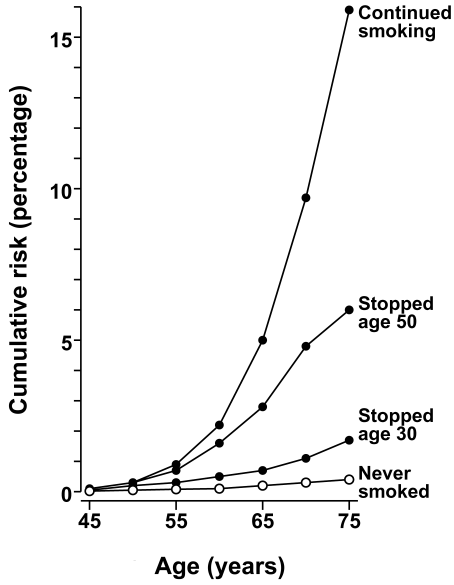
smokers (10–20 cigarettes per day) and 'heavy' smokers (21–39 cigarettes per day), the annual death rate from lung cancer at age 55–64 was higher the younger the age at which the men had started to smoke. Age at starting smoking cannot be separated from the duration of smoking in analyses of current smoking by attained age.



A consequence of the strong relationship between prolonged smoking and lung cancer risk is that the full effect of smoking in a population is not seen in national rates of lung cancer until regular smoking has been entrenched in that population for at least 50 years. The consequences of smoking on lung cancer may also be underestimated in epidemiological studies that do not include long-term smokers. Differences in the distribution of the age groups of the smokers being studied and in the duration of regular heavy smoking contribute to the quantitative variations in the age-specific absolute lung cancer rates and in the relative risks associated with current smoking. The maturation of the smoking epidemic is evident in temporal changes in age-specific death rates for lung cancer in countries where cigarette smoking has been common for many decades. The age-specific lung cancer rates reflect the ageing of successive birth cohorts of smokers. For example, Figure 2.1.1.5 depicts the changes in age-specific death rates from lung cancer in white and non-white men and women in the USA from 1930 to 1996. Within each age group, the death rate from lung cancer has first increased and then decreased, with the downturn in the age-specific death rate from lung cancer beginning earlier at younger than at older ages. These temporal patterns in lung cancer reflect historical patterns in cigarette smoking over the previous 10–60 years. Successive birth cohorts (generations) of men and women smoked progressively more than the previous generation over the first half of the twentieth century, and then progressively less until intensified marketing to adolescents began in the 1990s.

(ii) *Smoking cessation*

The effect of smoking cessation on relative risk for lung cancer has been evaluated by a large number of analytical studies. In many case–control studies (Table 2.1.1.8) and in cohort studies (Table 2.1.1.2) that examined the lung cancer risk among people who quit smoking cigarettes, a significant reduction in the relative risk of lung cancer was observed. This reduction in relative risk was observed in both men and women, among light (i.e. < 20 cigarettes/day) and moderate to heavy cigarette smokers (i.e. ≥ 20 cigarettes/day), and among those who typically smoked manufactured cigarettes as well as who rolled their own cigarettes. The reduction in risk was observed within 1–4 years of smoking cessation, and the magnitude of the reduction in relative risk increased with increased time since cessation.



However, comparisons between smokers and former smokers in particular populations were often made when the hazards among the continuing smokers in those populations were still far from maximal; therefore, the comparisons seriously underestimated the magnitude of the long-term benefits of stopping. The most accurate estimate of the benefit of smoking cessation comes from studies conducted in populations, like the United Kingdom, where the full hazards of continued smoking were already apparent and

Figure 2.1.1.5. Lung cancer mortality rates in US white and non-white men and women, 1930–1996

Source: US Vital Statistics

Figure 2.1.1.6. Cumulative lung cancer risk by smoking status and age at quitting smoking in men in the United Kingdom

From Peto *et al.* (2000)

where there were many long-term former smokers. For men in the United Kingdom, where the worst affected generation of smokers was that born around 1900, a study conducted in 1990 (and published 10 years later — Peto *et al.*, 2000) found a high lifelong risk of lung cancer among continuing smokers and substantially lower lifelong risks among those who stopped at 50 or, particularly, at 30 years of age (see Figure 2.1.1.6). Former smokers had significantly higher risks than men who had never smoked, but they also had very substantially lower lifelong risks than those who continued, with most of the benefit accruing not in the first decade after stopping, but in subsequent decades (see Figure 2.1.1.6).

(iii) *Type of cigarette and inhalation*

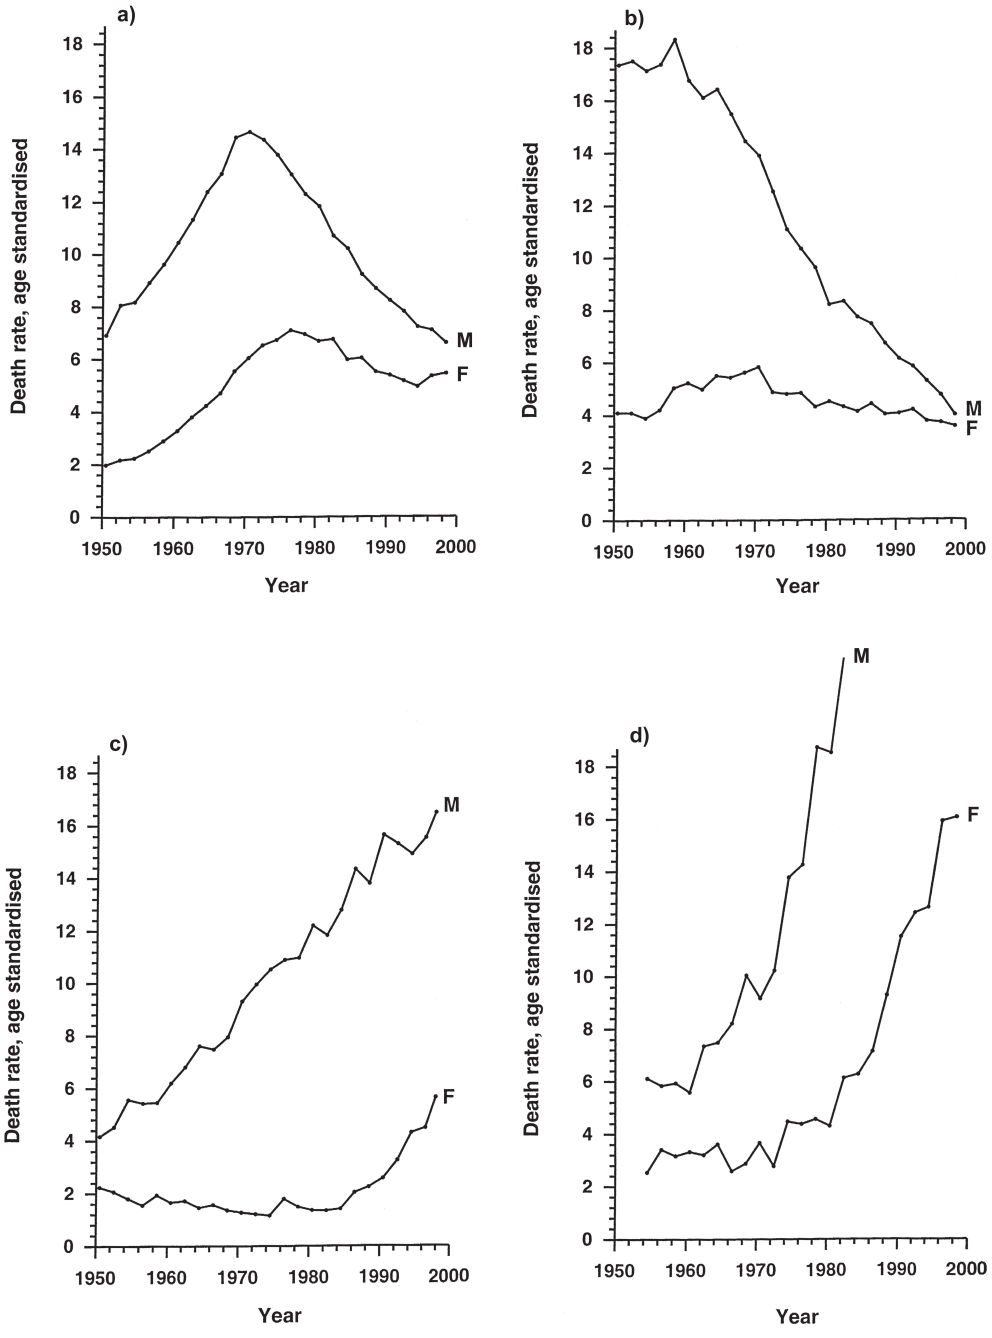
The *IARC Monograph* on tobacco smoking (IARC, 1986) concluded that case–control and cohort studies available at that time suggested that prolonged use of 'high-tar' and untipped cigarettes is associated with greater risks than prolonged use of filter-tipped and 'low-tar' cigarettes. The results of cohort and case–control studies on the type of cigarette, tar level in cigarettes, type of tobacco and inhalation are summarized in Table 2.1.1.3 and Tables 2.1.1.9, 2.1.1.10, 2.1.1.11 and 2.1.1.12, respectively.

As discussed in Section 1.1, cigarette composition changed substantially during the second half of the twentieth century with the introduction of blended tobacco, filter-tipped cigarettes and other changes intended to modify the nicotine and tar yield of these ciga-

rettes as measured by machine smoking. The actual impact of these changes on the exposure of an individual smoker to carcinogens is difficult to assesss because of the large increase in tobacco-specific nitrosamines from the introduction of blended tobacco, variability in curing processes over time and in different countries, and compensatory changes in smoking behaviour by smokers to maintain their accustomed level of nicotine intake. Most importantly, the majority of smokers have used several different products at different stages of their life as a smoker.

In the absence of large populations of smokers who have consumed a single tobacco product for many decades, epidemiologists have relied on three lines of evidence to examine the relationship between cigarette design and cancer risk. The first involves analytical studies that compare smoking histories (particularly the switch from unfiltered, high-tar cigarettes to filter-tipped medium-tar cigarettes) in relation to lung cancer; the second involves comparisons of different time periods of the epidemic in cohort studies of long duration; the third examines trends in age-specific death rates from lung cancer in different countries in relation to the types of cigarettes being smoked. Each of these approaches has its strengths and limitations, as discussed below.

Many case–control studies conducted since the 1960s have reported a somewhat lower risk for lung cancer among smokers of filter-tipped 'reduced yield' cigarettes than in smokers of untipped 'high-yield' cigarettes. These studies are summarized in Tables 2.1.1.3 and 2.1.1.9–2.1.1.10. A similar observation was made in an analysis of the CPS-I cohort by Hammond *et al*. (1976). The majority of case–control studies (Kaufman *et al*., 1989; Zang & Wynder, 1992; Harris *et al*., 1993; Benhamou *et al*., 1994; Kabat, 1996; Zang & Wynder, 1996) show a dose–response relationship between the tar content of the cigarette smoked and the relative risk for lung cancer. The greater risk associated with higher tar level has been shown in both sexes in both Kreyberg I and Kreyberg II histological types and in both squamous-cell carcinoma and in adenocarcinoma.



In cohort studies, the reported magnitude of the risk reduction associated with low-tar cigarettes ranged from 25–50% in the CPS-I cohort (Hammond *et al.*, 1976; Stellman & Garfinkel, 1989b) to 14% in the MRFIT cohort (Kuller *et al.*, 1991) and to no reduction in the Kaiser Permanente cohort (Sidney *et al.*, 1993). The studies comparing 'high-yield' and 'reduced yield' cigarettes have had limited ability to control for all the factors that affect smoking behaviour, compensatory changes or selection of type of cigarettes. Furthermore, since the quantification of the tar content of cigarettes varied somewhat from study to study, the measures of the magnitude of risk reduction are not directly comparable. In all of these studies, the risk for lung cancer in smokers greatly exceeded that in never-smokers and former smokers irrespective of the type of cigarette.

Several cohort studies have examined changes in risk for lung cancer among cigarette smokers in the United Kingdom and the USA during the mid-twentieth century, when most of the cigarettes smoked were untipped, high-tar types, and during the late twentieth century, when the majority of smokers used filter-tipped, intermediate yield cigarettes. These cohort studies have indicated that the relative and absolute risks for lung cancer associated with smoking continued to increase among older smokers, despite a dramatic

decrease in machine-measured tar delivery over the same time period. The increase in risk associated with smoking has been interpreted as evidence against the efficacy of lower yield products in reducing risk for lung cancer (Burns *et al*., 2001). However, the interpretation of the trend in risk from CPS-I to CPS-II is difficult because these cohorts represent time intervals in which there were major increases in the intensity of smoking by young people (Peto & Doll, 1984; IARC, 1986). A similar comparison was made for male smokers in the British Doctors' Study in which the first 20 years of follow-up (1951–70) were compared with the second 20 years (1971–90). Although the age-specific comparisons are based on a much smaller number of deaths in the British Doctors' Study than in the American Cancer Society cohorts, this study also showed higher age-standardized death rates from lung cancer during the second than during the first follow-up interval. A strength of these cohort studies is that they indicate that the introduction of filter-tipped cigarettes did not result in the expected rapid reduction in risk for lung cancer, especially among older smokers, for whom risk actually continued to increase. The principal limitation of these studies is that they cannot distinguish between potential changes in the pathogenicity of cigarettes and unmeasured differences in lifetime smoking, particularly differences in the intensity of smoking by young people.

Another line of evidence involves ecological comparisons of changes in age- and sex-specific death rates from lung cancer in various countries in relation to the type of cigarette being smoked. These national trends highlight major differences in lung cancer rates between men and women and across countries. In the United Kingdom, the lung cancer death rate in men aged 35–44 years decreased by more than 75% between the early 1960s and 2000, whereas the rate in women remained approximately stable. The decrease in lung cancer mortality among men in this age group exceeded the 48% decrease in smoking prevalence in British men aged 25–34 years over the same interval. In contrast, the decrease in death rates from lung cancer among men aged 35–44 years in the USA (Figure 2.1.1.7a) began later and has been smaller than that in the United Kingdom (Figure 2.1.1.7b), consistent with the later uptake of widespread cigarette smoking in the USA. The 54% decrease in death rates from lung cancer in this age range in the USA roughly equals the 51% decrease in age-specific smoking prevalence (Thun & Burns, 2001). Among men in France (Figure 2.1.1.7c), death rates from lung cancer have increased precipitously in men aged 35–44 years since 1950 and in women since 1985. It is plausible that the continued use of high-tar cigarettes may have influenced these patterns, but it is not possible to separate the effects of changing cigarette consumption from the effects of changing cigarette composition. A final example is that of Hungary, where death rates from lung cancer increased precipitously from 1960 to 1980 to levels exceeding the highest rates reported in the USA, and have subsequently declined (Figure 2.1.1.7d). A strength of the ecological data is that they suggest that the shift from very high-tar cigarettes to medium yield products may attenuate the lung cancer risk, as can be seen, for example, in men in the United Kingdom where this trend is not obscured by rapidly increasing lung cancer rates from increasing cigarette consumption. Limitations

Figure 2.1.1.7. Trends in lung cancer mortality rates in men and women, 35–44 years in a) USA, b) United Kingdom, c) France and d) Hungary

of the ecological studies are that such analyses lack data on individual exposure and outcomes and cannot control for potentially relevant covariates such as diet and air pollution.

The Working Group considered each of the lines of observational evidence that contribute to the assessment of the consequences of changes in cigarettes. Each has serious limitations that reflect the inherent difficulties of tracking the consequences of a single aspect of smoking that has varied over time concomitantly with other aspects of smoking, including intensity of smoking, particularly at younger ages. Successive birth cohorts have had differing profiles of exposure to cigarettes of differing characteristics. These patterns have varied between countries.

Nevertheless, after considering the limitations of the evidence, the Working Group concluded that changes in cigarettes since the 1950s have probably tended to reduce the risk for lung cancer associated with the smoking of particular numbers of cigarettes at particular ages. Supporting evidence for this conclusion came from the limited data from case–control and cohort studies on cigarette type and from the patterns of declining mortality rates from lung cancer among men in early middle age, particularly in the United Kingdom. However, the introduction of cigarettes that can be misperceived as 'safe' may well have adversely affected smoking uptake rates, cessation rates and consumption per smoker. Hence, the Working Group could not estimate the net impact of changes in cigarettes on national mortality rates. Moreover, there are still massive epidemics of lung cancer and other diseases caused by cigarette smoking in the United Kingdom, the USA and many other countries.

Differences in risk associated with type of tobacco, i.e. blond versus black, have been examined in case–control studies as summarized in Table 2.1.1.11. Relative risks are consistently higher among smokers of black tobacco than smokers of blond or mixed types.

(iv) *Histological type*

The major histological types of lung cancer are squamous-cell carcinoma, adenocarcinoma (including bronchioloalveolar), large-cell carcinoma and small-cell undifferentiated carcinoma. In the 1950s and 1960s, Doll *et al.* (1957) and Kreyberg (1962) found little or no relationship between tobacco smoking and adenocarcinoma. Similarly, early studies of bronchioloalveolar carcinoma reported no relation between tobacco smoking and this subtype of adenocarcinoma. Since that time a number of studies have examined this issue and are summarized in Table 2.1.1.13. In general, these more recent studies have demonstrated a statistically significant association and exposure–response relationship between tobacco smoke and all histological types of lung cancer. However, the association has been weaker historically for adenocarcinoma than for the other histological types of lung cancer.

There have been notable shifts over time in the incidence rates of lung cancer by histological type. In the initial decades of the smoking-related epidemic of lung cancer, squamous-cell carcinoma was the most common type of lung cancer observed among smokers and small-cell carcinoma was the next most common. In the USA, incidence

rates of adenocarcinoma increased steadily between 1973 and 1987, when adenocarcinoma supplanted squamous-cell carcinoma as the most frequent form of lung cancer (Travis *et al*., 1995). Similar increases in adenocarcinoma have been observed in Asia (Lam *et al*., 1987; Choi *et al*., 1994; Sobue *et al*., 1999) and in Europe (Levi *et al*., 1997; Russo *et al*., 1997).

A comparison of two large prospective cohort studies initiated by the American Cancer Society (CPS-I and CPS-II) in 1960 and 1980, respectively, indicates that the association between smoking and adenocarcinoma has strengthened in the most recent follow-up of these cohorts (Thun & Heath, 1997). The relative risk for adenocarcinoma increased for men from 4.6 (95% CI, 1.7–12.6) to 19.0 (95% CI, 8.3–47.7), and for women from 1.5 (95% CI, 0.3–7.7) to 8.1 (95% CI, 4.5–14.6) in CPS-I and CPS-II, respectively. The age-standardized rates for adenocarcinoma (44.2 for men and 18.1 for women per 100 000 person–years) were only slightly lower than the rates for squamous-cell carcinoma (60.2 for men and 21.7 for women) in the more recent study (CPS-II).

An association between cigarette smoking and bronchioloalveolar carcinoma has also been found (Morabia & Wynder, 1992; Falk *et al*., 1992; Morabia & Wynder, 1993).

The reasons for the increase in the incidence rate of adenocarcinoma in the general population and among smokers are unclear. One possible contributory factor may be related to advances in methods to detect tumours in the distal airways. Since the late 1960s, there have been a number of innovations that have probably improved the diagnosis of adenocarcinoma, such as flexible bronchoscopy, fine-needle aspiration and computerized scans. The histological classification of lung cancer has also improved. [The Working Group noted that these diagnostic advances would contribute to the rise in adenocarcinoma, but seem inadequate to explain the full increase and cannot explain the increased association with smoking.] There are no known risk factors other than smoking for adenocarcinoma of the lung that might explain the increase in incidence.

The other explanation that has been proposed is that changes in the formulation of cigarettes could have led to a the shift in histological type. The introduction of filter cigarettes in the 1950s may have resulted in deeper inhalation of smoke, and thus higher doses to the distal airways from which adenocarcinomas most commonly arise. In addition, blended reconstituted tobacco, introduced in the 1950s, releases higher concentrations of nitrosamines, which are known to induce adenocarcinomas in rodents (Hoffman & Hoffmann, 1997). Thun *et al*. (1997b) observed in an analysis of the Connecticut cancer registry data that there was a relationship between adenocarcinoma rates and birth cohort that peaked among people born between 1930 and 1939, which might be consistent with changes that occurred in filter usage and tobacco composition in the 1950s.

(*b*) *Population characteristics*

(i) *Lung cancer risk in women versus men*

There is currently inconsistent and inadequate epidemiological evidence to support the proposal that women are more susceptible than men to developing lung cancer as a

result of smoking. Several case–control (see Tables 2.1.1.5, 2.1.1.6, 2.1.1.8, 2.1.1.9, 2.1.1.10, 2.1.1.13) and cohort studies (Tables 2.1.1.1–2.1.1.3) have failed to show a greater relative risk in women (case–control studies: Higgins & Wynder, 1988; Lei *et al*., 1996; Xu *et al*., 1996; Yu & Zhao, 1996; Hu *et al*., 1997; Muscat *et al*., 1997; Jöckel *et al*., 1998; Wunsch-Filho *et al*., 1998; Kreuzer *et al*., 2000; Mao *et al*., 2001; Simonato *et al*., 2001; Stellman *et al*., 2001; cohort studies: Freund *et al*., 1993; Sidney *et al*., 1993; Islam *et al*., 1994; Nordlund *et al*., 1999), whereas several others have shown a greater relative risk among women (case–control studies: Gao *et al*., 1988; Hebert & Kabat, 1991; Risch *et al*., 1993; Yu & Zhao, 1996; Zang & Wynder, 1996; Pacella-Norman *et al*., 2002; cohort studies: Engeland *et al*., 1996a; Tulinius *et al*., 1997). What is most relevant is the absolute risk rather than the relative risk. All of the studies that postulate greater risk in women than men are cohort or case–control studies that have estimated relative risk, but not absolute risk (Risch *et al.*, 1993; Hoover, 1994; McDuffie, 1994; Wilcox, 1994). In a large prospective study, women have been shown to have lower death rates from lung cancer than do men within equivalent strata of age and smoking (Thun *et al*., 2000). Despite similar smoking characteristics among women and men up to and including early middle age in some countries in northern Europe, the lung cancer rates were the same in men and women (Nordlund *et al.*, 1999). Incidence rates for lung cancer in nonsmokers have generally been shown to be lower in women than men. This can result in large relative risks from an equivalent or even lower increase in absolute risk for lung cancer.

(ii) *Ethnicity*

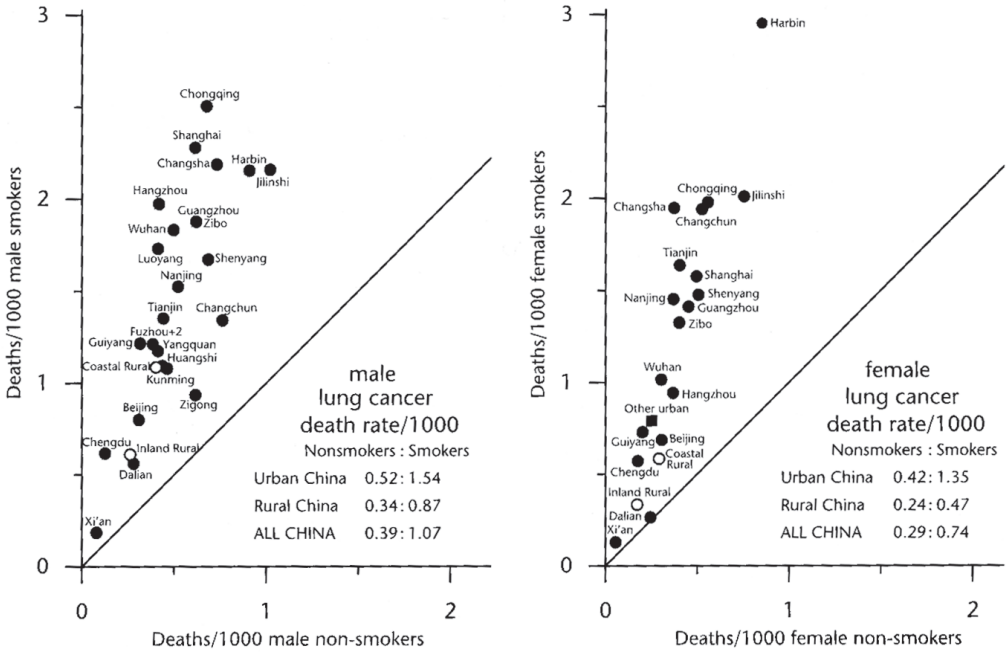
It has been postulated that susceptibility to lung cancer from tobacco smoking may differ by race and ethnicity. The best comparative data available are on risk in African Americans compared with risk in whites, and in Asian Americans compared with whites. Even for these groups, differences in nutritional and other factors between racial and ethnic groups complicate such comparisons.

African Americans versus Caucasians

Compared with white men, black men have a higher incidence of and death rate from lung cancer, younger age at diagnosis and shorter survival (Stewart, 2001). Furthermore, the racial and ethnic differences in smoking vary considerably depending on the parameter being measured. Black men and women begin smoking at a later age and consistently report smoking fewer cigarettes per day (Novotny *et al*., 1988). However, smoking prevalence has been higher in black than white men since 1950 (Burns *et al*., 1997) and the brands preferred by black smokers are more likely to be mentholated or to have higher machine-measured levels of nicotine and tar (King & Brunetta, 1999; Stellman *et al*., 2003). However, studies that have compared the risk associated with mentholated and non-mentholated cigarettes have not found any difference (Carpenter *et al.*, 1999). Black smokers have higher blood levels of cotinine, the main metabolite of nicotine, than do whites who smoke a similar number of cigarettes per day (Caraballo *et al*., 1998; King & Brunetta, 1999).

Several case–control studies have compared relative risks in whites with those in African Americans, especially in men (Harris *et al*., 1993; Schwartz & Swanson, 1997; Stellman *et al*., 2003). In a study that compared smokers of less than 41 pack–years with nonsmokers, African Americans had a higher relative risk than did whites aged 40–54 years (Schwartz & Swanson, 1997). In another study (Harris *et al.*, 1993), black smokers were at a higher risk only for Kreyberg II cancers. In the most recent study (Stellman *et al.*, 2003), similar risks for blacks and whites with similar smoking habits were reported.

Asians versus Caucasians



Comparisons of lung cancer risk in Caucasians with that in Chinese and Japanese populations are also perplexing. Absolute lung cancer rates were found to be high among nonsmoking women in certain areas of China, perhaps as a result of indoor cooking with poorly vented coal-fuelled stoves (Fraumeni & Mason, 1974; Law *et al*., 1976; Gao *et al*., 1988; Wu-Williams *et al*., 1990). Because of the high background rate, the absolute increase in risk for lung cancer among women who smoke in some areas of China is actually larger than the absolute increase in lung cancer risk among women who smoke in the USA. Peto *et al*. (1999) have demonstrated that the absolute death rate from lung cancer among female smokers in these areas in China is substantially higher than the average death rates from lung cancer among women in the USA (Figure 2.1.1.8; Thun *et al*., 1997c), despite a relative risk of approximately 2 associated with smoking in rural areas and a relative risk of 3 in urban areas.

The situation is substantially different in Japan, where lung cancer rates among men in the general population and among male smokers in large cohort studies (Wakai *et al*., 2001) remain lower than in North America (Stellman *et al*., 2001). Peto and others attribute this difference to the more recent initiation of regular heavy smoking, because consumption of cigarettes in Japan did not increase markedly until the 1970s, and the main increase in cigarette smoking prevalence occurred 40 years later in China than in the USA (Liu *et al*., 1998; Niu *et al*., 1998). However, the relative risk for lung cancer ranges between 3 and 5 among middle-aged women and men in the largely (95%) Chinese population of Hong Kong SAR, where cigarette smoking prevalence reached its peak about 20 years earlier than in mainland China (Lam *et al*., 2001). There is some evidence that differences in nicotine metabolism may contribute to differences in intensity of smoking between Caucasians and Chinese and Japanese. Benowitz *et al*. (2002) reported slower clearance and reduced intake of nicotine from cigarette smoking in Chinese-Americans than whites; they postulated that this may cause Asian smokers to smoke fewer cigarettes per day. This issue has yet to be resolved.

(*c*) *Lifetime probability that a smoker will develop lung cancer*

The lifetime probability that a smoker will develop lung cancer is conditional on life-time smoking practices and competing causes of death. The frequently quoted axiom that ‘only 10%’ of cigarette smokers develop lung cancer (Mabry *et al*., 1998) underestimated

Figure 2.1.1.8. Lung cancer mortality rates in male and female smokers and non-smokers aged 35–69 years in different parts of China, 1986–88

From Peto *et al.* (1999)

In comparison, the nationwide US lung cancer death rates in 1990, similarly standardized for age, were 1.4 per 1000 men and 0.6 per 1000 women, and 0.1 per 1000 male or female US nonsmokers.

the actual lifetime probability among smokers in the late twentieth century in countries such as the USA, where cigarette smoking has been entrenched for many decades and the death rates from competing conditions such as cardiovascular diseases have declined (Thun *et al*., 2002).

Mattson *et al*. (1987) estimated the probability that a male smoker, aged 35 years, would develop lung cancer by the age of 85 years if he continued smoking. In analyses of over 293 000 US Veterans followed from 1954 to 1962 (Kahn, 1966), it was estimated that 9.3% of men who smoked < 25 cigarettes per day and 17.9% of those who smoked ≥ 25 cigarettes per day at age 35 would develop lung cancer by the age of 85 years. This led to the estimate that 'only 10%' of smokers develop lung cancer (Mabry *et al*., 1998).

More recent studies indicate that the lifetime probability of a continuing cigarette smoker developing lung cancer has increased over time. Analyses of the American Cancer Society Cohort (CPS-II) have shown that the cumulative probability of death from lung cancer in male and female smokers aged ≥ 85 years, not conditioned on surviving other causes of death, reached 14.6% and 8.3%, respectively, compared with 1.1% among male and 0.9% among female lifelong nonsmokers of this age (Thun *et al*., 2002). If the impact

of competing causes of death were excluded from the calculation, the lifetime probabilities would be 24.1% and 11.0% in male and female smokers, respectively, and 1.6% and 1.1% in male and female never-smokers, respectively. The latter estimates are probably more relevant for estimating the fraction of genetically susceptible persons in the population than are the unconditional percentages, because they are independent of other causes of death. These estimates reflect only the risk of developing lung cancer from smoking; the estimates would be approximately 50% if they considered all of the conditions through which smoking causes premature death.

Falk *et al.* (1992)	USA, Louisiana	1979–82	Both sexes combined: 21/101	3/31	Cases: H Controls: H	Only bronchioloalveolar carcinomas. Matched by hospital, race, sex and age (5:1)
Jedrychowski *et al.* (1992)	Poland, Cracow	Jan. 1980–Dec. 1987	Men: 627/1343	16/289	Cases: P Controls: P (death certificates)	Interviews with next-of-kin; matched on sex, age and date of death
Jöckel *et al.* (1992)	Germany, 5 cities, 7 hospitals	Not stated	Men: 146/146/146 Women: 48/48/48	3/32/22 10/31/21	Cases: H Controls: H/P	Matched by sex and age
Liu (1992)	China: Beijing, Shenyang, Harbin, Shanghai, Nanjing, Shengzou, Taiyuan, Nanchang	1984–89	Both sexes combined: 4081/4338	1151/1979	Cases: P (7 studies)/H (1 study) Controls: P (7 studies)/ H (1 study)	Combined analysis of 8 studies; matched on age and sex
Lubin *et al.* (1992)	China, Yunnan, Gejiu	1984–88	Men: 427/1011	9/72	Cases: P Controls: P	Matched on age; city residents and Yunnan Tin Corporation workers
Morabia & Wynder (1992)	USA	1977–89	Both sexes combined: 87/286 non-cancer/ 297 cancer	15/97 non-cancer/122 cancer	Cases: H Controls: H	Only bronchioloalveolar carcinomas. Matched on sex, race, age, hospital, date of interview
Zang & Wynder (1992)	USA	1981–88	Men: 1380/2828 Women: 916/1839	51/820 83 /899	Cases: H Controls: H	Matched by age, sex, race and time of admission

Table 2.1.1.4 (contd)

Reference	Country	Study years	No. of cases/controls	No. of nonsmokers (cases/controls)	Source of cases and controls	Comments
Gao *et al*. (1993)	Japan, Nagoya	Jan. 1988–June 1991	Men: 282/282	13/56	Cases: H Controls: H	Matched by sex, age and date of first visit to the hospital
Ger *et al*. (1993)	China, Province of Taiwan	May 1990–July 1991	Men: 92/184/184 Women: 39/78/78	Both sexes combined: 48/111/118	Cases: H Controls: H/ neighbourhood	Matched on age, sex, date of interview and insurance status (H); age, sex and residence (neighbourhood)
Harris *et al*. (1993)	USA	1980–90	Men: white 2678/2445 black 238/169 Women: white 1394/1418 black 113/139	 83/581 4/36 145/776 14/80	Cases: H Controls: H	Controls matched by sex, race, age and year of interview
Hegmann *et al*. (1993)	USA, Utah	Oct. 1989–May 1991	Men: 182/2195 Women: 100/1087	Both sexes combined: 27/2080	Cases: P (cancer registry) Controls: P	Frequency-matched on age and sex
Liu *et al*. (1993)	China	June 1983–June 1984	Men: 224/224 Women: 92/96	12/44 38/69	Cases: H Controls: H	Individually matched on age, sex, residence and date of diagnosis/hospital admission
Osann *et al*. (1993)	USA, Orange County	Jan. 1984–Dec. 1986	Men: 1153/1851 Women: 833/1656	45/833 96/1093	Cases: H Controls: H	Data extracted from medical records
Pezzotto *et al*. (1993)	Argentina, Rosario	1987–91	Men: 215/433	4/116	Cases: H Controls: H	Matched on age
Risch *et al*. (1993)	Canada	Jan. 1981–March 1985	Men: 403/362 Women : 442 /410	12/85 52/214	Cases: H Controls: P	Male cases matched to female cases; controls matched on sex, residence and age
Agudo *et al*. (1994)	Spain	1989–92	Women: 103/206	80/183	Cases: H Controls: H	Matched for age at diagnosis, hospital and interviewer

Table 2.1.1.4 (contd)

Reference	Country	Study years	No. of cases/controls	No. of nonsmokers (cases/controls)	Source of cases and controls	Comments
Benhamou & Benhamou (1994)	France	1976–80	Men: 1334/2409 Women: 96/192	36/650 50/159	Cases: H Controls: H	Matched on age, sex, hospital and interviewer
Benhamou *et al*. (1994)	France	1976–80	Men: 1114/1466	Only lifelong smokers	Cases: H Controls: H	
De Stefani *et al*. (1994)	Uruguay, Montevideo	Jan. 1989–Dec. 1992	Men: 476/561	Only former and current smokers	Cases: H Controls: H	
Miller *et al*. (1994)	USA, Erie County, PA	1972–76, 1979–84	Women: 168/5235	28/3638	Cases: P Controls: P (deaths)	Nested in a retrospective population study
Sankanarayanan *et al*. (1994)	India, Trivandrum	1990	Men: 281/1207	28/767	Cases: H Controls: visitors and patients' bystanders	
Shimizu *et al*. (1994)	Japan, Tokyo	1973–91	Men: 413/82 Women: 192/101	37/65 43/21	Cases: H Controls: H	Information from hospital records; controls were patients with metastatic lung cancer
Sobue *et al*. (1994)	Japan, Osaka	Jan. 1986–Dec. 1988	Men: 1082/1141 Women: 294/1089	34/128 167/857	Cases: H Controls: H	Methods for selection of controls not stated
Suzuki *et al*. (1994)	Rio de Janeiro, Brazil	Aug. 1991–Feb. 1992	Men: 99/99 Women: 24/24	Both sexes combined: 11/55	Cases: H Controls: H	Matched on age, sex and race
Alavanja *et al*. (1995)	USA, Missouri	1986–92	Women: lifetime nonsmokers, 432/1168 long-term former smokers, 186/234	Not applicable	Cases: P Controls: P	Excludes current smokers A cancer group was also used as control, but data are not shown in tables
Siemiatycki *et al*. (1995)	Canada	Sept. 1979–June 1985	Men: 857/533	13/105	Cases: H Controls: P	Age-stratified, matched to age distribution of cases
De Stefani *et al*. (1996a)	Uruguay, Montevideo	May 1994–Dec. 1995	Men: 307/307 Women: 13/13	Both sexes combined: 20/108	Cases: H Controls: H	Frequency-matched on age and residence (urban/rural)

Table 2.1.1.4 (contd)

Reference	Country	Study years	No. of cases/controls	No. of nonsmokers (cases/controls)	Source of cases and controls	Comments
De Stefani *et al*. (1996b)	Uruguay, Montevideo	Jan. 1988–Dec. 1994	Men: 497/497	27/163	Cases: H Controls: H	Matched on sex, age and residence
Du *et al*. (1996)	China, Guangzhou	1985	Men: 566/566 Women: 283/283	Not given	Cases and controls: death registry	Review of published studies, with some updated data Matched on age, sex, race, hospital and date of admission
Kabat (1996)	USA	1969–91	Both sexes combined: 7553/17 992	Men: 2085/3951 Women: 1012/1891	Cases: H Controls: H	Matched on age, sex, race, hospital and date of admission
Lei *et al*. (1996)	China, Guangzhou	1986	Men: 563/563 Women: 229/229	41/123 85/147	Cases: P Controls: P	Matched on sex and closest birth date
Luo *et al*. (1996)	China, Fuzhou	1990–91 (1.5 years)	Both sexes combined: 102/306	37/160	Cases: H Controls: P	Frequency-matched by age and sex
Rylander *et al*. (1996)	Sweden	Jan. 1989–June 1993	Men: 308/644	16/160	Cases: H Controls: P	Matched by closest birth date, sex and residence
Shen *et al*. (1996)	China, Nanjing	1986–93	Both sexes combined: 163/163	No data	Cases: H Controls: P	Matched on age, sex, nationality and street of residence
Wang *et al*. (1996)	China, Guangzhou, Guangdong	1990–93	Men: 291/291 Women: 99/99	29/no data 82/no data	Cases: H Controls: H	Matched on sex, residence, education and age
Xu *et al*. (1996)	China, Shenyang, Liaoning	Sept. 1985–Sept. 1987	Men: 729/788 Women: 520/577	No data	Cases: P Controls: P	'Age and sex distribution of controls closely matched those of cases'
Yu & Zhao (1996)	China	1981–90	Both sexes combined: 5703/5669	1766/2644	Meta-analysis 15 studies	Matched on age, sex and residence

Table 2.1.1.4 (contd)

Reference	Country	Study years	No. of cases/controls	No. of nonsmokers (cases/controls)	Source of cases and controls	Comments
Zang & Wynder (1996)	USA	1981–94	Men: 1108/1122 Women: 781/948	*Men* SCC [2.3%†] AC [10.0%†] SCLC [0.0%†] Controls [52.6%†] *Women* SCC [7.3%†] AC [15.1%†] SCLC [2.1%†] Controls [71.0%†]	Cases: H Controls: H	Individually matched by age, sex, hospital and time of admission †% of nonsmokers for each histological type of lung cancer and % of nonsmoking controls
Barbone *et al*. (1997)	Italy, Trieste	1979–81; 1985–86	Men: 755/755	22/188	Cases and controls: autopsies	Matched on age and period of death
Dosemeci *et al*. (1997)	Turkey, Istanbul	1979–84	Men: 1210/829	142/293	Cases: H Controls: H	Matched by sex, age (within 5 years) and area of residence
Hu *et al*. (1997)	China, Heilongjiang	May 1985–April 1987	Men: 161/161 Women: 66/66	41/40 67/48	Cases: H Controls: H	Only large-cell cancer
Muscat *et al.* (1997)	USA	1980–95	Men: 228/2545 Women: 154/1715	7/650 13/936	Cases: H Controls: H	Only large-cell carcinoma Frequency-matched by age, sex, hospital and date of interview
Pawlega *et al*. (1997)	Poland, Cracow	Jan. 1992–Dec. 1994	Men: 176/341	4/92	Cases: P Controls: P	Matched by age
Pohlabeln *et al*. (1997)	Germany, Bremen, Frankfurt	1988–93	Men: 839/839	18/138	Cases: H Controls: P	Matched for age, sex and region
Rachtan & Sokolowski (1997)	Poland, Cracow	March 1991–June 1994	Women: 118/141	33/98	Cases: H Controls: H	Controls were next of kin of patients with diseases unrelated to smoking

Table 2.1.1.4 (contd)

Reference	Country	Study years	No. of cases/controls	No. of nonsmokers (cases/controls)	Source of cases and controls	Comments
Schwartz & Swanson (1997)	USA, Detroit, Michigan	Nov. 1984–June 1987	Men: white: 2767/1395 African American: 913/379 Women: white 1533/1492 African American: 375/426	 119/376 50/104 182/855 40/247	Cases: P Controls: P	African Americans compared with whites
Stellman *et al*. (1997a)	USA	1997–95	Men: 1442/876 Women: 850/467	Only current smokers	Cases: H Controls: H	Frequency-matched on age, sex, hospital and date of admission
Stellman *et al*. (1997b)	USA	1997–95	Men: 1366 SCC/ 1332 AC/3442 controls Women: 431 SCC/982 AC/ 2190 controls	Men: SCC 2%† AC 5.4%† Women SCC 6%† AC 15% † Controls: No data	Cases: H Controls: H	Frequency-matched on age, sex, hospital and date of admission †% of nonsmokers for each histological type of lung cancer
Wakai *et al*. (1997)	Japan, Okinawa	Jan. 1998–Nov. 1991	Men: 245/490 Women: 88/176	10/65 50/145	Cases: H Controls: P	Matched by sex, region and age; nonsmokers included occasional smokers
Jöckel *et al*. (1998)	Germany, Bremen, Frankfurt	1989–93	Men: 839/839 Women: 165/165	18/138 53/98	Cases: H Controls: P	Adjusted for age, region and exposure to asbestos
Khuder *et al*. (1998)	USA, Philadelphia	1985–87	Men: 482/1094	23/309	Cases: H Controls: P	Matched by race and age
Kreuzer *et al*. (1998)	Germany	1990–96	Men: young: 183/200 older: 1709/1761 Women: young: 68/80 older: 300/278	 6/54 22/403 7/38 95/177	Cases: H Controls: P	Cancer in young adults Frequency-matched on sex, age and region

2.1.2 *Cancer of the lower urinary tract*

The 'lower urinary tract' comprises the renal pelvis, ureter, bladder and urethra. Cancers originating in the urothelium at these sites are mostly transitional-cell carcinomas or squamous-cell carcinomas. These cancers are discussed together, unless a particular distinction has been made in the studies that were considered.

In the previous *IARC Monograph* on tobacco smoking (IARC, 1986), cancer of the lower urinary tract was identified as being causally associated with cigarette smoking.

(*a*) *Analytical studies*

Results in support of the association of cigarette smoking with cancer of the lower urinary tract have been reported from cohort studies conducted in the United Kingdom (British Doctors' Study), Sweden (Swedish Twin Registry Study, Swedish Census Study), Norway (Norwegian Cohort Study), Iceland (Reykjavík Study), the USA (American Cancer Society Study, US Veterans' Study, Californian Study, Cancer Prevention Study I, American Men of Japanese Ancestry Study, MRFIT Study, Adventists' Health Study), Canada (Canadian War Veterans' Study), China (Shanghai Men's Study), China, Province of Taiwan (Taiwanese Study), Japan (Life Span Study, Six-prefecture Study, Chiba Center Association Study). The design of these studies is described in the introduction to Section 2 and Table 2.1.

The designs of the available case–control studies are summarized in Table 2.1.2.1.

With the exception of the study by Anthony and Thomas (1970), in Leeds (United Kingdom) and the very small study of Liaw and Chen (1998) in China, Province of Taiwan, all the others have shown an association between cancer of the lower urinary tract and cigarette smoking. Irrespective of the design (cohort, hospital-based or population-based case–control), all other studies have found a positive association, and this overall result cannot be explained by bias. Potential confounders — in addition to age and gender — that may be considered are certain occupational exposures, particularly to aromatic amines, and schistosomiasis in developing countries.

However, Akiba and Hirayama (1990) and Momas *et al.* (1994a) reported estimates adjusted by occupation, which did not differ from other estimates. Two studies from Egypt (Makhyoun, 1974; Bedwani *et al*., 1998) and one study from Zimbabwe (Vizcaino *et al*., 1994) investigated smoking after stratification by bilharziasis (schistosomiasis); the risk of cancer of the lower urinary tract in smokers remained elevated after adjustment for urinary bilharziasis.

(i) *Number of cigarettes smoked and duration of cigarette smoking*

Tables 2.1.2.2 and 2.1.2.3 give the relative risks according to average daily number of cigarettes smoked. One case–control study conducted in Leeds, United Kingdom (Cartwright *et al*., 1983), failed to show a clear-cut dose–response relationship in men, although a statistically significant overall relative risk of 1.6 was found. [The Working

Group noted that the control group used in this study included patients with tobacco-related diseases, a choice that could have biased the result.] Considerable variations in the relationship between relative risks and average daily number of cigarettes smoked are evident. For male smokers of more than 20 cigarettes/day, the relative risks tend to be around 5.0 or higher in studies in Europe, and lower in studies in America and Japan. High estimates have been reported in particular from Uruguay (De Stefani *et al*., 1991), France (Clavel *et al*., 1989; Momas *et al*., 1994b), Denmark (Lockwood, 1961) and Italy (Vineis *et al*., 1984; Donato *et al*., 1997).

Twelve of the 42 studies with a case–control design and 10/24 of those with a cohort design reported a levelling-off of the dose–response curve. This phenomenon can be interpreted either as an effect of bias (underestimation of consumption by heavy smokers) or as a genuine effect, due, for example, to the saturation of metabolic enzymes (Vineis *et al*., 2000). [The Working Group noted that the wide variations in the dose–response relationship could be explained by a number of factors, namely, different study designs, different ways of smoking or different types of tobacco smoked. It was noted that the apparent levelling-off of the dose–response curve could reflect an artefact in data collection, due to under-reporting of levels of consumption by the interviewees.]

The 24 cohort studies have consistently shown an excess of deaths from bladder cancer among smokers; the relative risks were between 3.0 and 5.4 for smokers of 20 or more cigarettes/day (Table 2.1.2.2).

Duration of cigarette smoking showed a positive relationship with relative risks for bladder cancer in all the studies that have examined it (Table 2.1.2.4). Also, age at starting smoking (Table 2.1.2.4) has been found to be positively associated with risk; smokers who started smoking at an earlier age were at a higher risk for bladder cancer. However, duration, age at starting and age at stopping are closely correlated variables, and few studies have tried to disentangle them (Hartge *et al*., 1993).

When cancers of the renal pelvis and of the ureter are considered separately, a dose–response relationship with daily or cumulative consumption of tobacco is found, and relative risks are similar to those reported for cancer of the bladder (McCredie *et al*., 1982, 1983; McLaughlin *et al*., 1983, 1992).

(ii) *Effect of stopping cigarette smoking*

A lowering of risk after stopping cigarette smoking is seen in almost all the studies (Table 2.1.2.5), and it is particularly evident from studies conducted in the USA (Kahn, 1966; Wynder & Goldsmith, 1977; Rogot & Murray, 1980; Morrison *et al*., 1984; Mills *et al*., 1991), Canada (Howe *et al*., 1980), France (Clavel *et al*., 1989), Italy (Vineis *et al*., 1984; D'Avanzo *et al*., 1990; Donato *et al*., 1997), Germany (Pommer *et al*., 1999), the United Kingdom (Doll & Peto, 1976; Cartwright *et al.*, 1983; Morrison *et al*., 1984), Japan (Morrison *et al*., 1984) and Sweden (Steineck *et al*., 1988).

(iii) *Type of cigarette and effect of inhaling*

In six studies (Vineis *et al.*, 1984; Clavel *et al*., 1989; D'Avanzo *et al*., 1990; De Stefani *et al*., 1991; Lopez-Abente *et al*., 1991; Momas *et al*., 1994b) (Table 2.1.2.6), separate estimates were reported for the relative risks for lower urinary tract cancers for smokers of black (air-cured) and blond (flue-cured) tobacco. Relative risks for smokers of black tobacco were 1.5 to two times higher than those for smokers of blond tobacco, after adjustment for age, occupation, average daily consumption of cigarettes, years since stopping and use of a filter tip.

A strong effect of inhaling was shown in the studies by Clavel *et al*. (1989) and Lopez-Abente *et al*. (1991). A slight effect of inhaling was reported by Cole *et al*. (1971), Howe *et al.* (1980), Morrison *et al*. (1984) and Burch *et al*. (1989) but not by Lockwood (1961) (Table 2.1.2.6).

The effects of filter-tipped cigarettes have been analysed in several studies, with conflicting results (Table 2.1.2.7). A weak effect of filter-tipped cigarettes was reported by Howe *et al.* (1980), Cartwright *et al.* (1983), Vineis *et al*. (1984), López-Abente *et al*. (1991) and De Stefani *et al*. (1991), whereas no difference between the effects of smoking filter-tipped and untipped cigarettes was found in the studies by Wynder and Goldsmith (1977), Morrison *et al*. (1984) or Momas *et al*. (1994b).

(iv) *Histology*

Almost all of the cancers of the lower urinary tract encompassing bladder, renal pelvis and ureter are transitional-cell cancers in industrialized countries, but squamous-cell carcinomas are common in developing countries. One pooled analysis by Fortuny *et al.* (1999) (Table 2.1.2.3) considered non-transitional-cell bladder cancers, mainly epidermoid cancers, and found elevated relative risks in association with smoking and a positive dose–response relationship. A small study in Zimbabwe (Vizcaino *et al*., 1994) found that the association with smoking was present (but not statistically significant) only in transitional-cell carcinomas.

(*b*) *Population characteristics*

(i) *Effect of gender*

Tables 2.1.2.2 and 2.1.2.3 show the relative risks according to the number of cigarettes smoked, by gender. There are only slight differences between men and women, and this holds true for subsequent tables. The differences seem to be attributable more to chance (specifically because there have been fewer studies among women) than to real differences in susceptibility to the effects of tobacco smoking.

A population-based study was conducted in Los Angeles, USA, with the aim of addressing the gender differences in susceptibility to bladder cancer (Castelao *et al*., 2001). The risk for women was statistically significantly higher than that for men ($p = 0.016$ for interaction). Biochemical evidence was also provided: the slopes of the regression lines of 3-aminobiphenyl (3-ABP–) and 4-ABP–haemoglobin adducts by

number of cigarettes smoked per day were statistically significantly steeper in women than in men ($p < 0.001$ and 0.006, respectively).

(ii) *Effect of race/ethnicity*

Two studies considered the dose–response relationship in both whites and blacks living in the USA (Dunham *et al.*, 1968; Burns & Swanson, 1991). One study was conducted in Egypt (Makyoun, 1974), one in Iran (Sadeghi *et al.*, 1979), and several were conducted among Asians (e.g. Hirayama, 1977; Morrison *et al*., 1984; Akiba & Hirayama, 1990; Yuan *et al*., 1996). The differences between the various races and ethnic groups observed for the dose–response relationship are compatible with chance variation.

(*c*) *Pooled analysis*

The original data from 11 of the case–control studies of bladder cancer together with those from one unpublished study have been analysed together as part of a pooled analysis consisting of 3285 cases of bladder cancer (2600 men, 685 women) and 7940 controls (5524 men, 2416 women) (Brennan *et al.*, 2000, 2001). These studies were selected as they were participating in a parallel reanalysis of data on occupational exposures and bladder cancer in Europe. Two case–control studies each were from France, Spain and Italy, three from Germany and one each from Denmark and Greece (Vineis *et al*., 1985; Rebelakos *et al*., 1985; Claude *et al*., 1986; Jensen *et al*., 1987; Lopez-Abente *et al*., 1991; Clavel *et al*., 1989; Bolm-Audorff *et al.*, 1993; Hours *et al*., 1994; Greiser & Molzahn, 1997; Donato *et al*., 1997; Serra *et al*., 2000). All studies included both men and women.

(i) *Duration of smoking*

An increasing risk of bladder cancer was observed with increasing duration of smoking. The relationship appeared to be approximately linear for both men and women. The relative increase in risk was approximately 100% after 10–19 years of smoking (odds ratio, 2.0; 95% CI, 1.5–2.6 for men; odds ratio, 2.2; 95% CI, 1.4–3.5 for women), 200% after 20–29 years of smoking (odds ratio, 3.1; 95% CI, 2.5–3.9 for men; odds ratio, 2.5; 95% CI, 1.7–3.8 for women) and 300% after 40 years of smoking (odds ratio, 3.8; 95% CI, 3.1–4.6 for men; odds ratio, 3.9; 95% CI, 2.8–5.4 for women).

(ii) *Intensity of smoking*

A dose–relationship was observed between number of cigarettes smoked per day and bladder cancer up to an apparent threshold of 15–19 cigarettes per day (odds ratio, 4.5; 95% CI, 3.8–5.3 for men; odds ratio, 3.8; 95% CI, 2.7–5.4 for women), after which a plateau in the risk was observed for both male and female smokers of more than 20 cigarettes per day.

(iii) *Smoking cessation*

An immediate decrease in risk of bladder cancer was observed among men who gave up smoking. Compared with current smokers, this fall was close to 40% for male smokers who had stopped smoking between 1 and 4 years prior to diagnosis (odds ratio, 0.65;

95% CI, 0.53–0.79) and reached 60% after 25 years of cessation (odds ratio, 0.37; 95% CI, 0.30–0.45). However, even after 25 years, the risk was not as low as that for non-smokers (odds ratio, 0.20; 95% CI, 0.17–0.24). Among women, the immediate decrease in risk was approximately 30% for smokers who stopped smoking between 1 and 4 years prior to diagnosis. The risk did not appear to decrease substantially after this and, even after 25 years of cessation, it remained considerably above the level found for never-smokers.

(iv) *Attributable fraction*

The proportion of bladder cancer cases attributable to ever smoking, i.e. the population attributable risk (PAR), was calculated as 0.66 for men (95% CI, 0.61–0.70) and 0.30 (95% CI, 0.25–0.35) for women. Similarly, the PAR of bladder cancer cases attributable to current smoking was calculated as 0.32 (95% CI, 0.28–0.35) for men and 0.18 (95% CI, 0.14–0.22) for women. [The Working Group noted that the lower attributable proportions among women reflect the earlier stage of the smoking-related disease epidemic among women, and these attributable fractions may be expected to increase in the future as this epidemic becomes more widespread among women.]

Table 2.1.2.1. Case–control studies on tobacco smoking and lower urinary tract cancer: main characteristics of study design

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Lilienfeld *et al*. (1956) USA 1945–55	Men: 321 cases and 663 controls; women: 118 cases and 1205 controls	Hospital-based study; controls: 287 men with prostate cancers, 39 men with benign bladder conditions and 337 healthy men; 776 women with breast cancers, 110 women with benign bladder conditions and 319 healthy women
Lockwood (1961) Denmark 1956–57	Men: 282 cases and 282 controls; women: 87 cases and 87 controls	Population-based study; living cases from the Danish Cancer Registry (1956–57); controls selected from Population Registry
Schwartz *et al*. (1961) France Study started in 1954	Men: 214 cases and 214 controls	Hospital-based study; age-matched controls were subjects admitted to hospitals for accidents
Wynder *et al*. (1963a) USA 1960–61	Men: 300 cases and 300 controls; women: 70 cases and 70 controls	Hospital-based study, papillomas excluded; sex- and age-matched controls: cancers of respiratory system, upper alimentary tract and myocardial infarction excluded
Cobb & Ansell (1965) USA 1951–61	Men and women: 136 cases and 342 controls	Hospital-based study; 120 colon cancer controls and 222 controls with 'pulmonary problems'; data on smoking available for 131 cases
Staszewski (1966) Poland 1958–64	Men: 150 cases and 750 controls	Hospital-based study; age-matched controls with cancer or other diseases
Dunham *et al*. (1968) USA 1958–64	Men: 334 cases and 350 controls; women: 159 cases and 177 controls	402 incident cases in New Orleans and 91 prevalent cases or cases not living in the city; hospital controls, including unspecified numbers of patients with bronchitis, emphysema, myocardial infarction; 162 (29%) of eligible cases not interviewed
Anthony & Thomas (1970) UK 1958–67	Men: 381 cases and 275 controls	Hospital-based study; surgical controls (excluding patients with chest, genitourinary and malignant disease) in 1955–58

Table 2.1.2.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Cole *et al*. (1971) USA 1967–68	Men: 360 cases and 381 controls; women: 108 cases and 117 controls	Cases randomly selected among all (668) eligible incident cases occurring in 1967–68 in 87 cities of the Boston area (20–89 years old); controls: random sample of 20–89-year-old residents, matched for sex and age; interviews of 140/470 cases and 78/500 controls conducted with spouse or next of kin
Tyrell *et al.* (1971) Ireland 1967–68	Men: 200 cases and 200 controls; women: 50 cases and 50 controls	Hospital-based study; age- and sex-matched urological controls
Makhyoun (1974) Egypt 1966–71	Men: 365 cases and 365 controls	Hospital-based study; age-matched non-cancer controls; 278 cases and 278 matched controls had previous urinary bilharziasis
Morgan & Jain (1974) Canada	Men: 158 cases and 158 controls; women: 74 cases and 74 controls	Hospital-based study; controls matched for sex and age; postal questionnaires: responses were 67% (cases) and 57% (controls) among men; 73% (cases) and 57% (controls) among women
Schmauz & Cole (1974) USA	Men: 18 cases and 376 controls	Population-based study of cancer of the renal pelvis and ureter (see Cole *et al*., 1971, for design)
Wynder & Goldsmith (1977) USA 1969–74	Men: 574 cases and 574 controls; women: 158 cases and 158 controls	Hospital-based study on cases aged 40–80 years and controls matched for sex, ethnic group, hospital and age; controls had no 'tobacco-related condition'.
Miller *et al*. (1978) Canada	Men: 188 cases and 564 controls; women: 77 cases and 231 controls	Hospital-based study, using self-completed questionnaires of subjects over 40 years; two sex- and age-matched controls for each case
Sadeghi *et al*. (1979) Iran 1969–76	Men: 88 cases and 88 controls	Hospital-based study; sex- and age-matched hospital controls; patients with cancer, pulmonary and bladder disease excluded (23/122 cases excluded due to poor information)

Table 2.1.2.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Howe *et al*. (1980) Canada 1974–76	Men: 480 cases and 480 controls; women: 152 cases and 152 controls	Population-based study; eligible cases were all patients with newly diagnosed bladder cancer in 3 Canadian provinces (77% interviewed); controls matched for sex, age and neighbourhood (controls who refused were substituted); male cases had a higher level of education and income than controls.
Tola *et al*. (1980) Finland 1975–76	Men: 134 cases and 134 controls; women: 46 cases and 46 controls	Originally eligible cases were all those (274) reported to the Finnish Cancer Registry for 5 Finnish provinces; postal questionnaires sent to 269 cases and 271 sex- and age-matched hospital controls or their relatives; response rates were 80% (cases) and 81% (controls); source of information was a relative for 39% of cases and 12% of controls.
McCredie *et al*. (1982) Australia 1977–80	Men: 27 cases and 70 controls; women: 40 cases and 110 controls	Cancer registry and hospital-based study; renal pelvis cancer cases; first control group were friends or relatives of other patients; second control group were subjects attending a screening clinic; 24 cases interviewed by their doctors, remaining cases and all controls interviewed by researchers; higher socio-economic status among screening clinic controls
Najem *et al*. (1982) USA 1978	Men: 65 cases and 123 controls; women: 10 cases and 19 controls	Hospital-based study; prevalent cases only; 2 controls per case matched for sex, age, ethnic group, place of birth and place of residence (patients with cancer and tobacco-related heart disease excluded)
Cartwright *et al*. (1983) UK 1978–81	Men: 932 cases and 1402 controls; women: 327 cases and 579 controls	90% of incident cases in West Yorkshire (1978–81) and prevalent cases included; sex- and age-matched hospital controls (25% arterial disease; 60% accident, minor surgery; 10% chest conditions)

Table 2.1.2.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
McCredie *et al*. (1983) Australia 1977–82 (ureter), 1980–82 (renal pelvis)	Men: 65 cases and 307 controls	Population-based (cancer registry) study; cancers of the ureter (36 cases) and renal pelvis (29 cases) only; controls were a random sample of the general population; questionnaires posted to cases and controls (no. of non-respondents not given); higher educational level among controls
McLaughlin *et al*. (1983) USA 1974–79	Men: 50 cases and 428 controls; women: 24 cases and 269 controls	Population-based study on cancer of the renal pelvis (71/74 were transitional-cell carcinomas); controls were (1) a random sample of the general population and (2) a group of deceased individuals matched to the deceased cases
Møller-Jensen *et al*. (1983) Denmark 1979–81	Men: 286 cases and 574 controls; women: 95 cases and 193 controls	Cases, two-thirds of all incident cases in Greater Copenhagen (under age 75 years); controls, a random sample of the general population (out of 1052 controls approached, 109 refused, 114 were not located and 39 were too ill)
Mommsen & Aagaard (1983) Denmark 1977–79 (men), 1977–80 (women)	Men: 165 cases and 165 controls; women: 47 cases and 94 controls	Population-based study; controls: random sample of general population; cases interviewed in hospital, controls by phone
Morrison *et al*. (1984) Japan and UK, 1976–78; USA, 1976–77	Men: Greater Manchester, 398 cases, 490 controls; Nagoya (Japan), 224 cases, 442 controls; Boston area, 427 cases, 391 controls Women: Greater Manchester, 155 cases, 241 controls; Nagoya, 66 cases, 146 controls; Boston area, 165 cases, 142 controls	Population-based study in Japan, UK and USA; 96% (Manchester), 84% (Nagoya) and 81% (Boston) of all incident cases (aged 21–89 years) were interviewed; controls were randomly selected from electoral registers; in Nagoya most cases were interviewed in hospital, all other groups at home; 95% of tumours were of the bladder.

Table 2.1.2.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Vineis *et al*. (1984) Italy 1978–83	Men: 512 cases and 596 controls	Hospital-based study; 210/512 prevalent cases; 225 age-matched controls (with urological disease); 287 cases and 371 unmatched controls from surgical departments (87 hernias, 41 peripheral arteriopathies and other diagnoses)
Rebekalos *et al.* (1985) Greece 1980–82	Men: 250 cases and controls; women: 50 cases and controls	Hospital-based study. Histologically confirmed cases of bladder cancer. Sex- and age-matched controls from accidents centre of another hospital (traumatic fractures, 185; other traumatic conditions, 30; osteoarthrosis, 32; rheumatoid arthritis, 28; other orthopaedic conditions, 24).
Claude *et al.* (1986) Germany 1977–82	Men: 340 cases and controls; women: 91 cases and controls	Hospital-based study; 21% of controls selected from homes for the elderly. Interviews carried out by medical students using a standardized questionnaire. 90% of cases had bladder tumours (remainder had cancers of renal pelvis, ureter or urethra or combinations of these). Male controls had prostate adenomas and infections (70%), urinary tract infections (20%). Female controls had urinary tract infections (68%) or no particular illness (24%).
Burch *et al.* (1989) Canada 1979–82	781 cases and 781 matched controls	Population-based study. Only 67% of eligible cases were interviewed. Response rate for controls, 53%.
Clavel *et al.* (1989) France 1984–87	477 cases and 477 matched controls	Hospital-based study using interview; 157 prevalent cases; controls: patients with tobacco-related conditions were excluded. Refusal rate not given
D'Avanzo *et al.* (1990) Italy 1985–89	337 cases and 392 controls	Hospital-based study using interviews. Refusals < 3%. Controls had trauma (30%), orthopaedic conditions (17%) and surgical conditions.

Table 2.1.2.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Harris *et al*. (1990) USA 1969 onwards	White men: 1114 cases, 3252 controls; black men, 84 cases, 271 controls; white women: 420 cases, 1289 controls; black women, 45 cases, 118 controls	Hospital-based study. Incident cases. Controls included gastrointestinal disease, infections, leukaemia, benign prostatic hypertrophy, benign neoplastic disease, other cancers and other causes. Controls were matched on sex, age, race, year of interview and hospital of diagnosis.
Burns & Swanson (1991) USA	White men: 1410 cases, 1615 controls; black men: 161 cases, 382 controls; white women: 504 cases, 1600 controls; black women, 85 cases, 382 controls	Population-based study; controls: incident cases of colorectal cancer. Telephone interviews. Response rates, 94% (cases) and 95% (controls)
De Stefani *et al*. (1991) Uruguay 1987–89	Men: 91 cases and 182 controls; women: 20 cases and 40 controls	Hospital-based study, only incident cases; 29% of controls had malignant tumours, 22% eye diseases. No refusals
López-Abente *et al*. (1991) Spain 1983–86	430 cases, 405 hospital controls and 386 population controls	Hospital and population-based study; 49% were prevalent cases. Controls matched by sex and age. Refusals: 5% of cases, 7% of hospital controls, 7% of population controls. Hospital controls: patients with tobacco-related diagnoses excluded
Kunze *et al*. (1992) Germany 1977–85	Men: 531 cases and 531 controls; women: 144 cases and 144 controls	Hospital-based study. Controls matched by sex and age; diagnoses included prostate hyperplasia (64% of men) or infection of urinary tract (73% of women)
McLaughlin *et al.* (1992) USA 1983–86	Men: 331 cases and 315 controls; women: 171 cases and 181 controls	Population-based study in New Jersey, Iowa and California. Incident cases of cancers of the renal pelvis and ureter, microscopically confirmed, aged 20–79 years, identified using the local population-based cancer registries; 58% of ascertained cases participated. Controls selected by random-digit dialling (< 65 years) or Health Care Financial Administration rosters (≥ 65 years), frequency-matched on age (5-year groups) and sex; response rate, 54–66%

Table 2.1.2.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Hartge *et al*. (1993) USA Study started in 1978	White men: 1925 cases, 3642 controls; black men: 88 cases, 277 controls; white women: 633 cases, 1295 controls; black women: 33 cases, 106 controls	Population-based study. Cases drawn from 5 states and 5 metropolitan areas in the SEER network of cancer registries in 1978; controls selected by random-digit dialling or Health Care Financing Administration files
Vena *et al*. (1993) USA 1979–85	White men: 351 cases and 855 controls	Population-based study. Only incident cases. Controls were matched on sex, age and neighbourhood. Response rates were 42% in controls and 76% in cases [sampling of controls not described].
Barbone *et al.* (1994) Italy 1986–90	273 cases and 573 controls	Hospital-based study using interviews. Controls had trauma (20%), orthopaedic conditions (35%), surgical conditions (26%).
Hours *et al*. (1994) France 1984–87	Men and women: 116 cases and 232 controls	Hospital-based study. Two groups of controls with diseases other than cancer, matched for sex, hospital, age and nationality, one from same hospital ward and one from another ward of same hospital as case; most frequent diagnoses among urological ward controls were benign adenoma of the prostate (48/116) and urinary lithiasis (22/116); most common among general hospital controls were cardiovascular (42/116), digestive system (10/116) and endocrine (11/116) diseases. Job/other histories obtained by interview. Papillomas of urinary bladder included; 30–75 years of age
Momas *et al*. (1994a,b) France 1987–89	219 cases and 794 controls	Population-based study. Controls sought from electoral rolls. Only incident cases. Cases and 558 controls interviewed by telephone, 236 controls by post. Response rate, 81% (telephone), 72% (postal) in controls and 219/272 (80.5%) cases
Sorahan *et al.* (1994) UK 1985–87	989 cases, 2059 population controls and 1599 patients of general practitioners	Mixed design (population controls and patients of general practitioners). Postal questionnaires. Response rate not given

Table 2.1.2.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Vizcaino *et al.* (1994) Zimbabwe 1963–77	Black men: 494 cases and 4412 controls; black women: 186 cases and 3789 controls	Analysis of data from Bulwayo cancer registry; controls comprised all other registered cancer cases excluding 'tobacco-related sites' (oesophagus, larynx and lung); interviews conducted either with subject at time of hospitalization or with relatives; individuals with current bilharzia or haematuria were excluded. Complete interview obtained for 72.2% of cases and 70.3% of controls
McCarthy *et al.* (1995) USA 1975–92	Men: 217 cases and 860 controls; women: 84 cases and 336 controls	Population-based study. Controls sampled from private census (covering 90% of residents), including information on smoking
Donato *et al.* (1997) Italy 1991–92	Men: 135 cases and 398 controls; women: 37 cases and 180 controls	Hospital-based study. Only incident cases. Controls had prostate adenoma (40%), urolithiasis (48%). Response rate not given.
Bedwani *et al.* (1998) Egypt 1994–96	Men: 151 cases and 157 controls	Hospital-based study; controls had traumatic and other orthopaedic conditions (35%), acute surgical diseases (27%), eye diseases (8%), miscellaneous (30%). Women were excluded due to low proportion of current smokers (1/39 cases); questionnaires completed by trained interviewers.
Pohlabeln *et al*. (1999) Germany 1989–92	Men: 239 matched pairs; women: 61 matched pairs (age and area of residence)	Hospital-based study. Incident cases. Response rate, 93% in cases and 98% in controls. Male controls had prostate adenoma (41%) or kidney stones (30%). Female controls had kidney stones (62%). Interviews
Pommer *et al*. (1999) Germany 1990–94	Men: 415 cases and 415 controls; women: 232 cases and 232 controls	Population-based study. Incident cases. Controls sought from municipality registry, matched on sex and age; 11% of cases and 29% of controls refused to participate.
Serra *et al*. (2000) Spain 1993–95	Men: 196 cases and 314 controls; women: 22 cases and 30 controls	Population-based study. Incidence cases, all histologically confirmed (93.6% transitional-cell carcinomas). Controls with no known benign or malignant tumour of the urinary tract, from the same county, selected using municipal-based census lists. Matched by sex, age and residence

Table 2.1.2.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Castelao *et al*. (2001) USA 1987–96	Men and women: 1514 cases and 1514 controls	Population-based study. Non-Asian patients with histologically confirmed bladder cancer. Controls matched by sex, age, race (non-Hispanic white, Hispanic, African American) and neighbourhood of residence. Structured questionnaires were completed at an interview in the participant's home. Peripheral blood samples collected to measure 3- and 4-aminobiphenyl–haemoglobin adducts.
Combined analyses		
Fortuny *et al*. (1999) Europe 1983–95	Men and women: 146 cases and 292 controls	Combined analysis of 9 case–control studies (9/11 described in Brennan *et al*., 2000). Non-transitional-cell carcinoma of the bladder only.
Brennan *et al*. (2000, 2001) Europe 1976–96	Men: 2600 cases and 5524 controls; women: 685 cases and 2416 controls	Combined analysis of 11 case–control studies. Recruitment of cases was hospital-based, that of controls either hospital-based (7 centres), population-based (3 centres) or both (1 centre). Diseases of hospital-based controls varied among centres, although all subjects were affected by diseases unrelated to smoking.

Table 2.1.2.2. Cohort studies on tobacco smoking and cancer of the lower urinary tract: intensity of smoking

Reference Country and years of study	Cohort study Subjects	Smoking categories	Relative risk (no. of cases or 95% CI)	Comments
Hammond & Horn (1958a,b) USA 1952–55	American Cancer Society (9-state) Study 187 783 men	Cig/day 1–9 10–20 > 21	 2.0 (14) 2.0 (42) 3.4 (41)	Microscopically verified cancer of the genitourinary system

Table 2.1.2.2 (contd)

Reference Country and years of study	Cohort study Subjects	Smoking categories	Relative risk (no. of cases or 95% CI)	Comments
McLaughlin *et al*. (1995) USA 1954–80	US Veterans' Study 293 958 men	Cig/day 1–9 10–20 31–39 ≥ 40	 1.1 (0.8–1.5) 2.3 (1.9–2.7) 2.7 (2.2–3.3) 2.2 (1.5–3.3)	Adjusted for age and calendar period *p* for trend ≤ 0.01
Engeland *et al*. (1996) Norway 1966–93	Norwegian Cohort Study 11 857 men, 14 269 women	Men Cig/day 1–4 5–9 10–14 ≥ 15	 2.5 (1.5–4.0) 2.7 (1.6–4.5) 3.4 (2.1–5.4) 5.1 (3.1–8.4)	Adjusted for age
		Women Cig/day 1–4 5–9 10–14 ≥ 15	 1.5 (0.7–3.2) 2.2 (1.0–4.7) 5.4 (2.8–11) 7.9 (3.3–19)	
Murata *et al*. (1996) Japan 1984–93	Chiba Center Association Study 17 200 men	1–10 11–20 ≥ 21	2.6 2.3 1.3	Adjusted for age and county
Yuan *et al*. (1996) China 1986–93	Shanghai Men's Study 18 244 men	Cig/day < 20 ≥ 20	 2.1 1.7	Adjusted for age
Nordlund *et al*. (1997) Sweden 1963–89	Swedish Census Study 25 829 women	Cig/day 1–7 8–15 ≥ 16	 1.9 (0.98–3.6) 2.9 (1.4–5.8) 3.4 (1.2–9.7)	
Tulinius *et al*. (1997) Iceland 1968–95	Reykjavík Study 11 366 men	Cig/day 1–14 15–24 ≥ 25	 1.5 (0.7–3.0) 2.6 (1.4–4.7) 4.6 (2.4–6.9)	
Liaw & Chen (1998) China, Province of Taiwan 1982–94	Taiwanese Study 11 096 men	Smoker	0.5 (0.2–1.7)	Very small study

Table 2.1.2.3. Case–control studies on tobacco smoking and cancer of the lower urinary tract: intensity of smoking

Reference Country and years of study	Subjects	Smoking categories[a]	Relative risk (no. of cases/deaths or 95% CI)	Comments
Lilienfeld *et al*. (1956) USA 1945–55	Men	Nonsmoker	1.0 (51)	Crude risks calculated by the Working Group; unadjusted
		Smoker	2.1 (151)	
	Women	Nonsmoker	1.0 (108)	
		Smoker	0.4 (10)	
Lockwood (1961) Denmark 1956–57	Men	Nonsmoker	1.0 (24)	Crude risks calculated by the Working Group
		1–10 g tobacco/day	1.3 (16)	
		11–20 g tobacco/day	3.3 (40)	
		21–30 g tobacco/day	9.5 (18)	
		≥ 31 g tobacco/day	15.8 (10)	
	Women	Nonsmoker	1.0 (49)	
		1–10 g tobacco/day	0.9 (8)	
		11–20 g tobacco/day	4.6 (4)	
		≥ 21 g tobacco/day	–	No cases or controls
Schwartz *et al*. (1961) France 1954 onwards	Men	Nonsmoker	1.0 (24)	Crude risks calculated by the Working Group
		1–9	1.4 (31)	
		10–19	2.1 (69)	
		20–29	2.6 (63)	
		≥ 30	3.8 (15)	

Table 2.1.2.3 (contd)

Reference Country and years of study	Subjects	Smoking categories[a]	Relative risk (no. of cases/deaths or 95% CI)	Comments
Wynder *et al*. (1963a) USA 1960–61	Men	Nonsmoker	1.0 (21)	Crude risks calculated by the Working Group
		1–9	2.1 (12)	
		10–15	1.5 (15)	
		16–20	2.8 (86)	
		21–34	5.2 (63)	
		≥ 35	5.7 (78)	
	Women	Nonsmoker	1.0 (43)	
		1–9	3.1 (9)	
		10–20	3.3 (14)	
		≥ 21	–	4 cases, 0 controls
Cobb & Ansell (1965) USA 1951–61	Men and women	Nonsmoker	1.0 (6)	Hospital controls with colon cancer only; heavy smokers smoked > 1 pack of cigarettes/day for ≥ 30 years; age-adjusted relative risks calculated by the Working Group
		Light and medium smoker	3.0 (21)	
		Heavy smoker	10.3 (104)	
Staszewski (1966) Poland 1958–64	Men	Nonsmoker	1.0 (10)	Nonsmoker included smokers of < 1 g tobacco per day for < 1 year.
		Smoker	2.7 (140)	
Dunham *et al*. (1968) USA 1958–64	Men			
	White	Nonsmoker	1.0 (55)	Crude risks calculated by the Working Group
		< 10	1.2 (19)	
		10–19	2.1 (76)	
		≥ 20	1.1 (114)	

Table 2.1.2.3 (contd)

Reference Country and years of study	Subjects	Smoking categories[a]	Relative risk (no. of cases/deaths or 95% CI)	Comments
	Black	Nonsmoker	1.0 (14)	
		< 10	0.9 (9)	
		10–19	2.7 (25)	
		≥ 20	1.9 (21)	
	Women			
	White	Nonsmoker	1.0 (77)

		1–10	1.7 (0.9–3.3)	
		11–20	2.3 (1.3–4.2)	
		≥ 21	2.4 (1.1–5.1)	
Miller *et al*. (1978) Canada	Men	Nonsmoker	1.0	
		Ever-smoker	1.6	
	Women	Nonsmoker	1.0	
		Ever-smoker	0.8	
Sadeghi *et al*. (1979) Iran 1969–76	Men	Nonsmoker	1.0 (17)	
		Smoker	2.0 (27)	

Table 2.1.2.3 (contd)

Reference Country and years of study	Subjects	Smoking categories[a]	Relative risk (no. of cases/deaths or 95% CI)	Comments
Howe *et al*. (1980) Canada 1974–76	Men	Nonsmoker	1.0	
		< 10	2.6 (1.7–4.4)	
		10–20	3.8 (2.6–6.0)	
		> 20	5.1 (3.5–8.6)	
	Women	Nonsmoker	1.0	
		≤ 15	2.3 (1.3–4.6)	
		> 15	2.6 (1.4–6.9)	
Tola *et al*. (1980) Finland 1975–76	Men	Nonsmoker	1.0 (19)	Crude relative risks calculated by the Working Group
		Ever-smoker	1.9 (114)	
	Women	Nonsmoker	1.0 (25)	
		Ever-smoker	5.4 (17)	
McCredie *et al*. (1982) Australia 1977–80	Men	Nonsmoker	1.0	Cancer of renal pelvis; first set of controls, 'contacts'; second set of controls, 'screening clinic'; relative risks adjusted for consumption of analgesics
		Smoker (contacts)	1.0 (0.2–4.3)	
		Smoker (screening clinic)	2.8 (0.7–10.4)	
	Women (cancer of renal pelvis)	Nonsmoker	1.0	
		Smoker (contacts)	2.2 (0.8–5.9)	
		Smokers (screening clinic)	7.0 (2.5–19.7)	

Table 2.1.2.3 (contd)

Reference Country and years of study	Subjects	Smoking categories[a]	Relative risk (no. of cases/deaths or 95% CI)	Comments
Mommsen *et al*. (1982); Mommsen & Aagaard (1983); Mommsen *et al*. (1983) Denmark 1977–80	Men	Nonsmoker	1.0	Crude odds ratios; Figure 1 in Mommsen & Aagaard (1983) suggests that relative risks are around 6.5 for smokers of 201–300 and 9.5 for smokers of 301–400 (years × no. of cigarettes/day) during lifetime
		Smoker	1.9 (1.2–3.0)	
	Women	Nonsmoker	1.0	
		Smoker	1.9 (0.9–3.9)	
Najem *et al*. (1982) USA 1978	Men and women	Nonsmoker	1.0	Data not given separately
		Smoker	2.0 (1.1–3.7)	

Cartwright *et al*. (1983) UK 1978–81

Incident and prevalent cases considered together; reference category included nonsmokers (< 1000 cigarettes in lifetime)

		Duration of cigarette smoking (years)					
		≤ 5	6–15	16–25	26–35	36–45	≥ 46
Men	< 10	1.0	0.85	1.3	1.6	1.3	1.9
	10–20	1.0	1.8	1.8	1.5	1.7	1.8
	≥ 21	1.0	1.4	1.1	1.3	1.5	0.85
Women	< 10	1.0	2.4	1.2	1.4	1.4	1.6
	10–20	1.0	1.0	2.0	1.5	1.6	1.5
	≥ 21	Insufficient data					

Table 2.1.2.3 (contd)

Reference Country and years of study	Subjects	Smoking categories[a]	Relative risk (no. of cases/deaths or 95% CI)	Comments
McCredie *et al*. (1983) Australia 1977–82	Men	Nonsmoker	1.0	Cancer of the ureter; relative risks adjusted for phenacetin consumption and age
		1–249 kg tobacco in lifetime	1.9	
		≥ 250 kg tobacco in lifetime	4.6	
		Nonsmoker	1.0	Cancer of renal pelvis
		1–249 kg tobacco in lifetime	1.3	
		≥ 250 kg tobacco in lifetime	4.2	
McLaughlin *et al*. (1983) USA 1974–79	Men	Nonsmoker	1.0 (3)	Cancer of renal pelvis; smoking categories: light, ≤ 32 pack–years of cigarettes; moderate, 33–57; heavy, ≥ 58; relative risks adjusted for age and type of respondent (living case/control or next of kin)
		Light smoker	5.5 (1.4–25.5)	
		Moderate smoker	9.6 (2.5–43.4)	
		Heavy smoker	10.7 (2.7–48.9)

2.1.3 *Renal-cell carcinoma*

The evidence available at the time of the *IARC Monograph* on tobacco smoking (IARC, 1986) did not allow the conclusion that there is a causal association between kidney cancer and tobacco smoking.

The designs of the cohort studies are described in the introduction to Section 2 and Table 2.1 and those of the available case–control studies are summarized in Table 2.1.3.1.

Tables 2.1.3.2 and 2.1.3.3 summarize the results of the cohort and case–control studies. Most (12/21) of these studies show a significant increase in risk and a positive association with the number of cigarettes smoked, although tests for trend were rarely reported. The increase in risk associated with smoking 20 cigarettes per day is above 1.3 (e.g. Benhamou *et al*., 1993; Kreiger *et al*., 1993; Nordlund *et al*., 1997). The results are consistent across study designs (cohort studies, hospital- and population-based case–control studies) and in both sexes.

Studies that looked at the effect of duration of smoking and/or age at starting smoking (La Vecchia *et al.*, 1990; McCredie & Stewart, 1992; Benhamou *et al.*, 1993; Kreiger *et al.*, 1993; McLaughlin *et al.*, 1995a; Nordlund *et al*., 1997; Yuan *et al.*, 1998) found only a weak association. The relative risk for former smokers was investigated in most studies, and all but three studies (Talamini *et al.*, 1990; Schlehofer *et al.*, 1995; Nordlund *et al.*, 1997) showed a lower risk than in current smokers, although it was not always below unity. A significant negative trend was observed with increasing number of years since quitting in five (McLaughlin *et al.*, 1984; La Vecchia *et al.*, 1990; McCredie & Stewart, 1992; McLaughlin *et al.*, 1995a; Yuan *et al.*, 1998) of six studies.

Other known risk factors for kidney cancer include raised body-mass index (obesity) and hypertension. A few studies have adjusted for these potential confounders. La Vecchia *et al.* (1990), Talamini *et al.* (1990), McCredie and Stewart (1992), Kreiger *et al.* (1993), McLaughlin *et al.* (1995a), Yuan *et al.* (1998) and Chow *et al.* (2000) adjusted for body-mass index, whereas Kuller *et al.* (1991) and Chow *et al.* (2000) adjusted for blood pressure. Their results suggest that there is no confounding effect of body-mass index or hypertension. It should be noted that confounding from body-mass index is likely to attenuate the association between kidney cancer and smoking, because smoking tends to induce a decrease in body-mass index. Therefore, an assessment of risk stratified by body-mass index would be more appropriate than adjustment for it. A large cohort study has evaluated the changes in body-mass index and blood pressure on the risk for kidney cancer (Chow *et al.*, 2000). As compared with men in the lowest three-eighths of the cohort for body-mass index, men in the middle three-eighths had a 30–60% greater risk for renal-cell cancer, and men in the highest two-eighths had nearly double the risk. After adjustment for body-mass index and hypertension, current and former smokers still had a greater risk for renal-cell cancer.

Table 2.1.3.1. Case–control studies on tobacco smoking and renal cancer: main characteristics of study design

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
Schwartz *et al*. (1961) France started 1954	Men: 69 cases and 69 controls	Hospital-based study; controls had been admitted to hospitals for accidents; matched on age, hospital group, interviewer and date of interview
Bennington & Laubscher (1968) USA 1951–66	Men: 88 cases and 170 controls; women: 12 cases and 20 controls	Hospital-based study; information on smoking habits retrieved from clinical records; information lacking for 22/122 cases and 70/190 controls (the latter were replaced)
Wynder *et al*. (1974) USA 1965–73	Men: 129 cases and 256 controls; women: 73 cases and 138 controls	Hospital-based study; controls were patients admitted for conditions not related to smoking (75% of which were malignant neoplasms) and age-matched to the cases.
Armstrong *et al*. (1976) UK 1972–74	Men: 74 cases and 74 controls; women: 32 cases and 32 controls	Hospital-based study; age- and sex-matched hospital controls (tobacco-related diseases not excluded); 48% of eligible cases in Oxford area and 44% in London could not be interviewed (mostly because of death); 19 lost controls replaced
McLaughlin *et al*. (1984) USA 1974–79	Men: 313 cases and 428 controls; women: 182 cases and 269 controls	Population-based study; all newly diagnosed cases in the Minneapolis-St Paul area; controls: age- and sex-stratified random sample of the population and 495 randomly selected deceased individuals matched (for age, sex and year of death) to deceased cases
La Vecchia *et al.* (1990) Italy 1985–89	Men: 85 cases; women: 46 cases; 394 matched controls	Hospital-based study using interviews. Incident cases confirmed histologically; median age, 60 years. Controls with traumas (30%), non-traumatic orthopaedic conditions (17%), acute medical (13%) and surgical (6%) diseases and others (34%); median age, 60 years. > 97% participation rate for cases and controls
Talamini *et al*. (1990) Italy 1986–89	Men: 150 cases and 445 controls; women: 90 cases and 220 controls	Hospital-based study using interviews. Cases confirmed histologically; aged 20–74 years; 97% response rate. Controls mainly with non-traumatic orthopaedic, traumatic and surgical conditions and eye diseases; matched by age (5-year groups), sex, area of residence and hospital; tobacco-, alcohol- and hormone-related diseases excluded; 96% participation rate

Table 2.1.3.1 (contd)

Reference Country and years of study	Numbers of cases and controls	Criteria for eligibility and comments
McCredie & Stewart (1992) Australia 1989–90	Men: 310 cases and 231 controls; women: 179 cases and 292 controls	Population-based study using interviews. Cases ascertained from Cancer Registry, confirmed by histology (87%), fine needle aspiration cytology (1%) or computerized tomography, ultrasound or contrast radiography (8%); aged 20–79 years; 66% of eligible cases. Controls randomly selected from electoral roll; 65% participation rate
Benhamou *et al.* (1993) France 1987–91	Men: 138 cases and 235 controls; women: 58 cases and 112 controls	Hospital-based study. Interviews. Cases confirmed histologically; 100% of eligible cases. Controls with malignant diseases (161) and non-malignant diseases (186). Individually matched by age (± 5 years), sex, hospital and interviewer; tobacco-related diseases, liver cirrhosis and diabetes excluded; 99% participation rate
Kreiger *et al.* (1993) Canada 1986–87	Men: 312 cases and 664 controls; women: 201 cases and 705 controls	Population-based study using a questionnaire. Incident cases confirmed histologically; aged 25–69 years; 81% of eligible cases. Controls randomly selected from general population matched (1:1) for men and (1:2) for women by age, sex and area of residence; 72% participation rate
McLaughlin *et al.* (1995a) Australia, Denmark, Germany, Sweden and USA 1989–92	Men: 1050 cases and 1429 controls; women: 682 cases and 880 controls	Population-based study using interviews. Cases ascertained from cancer registries, confirmed by histology or cytology; aged 20–79 years; 72% of eligible cases. Controls selected from different population rosters, matched by age (5-year groups) and study area; 75% of eligible controls
Schlehofer *et al.* (1995) Germany 1989–91	Men: 185 cases; women: 92 cases; 286 matched controls	Population-based study using interviews. Cases confirmed histologically; 70% aged ≥ 55 years; 85% participation rate. Controls randomly selected from population register, matched for age (± 1 year) and sex; 75% participation rate
Yuan *et al.* (1998) USA 1986–94	Men: 781 cases and 781 controls; women: 423 cases and 423 controls	Population-based study using interviews. Cases ascertained through Cancer Registry, confirmed histologically; non-Asian, aged 25–74 years; 70% of eligible cases. Controls selected from residence area of cases at the time of diagnosis; individually matched on age (± 5 years), sex, race and neighbourhood; 70% were first chosen controls.

Table 2.1.3.2. Cohort studies on tobacco smoking and kidney cancer: intensity of smoking

Reference Country and years of study	No. of subjects (M, F)	No. of events	Smoking categories	Relative risk (95% CI)	Comments

2.1.4 *Upper aerodigestive tract*

Evidence relating to cancers of the upper aerodigestive tract obtained from relevant cohort and case–control studies on specific sites is described in Sections 2.1.4.a to 2.1.4.f, whereas studies that looked at several subsites combined are described in Section 2.1.4.g.

Most of the cohorts in which these studies were conducted have been described in the introduction to Section 2 and Table 2.1. In addition, in 1975, Tomita *et al.* (1991) established a cohort of 38 621 men, aged 20–55 years, who worked for the East Japan Railway Company. The response rate was 98% and after exclusions and loss to follow-up, 37 645 men were included in the analysis. The health status of the subjects was followed until 1985 using records of medical examinations, mutual-aid pensions and notices of deaths.

The major confounders for the relationship between smoking and several cancers of the upper aerodigestive tract are alcohol consumption and use of any form of smokeless tobacco. In general, the studies examined in the Working Group had adjusted for these two confounders when appropriate.

Some studies also adjusted for dietary intake, especially of fruits and vegetables, although few reported stratified relative risks.

(*a*) *Oral cancer*

Tobacco smoking was shown to be causally related to oral cancer by the previous *IARC Monograph* on tobacco smoking (IARC, 1986) and even earlier by other agencies. Since 1986, many more studies have been reported on the relationship between oral cancer and cigarette smoking. New studies include three cohort studies (Table 2.1.4.1), 16 case–control studies (Tables 2.1.4.2–2.1.4.5), and two case-series reports (Table 2.1.4.6).

(i) *Intensity and duration of smoking*

Intensity of smoking was measured in almost all cohort and case–control studies (Tables 2.1.4.1 and 2.1.4.3, respectively). In addition to the number of cigarettes or amount of tobacco smoked daily, cumulative exposure to cigarette smoke was also measured in terms of pack–years, tobacco–years or lifetime tobacco consumption. The link between duration of cigarette consumption and oral cancer was examined in eight case–control studies. Five case–control studies also considered age at starting smoking.

McLaughlin *et al*. (1995) in the US Veterans' Study divided the number of cigarettes smoked per day into four categories and reported a positive, statistically significant trend.

Eleven case–control studies also reported a dose-dependent increase in risk with increasing number of cigarettes smoked daily or increasing daily tobacco consumption (Franceschi *et al.*, 1990; Nandakumar *et al.*, 1990; Zheng *et al.*, 1990; Choi & Kahyo, 1991; Oreggia *et al.*, 1991; Franceschi *et al.*, 1992; Bundgaard *et al.*, 1995; Zheng *et al.*, 1997; De Stefani *et al.*, 1998; Franceschi *et al.*, 1999; Hayes *et al.*, 1999). Whenever analysed, the trend was always statistically significant (Franceschi *et al.*, 1990; Oreggia *et al.*, 1991; Franceschi *et al.*, 1992; Bundgaard *et al.*, 1995; Hayes *et al.*, 1999).

Several case–control studies have reported exposure to tobacco in other ways. Bundgaard *et al.* (1995) used lifetime tobacco consumption divided into four categories and reported a positive, significant trend after adjustment for life-time consumption of alcohol and other risk factors. A positive trend was also found in all studies that have analysed consumption in pack–years or tobacco–years (Zheng *et al.*, 1990; Maier *et al.*, 1992a; Macfarlane *et al.*, 1995; Hung *et al.*, 1997; Zheng *et al.*, 1997; De Stefani *et al.*, 1998).

Eight studies (Franceschi *et al.*, 1990; Nandakumar *et al.*, 1990; Zheng *et al.*, 1990; Choi & Kahyo, 1991; Oreggia *et al.*, 1991; Franceschi *et al.*, 1992; Zheng *et al.*, 1997; De Stefani *et al.*, 1998) classified the duration of smoking in up to four categories, and all but one study (Nandakumar *et al.*, 1990) reported increased relative risks and a positive trend.

Two out of five studies (Choi & Kahyo, 1991; Oreggia *et al.*, 1991; Franceschi *et al.*, 1990, 1992; Zheng *et al.*, 1997) reported a statistically significant trend of increasing risk with decreasing age at starting smoking (Franceschi *et al.*, 1990, 1992).

(ii) *Cessation of smoking*

One cohort study (McLaughlin *et al.*, 1995; Table 2.1.4.1) and eight case–control studies (Zheng *et al.*, 1990; Choi & Kahyo, 1991; Oreggia *et al.*, 1991; Franceschi *et al.*, 1992; Ko *et al.*, 1995; Zheng *et al.*, 1997; De Stefani *et al.*, 1998; Schildt *et al.*, 1998; Table 2.1.4.3) provided point estimates for former smokers. Relative risks among former smokers were always lower than those for current smokers and in half of these studies almost reached unity (Zheng *et al.*, 1990; Choi & Kahyo, 1991; Zheng *et al.*, 1997; Schildt *et al.*, 1998). Seven case–control studies examined the relative risk by years since quitting and all reported a negative trend (Table 2.1.4.4). The risk for oral cancer declines rather rapidly following cessation of smoking, with relative risks compared with those in non-smokers decreasing to near unity after 10 or more years (Franceschi *et al.*, 1990, 1992; De Stefani *et al.*, 1998). When calculated, the trend was always statistically significant (Franceschi *et al.*, 1990; Oreggia *et al.*, 1991; Franceschi *et al.*, 1992).

(iii) *Type of cigarette*

The effect of the type of cigarette smoked was examined in several case–control studies. The characteristics of the cigarettes included the presence of a filter, the type of tobacco, the tar content and whether the product was manufactured or hand-rolled (Table 2.1.4.5). Two studies reported a statistically significantly higher relative risk for black than for blond tobacco (Oreggia *et al.*, 1991; De Stefani *et al.*, 1998). Similarly, a much higher relative risk was found for hand-rolled cigarettes than for manufactured cigarettes, and plain cigarettes had a much higher relative risk than filter-tipped cigarettes (De Stefani *et al.*, 1998). The differences between black and blond tobacco and between hand-rolled and manufactured cigarettes persisted after stratification by duration of smoking (De Stefani *et al.*, 1998). Also smoking cigarettes with a high-tar content led to higher relative risks than smoking cigarettes with a low-tar content (Franceschi *et al.*, 1992).

(iv) *Sex*

Sex-specific effects were examined in two case–control studies (Zheng *et al.*, 1990; Hayes *et al.*, 1999; Table 2.1.4.3). In both studies, the relative risks for all categories of intensity, duration of smoking and pack–years were higher for women than for men.

(v) *Case-series reports*

Case-series reports are the only data available from Jordan and Myanmar; the results are given in Table 2.1.4.6. These data are of limited value in assessing causality, but have been included for the sake of completeness.

(*b*) *Sinonasal cancer*

The Life Span Study in Japan (Akiba, 1994) examined the association of tobacco use with sinonasal cancer (see introduction to Section 2 for cohort description). A total of 26 cases of sinonasal cancer were identified among 61 505 adults during follow-up. Relative risks, adjusted for sex, location, population group, atomic bomb exposure, year of birth and attained age, increased to 2.9 (95% CI, 0.5–) and 4.0 (95% CI, 1.2–) for former and current smokers, respectively, when compared with nonsmokers [upper confidence limits could not be obtained].

A total of nine case–control studies were examined: the study designs and results are presented in Tables 2.1.4.7 and 2.1.4.8, respectively. When histological types were combined, all studies found an increased relative risk associated with cigarette smoking, but only one was statistically significant (Caplan *et al.*, 2000).

Seven studies analysed the dose–response in terms of intensity of smoking (cigarettes/day), duration of smoking or pack–years. A positive significant trend was found in five studies (Brinton *et al.*, 1984; Hayes *et al.*, 1987; Fukuda & Shibata, 1990; Zheng *et al.*, 1993; Caplan *et al.*, 2000) and was suggested in the other two (Strader *et al.*, 1988; Zheng *et al.*, 1992a).

One study (Zheng *et al.*, 1993) examined the residual risk after cessation of smoking and found a significant decrease in risk for sinonasal cancer associated with increasing number of years since cessation. In a previous study, the same authors had found a negative, non-significant association (Zheng *et al.*, 1992a).

Five studies analysed squamous-cell carcinomas and adenocarcinomas separately (Brinton *et al.*, 1984; Hayes *et al.*, 1987; Strader *et al.*, 1988; Zheng *et al.*, 1992b; ‘t Mannetje *et al.*, 1999). In all studies, there was clearly a significantly increased relative risk for squamous-cell carcinomas, whereas the relative risk was generally not increased for adenocarcinomas.

The evidence of an association between tobacco smoking and sinonasal cancer is based on the results from case–control studies, each of which may be subject to different sources of bias. However, several arguments support the existence of a causal association. These are: presence of a dose–response relationship in most studies; the decrease in relative risk associated with time since quitting; the consistently higher relative risks for squamous-cell carcinoma than for adenocarcinoma; and the lack of potential confounders.

(*c*) *Nasopharyngeal carcinoma*

(i) *Cohort studies*

The risk for nasopharyngeal carcinoma was examined in relation to tobacco use in two cohort studies (Table 2.1.4.9). One study, conducted in a low-risk area (Chow *et al.*, 1993), reported a significant increase in risk among smokers and suggested positive dose–response relationships by duration of smoking and age at starting smoking. The other study, conducted in China, Province of Taiwan, an area in which nasopharyngeal cancer area is endemic, reported a similarly increased risk, but it was not statistically significant (Liaw & Chen, 1998).

(ii) *Case–control studies*

The study designs and the results of the case–control studies on the association of nasopharyngeal carcinoma with cigarette smoking are given in Tables 2.1.4.10 and 2.1.4.11, respectively.

The results of nine informative case–control studies were available (Lin *et al.*, 1973; Yu *et al.*, 1990; Nam *et al*., 1992; West *et al.*, 1993; Ye *et al.*, 1995; Zhu *et al*., 1995; Vaughan *et al*., 1996; Cao *et al.*, 2000; Yuan *et al*., 2000). In all these studies, the risk for nasopharyngeal carcinoma was higher in smokers than in nonsmokers.

In the three studies conducted in the USA, where the incidence rate for nasopharyngeal carcinoma is low (Nam *et al.*, 1992; Zhu *et al.*, 1995; Vaughan *et al.*, 1996), the relative risks for current smokers ranged between 2 and 4. In a study conducted in Shanghai, an area of China in which nasopharyngeal carcinoma is not endemic (Yuan *et al*., 2000), the relative risk was just below 2. One study from the Philippines reported a sevenfold increase in risk after more than 30 years of smoking (West *et al.*, 1993). The four studies (Lin *et al*., 1973; Yu *et al*., 1990; Ye *et al.*, 1995; Cao *et al.*, 2000 [small sample size]) conducted in areas of China in which nasopharyngeal carcinoma is endemic (Taiwan, Guangzhou and Sihui) found relative risks for ever smoking ranging between 2 and 5.

A statistically significant dose–response relationship was detected in six studies that reported the effects of daily or cumulative exposure to tobacco smoke (Yu *et al.*, 1990; Nam *et al*., 1992; Zhu *et al*., 1995; Vaughan *et al*., 1996; Cao *et al.*, 2000; Yuan *et al*., 2000) and suggested in two others (Lin *et al.*, 1973; West *et al.*, 1993). Two studies investigated the effect of quitting smoking and found that the risk of nasopharyngeal carcinoma decreased with increasing time since quitting (Nam *et al*., 1992; Vaughan *et al*., 1996).

In the remaining studies, five from areas in which nasopharyngeal carcinoma is endemic (Ng, 1986; Yu *et al*., 1986; Sriamporn *et al*., 1992; Zheng *et al*., 1994 [small sample size]; Cheng *et al*., 1999) and five from areas in which it was not endemic (Henderson *et al*., 1976; Lanier *et al.*, 1980; Mabuchi *et al.*, 1985; Ning *et al*., 1990; Armstrong *et al.*, 2000), the relative risks for nasopharyngeal carcinoma for ever smoking were not significantly increased (Lanier *et al.*, 1980; Mabuchi *et al.*, 1985; Cheng *et al*., 1999; Armstrong *et al.*, 2000) or were similar to those of nonsmokers (Henderson *et al*., 1976; Ng, 1986; Yu *et al*., 1986; Ning *et al*., 1990; Sriamporn *et al*., 1992; Zheng *et al*., 1994).

In the two studies that distinguished between different histological types, relative risks were higher for keratinized (squamous-cell) carcinoma than for unkeratinized carcinoma (Zhu *et al*., 1995; Vaughan *et al*., 1996).

In the three studies in which men and women were analysed separately, the relative risks were found to increase similarly in both sexes (Lin *et al.,* 1973; Nam *et al*., 1992; Yuan *et al.,* 2000).

Although the interpretation of the results is complicated by small sample sizes, the different criteria used for the selection of controls and the problem of control groups with smoking-related diseases, the combined evidence shows an association between tobacco smoking and nasopharyngeal carcinoma in both endemic and non-endemic areas. Infection with Epstein–Barr virus (human herpesvirus 4), a major cause of nasopharyngeal carcinoma worldwide (IARC, 1997), has not been controlled for in any of the available studies. However, it is unlikely that confounding by infection with Epstein–Barr virus would explain the observed association between tobacco smoking and risk for nasopharyngeal carcinoma. On the other hand, most studies have adjusted for other known and suspected causes of nasopharyngeal carcinoma including intake of Chinese-style salted fish, other dietary factors, alcohol drinking and family history of nasopharyngeal carcinoma, suggesting only a limited confounding effect of these factors.

(*d*) *Cancer of the pharynx*

Tobacco smoking was considered to be an important cause of oropharyngeal and hypopharyngeal cancers in the previous *IARC Monograph* on tobacco smoking (IARC, 1986). Since then more epidemiological studies have yielded results that lend further support for the association. Many studies, however, combine cancers of the oral cavity and of the pharynx (see Section 2.1.4.g). This section summarizes the evidence from three cohort studies (Table 2.1.4.12) and 12 case–control studies (Tables 2.1.4.13 and 2.1.4.14) that reported results specifically on oropharyngeal and hypopharyngeal cancer, or on pharyngeal cancer in general; the latter may include data on nasopharyngeal cancer.

The risk for pharyngeal cancer was significantly increased in smokers in one cohort study (McLaughlin *et al.*, 1995; Table 2.1.4.12) and all but one of the case–control studies (Rao *et al.*, 1999; Table 2.1.4.14). The trend of increasing risk associated with increasing daily or cumulative consumption of cigarettes was evident from all these studies, particularly those from Europe (Brugere *et al.*, 1986; Tuyns *et al.*, 1988; Franceschi *et al.*, 1990; Maier *et al.*, 1994; Franceschi *et al.*, 1999), Uruguay (De Stefani *et al.*, 1998) and the USA (McLaughlin *et al.*, 1995), and less strongly so in studies from Canada (Elwood *et al.*, 1984) and the Republic of Korea (Choi & Kahyo, 1991).

Two case–control studies showed that the risk increased with decreasing age at starting smoking (Table 2.1.4.14; Franceschi *et al.*, 1990; Choi & Kahyo, 1991), but duration and intensity of smoking were not adjusted for.

The influence of cessation of smoking is also evident in all studies where this aspect has been investigated. Former smokers had consistently lower relative risks than did current smokers in both cohort (McLaughlin *et al.*, 1995) and case–control studies (Choi

& Kahyo, 1991; De Stefani *et al.*, 1998). In comparison with nonsmokers, the relative risks for former smokers who had quit smoking for more than 10 years were between 2 and 4 (Franceschi *et al.*, 1990; De Stefani *et al.*, 1998; La Vecchia *et al.*, 1999a), whereas the relative risks for current smokers in these studies were 10–14. In one study in Brazil (Schlecht *et al.*, 1999), relative risks for former smokers who had stopped smoking for more than 10 years approached 1, whereas that for current smokers was just below 6.

Consumption of black tobacco, hand-rolled cigarettes or plain cigarettes (Table 2.1.4.14) resulted in a higher risk for pharyngeal cancer than consumption of blond tobacco, manufactured cigarettes or filter-tipped cigarettes (De Stefani *et al.*, 1998).

(*e*) *Cancer of the oesophagus*

Early studies on the association of tobacco smoking and oesophageal cancer usually examined the risk for cancer of the oesophagus without further specification; sometimes studies reported on cancer of the oesophagus and gastric cardia combined, or specifically on squamous-cell carcinoma of the oesophagus, which was at that time the predominant histological type of oesophageal cancer. Consequently, the results of the early investigations are mainly applicable to squamous-cell carcinoma of the oesophagus. In the previous *IARC Monograph* on tobacco smoking (IARC, 1986), oesophageal cancer was considered to be causally related to cigarette smoking. Many more epidemiological studies have since been conducted, and results of these studies further support this conclusion.

(i) *Squamous-cell carcinoma and unspecified cancer of the oesophagus*

The 19 cohort and 35 case–control studies summarized in this section are described in Tables 2.1.4.15 and 2.1.4.16–2.1.4.19, respectively. All but two cohort studies (Doll *et al.*, 1980; Liaw & Chen, 1998), and all case–control studies, conducted in China, Iceland, Japan, Sweden, the United Kingdom and the USA (Table 2.1.4.17), showed that the risk for oesophageal cancer was associated with cigarette smoking. In one study (Li *et al.*, 1989), the elevated risk was observed only in an area with a relatively low incidence rate of oesophageal cancer. However, two later studies in the same area, Lin County, China, found a twofold increase in risk for oesophageal cancer among smokers (Gao *et al.*, 1994; Lu *et al.*, 2000).

In most positive cohort studies and in most case–control studies with relatively large sample sizes, the risk for oesophageal cancer was shown to increase with increasing duration of smoking (one cohort and 12 case–control studies) or number of cigarettes smoked daily (11 cohort and 21 case–control studies), and to decrease with increasing age at starting smoking (six case–control studies; Tables 2.1.4.15 and 2.1.4.17). In comparison with pharyngeal and laryngeal cancers, relative risks for oesophageal cancer estimated by duration and by intensity of smoking were somewhat lower (see Sections 2.1.4.d and 2.1.4.f, respectively).

One cohort (Guo *et al.*, 1994; Table 2.1.4.15) and 10 case–control studies (Table 2.1.4.18) investigated the effect of cessation of smoking on risk for oesophageal cancer. Although not all studies analysed the trend, all found a decreasing risk with increasing number of years since quitting. In some studies, the risk first started to decrease after 10 years of cessation (Brown *et al.*, 1988; Rolón *et al.*, 1995; Gammon *et al.*, 1997; Castellsagué *et al.*, 1999).

Consumption of black tobacco (Table 2.1.4.19) resulted in a higher risk for oesophageal cancer than did consumption of blond tobacco (De Stefani *et al.*, 1990; Rolón *et al.*, 1995; Castellsagué *et al.*, 1999). Similarly, smoking untipped cigarettes generally resulted in a higher risk for oesophageal cancer than smoking filter-tipped cigarettes (Vaughan *et al.*, 1995; Gammon *et al.*, 1997; Castellsagué *et al.*, 1999).

One study from the USA reported relative risks separately for blacks and whites (Brown *et al.*, 1994a). Relative risks adjusted for alcohol consumption, age and income were very similar for former and current smokers and for the number of cigarettes smoked per day and duration of smoking (Table 2.1.4.17).

(ii) *Adenocarcinoma of the oesophagus*

During recent decades incidence rates for adenocarcinoma of the oesophagus and gastric cardia have increased steadily in the USA, whereas the incidence rate for squamous-cell carcinoma of the oesophagus has remained relatively stable (Blot *et al.*, 1991). An increase in the incidence of adenocarcinoma of the distal oesophagus and cardia has also been noted in the United Kingdom (Powell & McConkey, 1990). Since 1990, a number of studies have focused on the risk factors for adenocarcinoma of the oesophagus.

Confounding

The study designs and results of 10 case–control studies on the association of cigarette smoking and adenocarcinoma of the oesophagus are presented in Tables 2.1.4.20 and 2.1.4.21, respectively.

With the exception of two studies (Levi *et al.*, 1990; Wu *et al.*, 2001), all studies adjusted for alcohol intake as a potential confounder. Most of these studies were conducted in the USA (Kabat *et al.*, 1993; Brown *et al.*, 1994b; Vaughan *et al.*, 1995; Zhang *et al.*, 1996; Gammon *et al.*, 1997) or in the Netherlands (Menke-Pluymers *et al.*, 1993), where chewing of betel quid with tobacco or use of other forms of smokeless tobacco are probably not strong confounders. One study conducted in Sweden was adjusted for snuff use (Lagergren *et al.*, 2000).

Intensity and duration of smoking

Six studies, three that included only cases of adenocarcinoma of the oesophagus (Menke-Pluymers *et al.*, 1993; Gammon *et al.*, 1997; Wu *et al.*, 2001) and three that included cases of adenocarcinoma of the oesophagus, gastro-oesophageal junction and gastric cardia combined (Kabat *et al.*, 1993; Brown *et al.*, 1994b; Vaughan *et al.*, 1995),

showed a significant positive association of adenocarcinoma of the oesophagus with cigarette smoking; the relative risks were somewhat lower than those for squamous cell carcinoma of the oesophagus. Three studies, one in China (Gao *et al.*, 1994), one in Sweden (Lagergren *et al.*, 2000) and one in the USA (Zhang *et al.*, 1996), reported similarly elevated relative risks, but these risks were not statistically significant; in some studies this was probably because of the relatively small number of cases involved.

Of those studies that reported risks adjusted for alcohol consumption, a positive, significant dose–response relationship (Table 2.1.4.21) was found with intensity of smoking (Kabat *et al.*, 1993; Brown *et al.*, 1994b; Gammon *et al.*, 1997), duration of smoking (Gammon *et al.*, 1997) and/or pack–years (Vaughan *et al.*, 1995; Zhang *et al.*, 1996; Gammon *et al.*, 1997).

Cessation of smoking

Six studies provided point estimates for former smokers (Table 2.1.4.21). In five studies, relative risks were lower in former smokers than in current smokers, although they remained elevated (Kabat *et al.*, 1993; Gao *et al.*, 1994; Vaughan *et al.*, 1995; Gammon *et al.*, 1997; Wu *et al.*, 2001), and were increased in the sixth study (Lagergren *et al.*, 2000). The decrease in relative risk associated with years since cessation was weak, but a significant trend was found in two out of four studies (Gammon *et al.*, 1997; Wu *et al.*, 2001).

Sex

Kabat *et al.* (1993) examined risks for men and women separately and observed similar patterns in both sexes, although risks among current smokers and heavy smokers were somewhat higher for women than for men.

Overall, several well-conducted case–control studies, many from the USA, reported a statistically significantly higher risk for adenocarcinoma of the oesophagus in smokers than in nonsmokers. Positive dose–response relationships obtained using various indicators of amount smoked support a causal association, which is further corroborated by the findings of decreasing risks after smoking cessation. Several of these studies reported relative risks adjusted for alcohol consumption and other potential confounders. Further risk factors, such as chewing betel quid with tobacco or use of other forms of smokeless tobacco, have not been considered, but are not likely to be strong confounders. Studies from China and Europe also found increased risks for smokers.

(*f*) *Cancer of the larynx*

In the previous *IARC Monograph* on tobacco smoking (IARC, 1986), laryngeal cancer was one of the cancers strongly associated with cigarette smoking. Since then, more epidemiological evidence has become available to strengthen the conclusion.

(i) *Potential confounders*

Other causes of laryngeal cancer include alcohol consumption, some occupational exposures (e.g. sulfuric acid; IARC, 1992) and possibly some dietary habits. In investigating associations between smoking and laryngeal cancer, potential confounding by alcohol consumption is a concern. However, the risks associated with smoking are also modified by alcohol consumption (see Section 2.3). Consequently, the risk should be examined within strata of alcohol consumption and the joint effects of smoking and alcohol should be evaluated.

(ii) *Intensity and duration of smoking*

In all the cohort studies and case–control studies analysed (Tables 2.1.4.22–2.1.4.24) that were carried out in Asia, Europe and North and South America, the risk for laryngeal cancer was consistently higher in smokers, and a positive significant trend was observed with increasing duration and intensity of smoking.

In most case–control studies, the relative risks for laryngeal cancer were near to or greater than 10 for smokers who had smoked for longer than 40 years (Falk *et al.*, 1989; Zheng *et al*., 1992c) or had smoked more than 20 cigarettes per day (Tuyns *et al.*, 1988; Falk *et al.*, 1989; Choi & Kahyo, 1991; Zatonski *et al.*, 1991; Muscat & Wynder, 1992; Zheng *et al.*, 1992c; Hedberg *et al.*, 1994; Sokic *et al.*, 1994). Cancer of the larynx in nonsmokers is so rare that several studies used light smokers as the reference category (Herity *et al.*, 1982; Olsen *et al.*, 1985; De Stefani *et al.*, 1987; Zatonski *et al.*, 1991; López-Abente *et al.*, 1992; Maier & Tisch, 1997). Consequently, relative risks were lower in these studies, although the increases were still statistically significant.

Two case–control studies reported odds ratios for cancer of the larynx that increased with decreasing age of starting smoking (Franceschi *et al*., 1990; Zatonski *et al*., 1991; Table 2.1.4.24).

(iii) *Cessation of smoking*

The risk for cancer of the larynx declines rather rapidly after cessation of smoking (Table 2.1.4.25). No detectable elevation compared with never-smokers was seen among subjects who had quit smoking for at least 10 years (Franceschi *et al.*, 1990; Ahrens *et al.*, 1991; Schlecht *et al.*, 1999).

(iv) *Type of cigarette*

Some investigators considered the role of type of tobacco (Table 2.1.4.26) and reported a 2.5-fold higher risk in smokers of black tobacco than in smokers of blond tobacco (Tuyns *et al*., 1988; López-Abente *et al*., 1992; De Stefani *et al*., 1987). Smoking untipped cigarettes also led to a higher risk than smoking filter-tipped cigarettes (Wynder & Stellman, 1979; Tuyns *et al*., 1988; Falk *et al*., 1989).

(v) *Subsites*

Five studies investigated the risk for glottic and supraglottic cancer separately (Olsen *et al.*, 1985; Tuyns *et al.*, 1988; López-Abente *et al.*, 1992; Maier *et al.*, 1992b; Muscat

& Wynder, 1992). The cancer risk increased with increasing amount smoked per day and with cumulative exposure for both subsites (Table 2.1.4.24). In addition, the observed relative risks were up to 10-fold higher for supraglottic cancer than for glottic cancer (Maier *et al.*, 1992b).

(vi) *Sex*

Few studies investigated sex-specific effects. One cohort study (Raitiola & Pukander, 1997) reported similar risks for both men and women (Table 2.1.4.22), whereas in two case–control studies (Zheng *et al.*, 1992c; Tavani *et al.*, 1994), the relative risks for women were up to 10-fold higher than for the corresponding categories in men, perhaps because of the small number of cases involved (Table 2.1.4.24).

(*g*) *Cancer of the upper aerodigestive tract*

Cancers of the upper aerodigestive tract traditionally comprise cancers of the oral cavity, pharynx, larynx and oesophagus. In epidemiological studies, especially in cohort studies in which there are few cases at some sites, investigators often combine several cancer sites and term these 'cancer of the upper aerodigestive tract'. This section summarizes the data from 16 cohort studies (Table 2.1.4.27), 26 case–control studies (Tables 2.1.4.28–2.1.4.31) and one case-series report (Table 2.1.4.32).

(i) *Intensity and duration of smoking*

The results from the cohort studies are presented in Table 2.1.4.27. In all but two cohort studies, both from Japan (Kono *et al.*, 1987; Akiba, 1994), the risk for cancer of the upper aerodigestive tract was strongly associated with cigarette smoking. Relative risks increased with increasing daily cigarette consumption (Hammond & Horn, 1958; Doll *et al.*, 1980; Akiba & Hirayama, 1990; Kuller *et al.*, 1991; Doll *et al.*, 1994; Chyou *et al.*, 1995; Engeland *et al.*, 1996; Murata *et al.*, 1996; Yuan *et al.*, 1996; Kjaerheim *et al.*, 1998; Liaw & Chen, 1998), duration of smoking (Chyou *et al.*, 1995) or pack–years (Liaw & Chen, 1998).

Details of the case–control studies are presented in Table 2.1.4.28 and their results in Table 2.1.4.29. Intensity of smoking was measured in most of these studies. In addition to, or instead of, the number of cigarettes or grams of tobacco smoked per day, exposure to tobacco smoke was also measured in terms of pack–years, lifetime consumption or cumulative tar. The link between duration of smoking and cancer of the upper aerodigestive tract was examined in 10 case–control studies (Blot *et al.*, 1988; Merletti *et al.*, 1989; Barra *et al.*, 1991; De Stefani *et al.*, 1992; Franceschi *et al.*, 1992; Day *et al.*, 1993; Mashberg *et al.*, 1993; Kabat *et al.*, 1994; Lewin *et al.*, 1998; Bosetti *et al.*, 2000). Six case–control studies also considered age at starting smoking (Blot *et al.*, 1988; Merletti *et al.*, 1989; Barra *et al.*, 1991; Franceschi *et al.*, 1992; Day *et al.*, 1993; Lewin *et al.*, 1998).

All but one study (Rao *et al.*, 1999) reported an increase in risk for cancer of the upper aerodigestive tract associated with cigarette smoking. A clear dose–response relationship

was seen with increasing daily tobacco consumption and duration of smoking as well as with decreasing age at starting smoking in most of the studies examined.

(ii) *Cessation of smoking*

Eight cohort studies (Doll *et al.*, 1980; Tomita *et al.*, 1991; Akiba, 1994; Doll *et al.*, 1994; Chyou *et al.*, 1995; Engeland *et al.*, 1996; Nordlund *et al.*, 1997; Kjaerheim *et al.*, 1998) provided point estimates for former smokers (Table 2.1.4.27). The relative risks for former smokers were always lower than those for current smokers.

Nine case–control studies examined the relative risk by years since quitting and generally reported a negative trend, which was statistically significant whenever analysed (Table 2.1.4.30).

(iii) *Type of cigarette*

The type of cigarette was examined in several case–control studies: characteristics studied included the use of a filter, the type of tobacco, the tar content and whether the product was manufactured or hand-rolled (Table 2.1.4.31). Consumption of black tobacco, untipped cigarettes, hand-rolled cigarettes, or cigarettes with a high-tar yield led to a higher risk than consumption of blond tobacco (Merletti *et al.*, 1989), filter-tipped cigarettes (Merletti *et al.*, 1989; Mashberg *et al.*, 1993; Kabat *et al.*, 1994), manufactured cigarettes (De Stefani *et al.*, 1992) or low-tar cigarettes (Franceschi *et al.*, 1992), respectively, except in one multivariate analysis (Merletti *et al.*, 1989).

(iv) *Sex*

Sex-specific effects were analysed in two cohort studies (Hammond & Seidman, 1980; Akiba & Hirayama, 1990; Table 2.1.4.27) and four case–control studies (Table 2.1.4.29). Both cohort studies reported a higher relative risk for male smokers than for female smokers. One case–control study (Merletti *et al*., 1989) also reported higher relative risks for men than for women (Table 2.1.4.31), and the trends were generally in the same direction for both men and women in all categories. An exception to the pattern was that for women the relative risk for smoking filter-tipped cigarettes was higher than that for smoking untipped cigarettes.

Three case–control studies (Blot *et al.*, 1988; Kabat *et al.*, 1994; Muscat *et al.*, 1996) found that the relative risks were higher for women than for men in all categories of intensity of smoking (number of cigarettes per day), cumulative exposure (cumulative tar consumption, pack–years, duration of smoking) and age at starting smoking, as well as for former smokers. However, the trends were always in the same direction and of the same order of magnitude.

Overall, the strength of association was generally similar, especially when taking into account the fact that women generally under-report levels of smoking and that most studies included many fewer women than men.

(v) *Ethnicity*

Relative risks were reported separately for blacks and whites in a large case–control study from the USA (Day *et al.*, 1993; Table 2.1.4.29). Relative risks adjusted for alcohol consumption, sex and other relevant variables were very similar for the number of cigarettes smoked per day, years of cigarette smoking, age at starting smoking and number of years since stopping smoking.

(vi) *Case-series report*

One case-series report from Saudi Arabia, from where no other information was available, is presented in Table 2.1.4.32. The data are of limited value in assessing causality, but have been included for the sake of completeness.

(vii) *Second primary tumours*

The occurrence of second primary tumours was investigated in three studies (Day *et al.*, 1994; Barbone *et al.*, 1996; Cianfriglia *et al.*, 1999) and their results are presented in Table 2.1.4.33. All these studies showed an increased risk of second upper aerodigestive tract cancer after a previous cancer in the same organs.

The similarity in the association observed between tobacco smoking and cancers of various upper aerodigestive organs is consistent with the concept of field cancerization, i.e. the concomitant occurrence of carcinogenic alterations in different areas of the mucosa of the upper aerodigestive tract.

Table 2.1.4.1. Cohort studies on tobacco smoking and cancer of the oral cavity

Reference Country and years of study	Subjects	Cancer site ICD code	Smoking categories	Number of cases	Relative risk	95% CI	Comments

Table 2.1.4.2. Case–control studies on tobacco smoking and oral cancer: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Franceschi *et al.* (1990) Italy 1986–89	Men: 157 cases and 1272 controls	Hospital-based study Cases of cancer of the oral cavity, histologically confirmed, aged < 75 years; 98% response rate Controls were inpatients with acute conditions unrelated to tobacco or alcohol consumption, without malignant tumours, chosen on the basis of area of residence and age (± 5-year categories); 97% response rate
Nandakumar *et al.* (1990) India 1982–84	Men: 115 cases and 115 controls; women: 233 cases and 233 controls	Hospital-based study 93% cases histologically confirmed Controls: patients attending the same hospital during the same period, with no diagnosis of cancer, individually matched on sex, age and residence
Zheng *et al.* (1990) China 1988–89	Men: 248 cases and 248 controls; women: 156 cases and 156 controls	Hospital-based study in seven hospitals from the Beijing area Cases histologically confirmed, mainly squamous-cell carcinoma Controls randomly selected from non-cancer patients diagnosed within 1 year of interview, individually matched on age and sex
Choi & Kahyo (1991) Republic of Korea 1986–89	Men: 113 casess and 339 controls; women: 44 cases and 132 controls	Based on several studies within the Korea Cancer Centre Hospital Some cases histologically confirmed Controls selected from patients excluding individuals with cancers at other sites or tobacco- and alcohol-related diseases, matched 3:1 on age, sex and admission date
Oreggia *et al.* (1991) Uruguay 1987–89	Men: 57 cases and 353 controls	Hospital-based study in the university hospital at Montevideo Cases histologically confirmed as squamous-cell carcinoma Controls selected from patients with conditions unrelated to tobacco or alcohol consumption

Table 2.1.4.2 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Franceschi *et al.* (1992) Italy 1986–90	Men: 102 cases and 726 controls	Hospital-based study in the Pordenone province and the greater Milan area (Lombardy region) Cases histologically confirmed Non-cancer controls admitted to the same hospitals for acute illnesses unrelated to tobacco or alcohol consumption
Maier *et al.* (1992a) Germany 1987–88	Men: 200 cases and 800 controls	Hospital-based study in two university clinics in Giessen and Heidelberg Cases histologically confirmed as squamous-cell carcinoma of the oral cavity, oropharynx, hypopharynx or larynx Non-cancer controls, matched 4:1 on age and residential area
Bundgaard *et al.* (1995) Denmark 1986–90	Men: 97 cases and 250 controls; women: 64 cases and 150 controls	Population-based study Cases histologically confirmed as primary squamous-cell carcinoma and verrucous carcinoma Controls drawn from the Danish Central Population Register, matched on sex and age
Ko *et al.* (1995) China, Province of Taiwan 1992–93	Men: 104 cases and 194 controls; women: 3 cases and 6 controls	Hospital-based study in a dentistry department Cases histologically confirmed Controls: non-carcinoma patients treated in the hospital's ophthalmology and physical check-up departments, matched on sex and age
Macfarlane *et al.* (1995) China, 1988–89 Italy, 1975–83 USA, 1982–84	Men: 549 cases and 834 controls; women, 286 cases and 466 controls	Meta-analysis of three studies in Beijing, Turin and New York Cases histologically confirmed Population and hospital controls

Table 2.1.4.2 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Hung *et al.* (1997) China, Province of Taiwan 1996	Men: 41 cases and 123 controls	Population-based study Cases histologically confirmed Controls randomly selected from household registration offices in Taipei, matched 3:1 on age and ethnicity
Zheng *et al.* (1997) China 1988–89	Men: 65 cases and 65 controls; women: 46 cases and 46 controls	Hospital-based study in seven hospitals from the Beijing area Cases histologically confirmed Controls randomly selected from non-cancer patients attending the same hospital for conditions unrelated to smoking or alcohol consumption, matched on age and sex
De Stefani *et al.* (1998) Uruguay 1992–96	Men: 206 cases and 437 controls	Hospital-based study Cases histologically confirmed as squamous-cell carcinoma of the oral cavity Controls with diseases unrelated to smoking or alcohol consumption, without non-neoplastic lesions of the oral cavity and pharynx, selected from the same hospital, frequency-matched by age (10-year periods), residence and urban/rural status
Schildt *et al.* (1998) Sweden 1980–89	Men: 237 cases and 237 controls; women: 117 cases and 117 controls	Population-based study Histologically confirmed cases of squamous-cell oral cancer reported to Cancer Registry Living controls drawn from the National Population Registry, deceased controls from the National Registry for Causes of Death; all controls matched on age, sex, residence and year of death (for deceased controls)

Table 2.1.4.2 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Franceschi *et al.* (1999) Italy and Switzerland 1992–97	Men: 274 cases and 1254 controls	Multicentre hospital-based study Cases histologically confirmed Controls admitted for acute non-neoplastic conditions unrelated to alcohol abuse or tobacco smoking, frequency-matched by age and area of residence
Hayes *et al.* (1999) Puerto Rico 1992–95	Men: 298 cases and 417 controls; women: 69 cases and 104 controls	Population-based study Cases histologically confirmed, reported to the Central Cancer Registry Controls younger than 65 years selected from residents of the neighbourhood; controls aged 65 years and over selected from the rosters of the Health Care Financing Administration

Table 2.1.4.7. Case–control studies on tobacco smoking and sinonasal cancer: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility
Brinton *et al.* (1984) USA 1970–80	Men: 93 cases and 183 controls; women, 67 cases and 1076 controls	Hospital-based study in four hospitals in two states Cases diagnosed as cancer of the nasal cavity (61), maxillary sinus (71) or other sinuses (28), histologically confirmed as squamous-cell carcinomas (54%), adenocarcinomas (15%) or others (31%), aged ≥ 18 years; response rate, 83% Controls (178 hospital controls for living cases and 112 death certificate controls for deceased cases), matched on hospital, admission year, age, sex, race and residence; response rate, 78%; cancers and other conditions of upper aerodigestive tract were excluded.
Ng (1986) Hong Kong SAR 1974–81	Men: 157 cases and 158 controls; women: 68 cases and 68 controls	Hospital-based study at the Institute of Radiology and Oncology Cases of cancers of the nasal fossa (82), maxillary sinus (110) and other sinuses (33), aged ≥ 18 years Controls with all other malignancies except nasopharyngeal cancer, randomly selected and individually matched on admission year, age (± 5 years), sex, race and resident status
Hayes *et al.* (1987) The Netherlands 1978–81	Men: 92 cases and 195 controls	Population-based study Cases of cancers of the nasal cavity and sinuses, including 28 deceased cases, histologically confirmed as squamous-cell carcinomas (54%) or adenocarcinomas (26%), aged 35–79 years; response rate, 79% Controls included a random sample of residents in the country and of persons deceased during 1980; response rate, 75%
Strader *et al.* (1988) USA 1979–83	Men: 33 cases and 327 controls; women: 20 cases and 225 controls	Population-based study in Washington Cases identified by the population-based cancer registry, histologically confirmed as squamous-cell carcinomas (51%), adenocarcinomas (11%) or other types (38%), aged 20–74 years; response rate, 72% Controls selected by random-digit dialling and matched by age and sex; 83% of eligible controls participated
Fukuda & Shibata (1990) Japan 1982–86	Men: 125 cases and 250 controls; women: 44 cases and 88 controls	Population-based study in Hokkaido Incident cases of squamous-cell carcinoma of the maxillary sinus, aged 40–79 years; response rate, 96.6% Controls matched by sex, age and area of residence; response rate, 93.4%

Table 2.1.4.7 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility
Zheng *et al.* (1992b) China 1988–90	Men: 39 cases and 269 controls; women: 21 cases and 145 controls	Population-based study conducted in Shanghai Cases of cancers of the nasal cavity, paranasal sinuses and middle ear, including 40% of squamous-cell carcinomas, aged 20–75 years; response rate, 95.2% Controls frequency matched on sex and age; response rate, 89.6%
Zheng *et al.* (1993) USA 1986	White men: 147 cases and 449 controls	Data from the 1986 US National Mortality Followback Survey Deaths from cancer of the maxillary sinus (76), nasal cavity (11), other sinuses (56) and auditory tube and middle ear (4), aged ≥ 45 years; response rate, 88% Controls aged ≥ 45 years who died from causes unrelated to smoking or alcohol consumption
't Mannetje *et al.* (1999) France, Germany, Italy, Netherlands and Sweden 1979–90	Men: 451 cases and 1464 controls; women: 104 cases and 241 controls	Pooled analysis of eight studies conducted in five European countries Cases of sinonasal cancer, histologically confirmed as squamous-cell carcinomas (43%), adenocarcinomas (29%), other types (26%) and of unknown histology (1%)
Caplan *et al.* (2000) USA 1984–88	Men: 70 cases and 1910 controls	Population-based study (Selected Cancers Study) Cases identified from the registries, histologically confirmed as carcinomas (74%) or non-carcinomas (26%), aged 35–60 years; response rate, 78% of all cases Controls selected by random-digit dialling, frequency-matched to another case group by geographical area and age (5-year groups)

Table 2.1.4.8. Case–control studies on tobacco smoking and cancer of the nasal cavity and sinuses

Reference Country and years of study	Cancer subsite ICD code	Exposure categories	Relative risk	95% CI	Comments
Brinton *et al.* (1984) USA 1970–80	Nasal cavity, sinuses ICD-8: 160.0; 160.2–5; 160.8–9	Squamous-cell carcinomas (n = 86)			Adjusted for sex

Table 2.1.4.10. Case–control studies on tobacco smoking and nasopharyngeal cancer: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Lin *et al.* (1973) China, Province of Taiwan 1969–71	Men and women: 343 cases and 1017 controls	Population-based study in eight cities and counties Cases reported by all the medical facilities in the study areas; 93% histologically confirmed; response rate, 79.4% Controls from neighbourhood individually matched by age (± 5 years) and sex; response rate, 85%
Henderson *et al.* (1976) USA 1960–74	Men: 105 cases and 179 controls; women: 51 cases and 88 controls	Population-based study in California Cases: 88 identified by the Los Angeles Cancer Surveillance Program in 1971–74, 27 by the California Tumor Registry in 1960–70, and 41 incident cases in 1972–74; mean age, 51.4 years Controls were in- and outpatients, individually matched on sex, age, race, area and socioeconomic class; mean age, 52.4 years
Lanier *et al.* (1980) USA 1966–76	Men and women: 13 cases and 13 controls	Population-based study among natives in Alaska Cases identified from pathology files and tumour registries of the Alaska Native Medical Center, aged 32–80 years Controls were apparently healthy, individually matched (1:1) by sex, age (± 2.5 years), race and area of residence
Mabuchi *et al.* (1985) USA 4 years	Men and women: 39 cases and 39 controls	Hospital-based study in five metropolitan areas Cases histologically confirmed; response rate, 64% Controls randomly selected from admissions, matched on age (± 3 years), sex, race, marital status, hospital and admission period
Ng (1986) Hong Kong SAR 1974–81	Men: 159 cases and 158 controls; women: 65 cases and 68 controls	Hospital-based study at the Institute of Radiology and Oncology, among Chinese Cases aged ≥ 18 years; mean age, 57 years Controls with all other malignancies except cancer of the nasal cavity and sinuses, selected in random order from patient's register, matched on admission year, age (± 5 years), sex, race and resident status; mean age, 57 years
Yu *et al.* (1986) Hong Kong SAR 1981	Men: 160 cases and 160 controls; women: 90 cases and 90 controls	Population-based study in 4 hospitals, among Chinese Incident cases histologically confirmed, aged ≤ 35 years; response rate, 94% Controls were friends, individually matched by age and sex
Ning *et al.* (1990) China 1981	Men: 68 cases and 204 controls; women: 32 cases and 96 controls	Population-based study in Tianjin city Cases identified from the population-based cancer registry histologically confirmed, aged ≤ 64 years; response rate, 61.3% Controls individually matched (3:1) on age, sex and race (Han); 97% first chosen controls participated
Yu *et al.* (1990) China 1983–85	Men: 209 cases and 209 controls; women: 97 cases and 97 controls	Population-based study in Guangzhou city Incident cases identified at the Tumor Hospital, histologically confirmed, aged < 50 years; response rate, 93% Controls individually matched by age (± 5 years) and sex

Table 2.1.4.10 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Nam *et al.* (1992) USA 1986	Men: 141 cases and 282 controls; women: 63 cases and 126 controls	Population-based mortality study among white Americans Cases taken from a random sample of all deaths in 1986, aged ≥ 25 years; response rate, 89% Controls had died from diseases unrelated to smoking or alcohol drinking, aged ≤ 65 years, randomly selected from the sex and age strata, individually matched (2:1)
Sriamporn *et al.* (1992) Thailand 1987–90	Men: 80 cases and 80 controls: women: 40 cases and 40 controls	Hospital-based study in north-eastern Thailand Cases diagnosed and attending radiation therapy at the hospital Controls admitted for other diseases excluding any cancers and respiratory diseases, matched by sex and age (± 5 years)
West *et al.* (1993) Philippines	Men: 76 cases; women: 28 cases; 205 controls	Hospital- and population-based study Incident cases recruited from Philippine General Hospital, histologically confirmed, < 10% ethnically Chinese, aged 11–83 years; response rate, 100% Controls: 104 hospital controls matched for sex, age and ward type; response rate, 100%; 101 community controls matched for sex, age and neighbourhood; response rate, 77%
Zheng *et al.* (1994) China 1986	Men: 64 cases and 128 controls; women: 24 cases and 48 controls	Population-based study in Wuzhou and Zangwu Incident cases, histologically confirmed; mean age, 41.6 years; response rate, 98% Controls from neighbourhood, individually matched (2:1) on sex, age (± 4 years) and place of residence
Ye *et al.* (1995) China	Men: 114 cases and 114 controls; women: 21 cases and 21 controls	Hospital-based study in teaching hospital Incident cases, histologically confirmed, 82% poorly differentiated Controls from the surgical and orthopaedic departments with non-cancer, non-respiratory diseases, individually matched on sex, age, admission date and residence or ethnicity
Zhu *et al.* (1995, 1997) USA 1984–88	Men: 113 cases and 1910 controls	Population-based study in eight cancer registries (Selected Cancers Study) Cases histologically confirmed including 73% of squamous-cell carcinomas, aged 15–39 years in 1968; response rate, 86.3% Controls selected by random digit dialling, frequency-matched to another case group; 83.1% of eligible controls
Vaughan *et al.* (1996) USA 1987–93	Men and women: 231 cases and 244 controls	Population-based study Cases identified by five population-based cancer registries, histologically confirmed as differentiated squamous-cell carcinomas (60%) or undifferentiated and nonkeratinizing carcinomas (28%); aged 18–74 years; response rate, 82% Controls selected by random-digit dialling and frequency-matched on sex and age (± 5 years); response rate, 70%

Table 2.1.4.10 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Cheng *et al.* (1999) China, Province of Taiwan 1991–94	Men: 114 cases and 104 controls; women: 260 cases and 223 controls	Population-based study in Taipei Incident cases identified in two hospitals, histologically confirmed, aged ≤ 75 years; 99% response rate Controls with no history of nasopharyngeal cancer, randomly selected using the National Household Registration System, individually matched on sex, age (± 5 years) and area of residence; response rate, 88%
Armstrong *et al.* (2000) Malaysia 1987–92	Men: 195 cases and 195 controls; women: 87 cases and 87 controls	Population-based study among Malaysian Chinese Cases (119 prevalent and 163 incident) diagnosed at four study centres, histologically confirmed, aged 19–74 years; response rate, 53% Controls with no history of cancer of the head, neck or respiratory system, randomly selected and pair-matched by age (± 3 years) and sex; response rate, 90%
Cao *et al.* (2000) China 1998–99	Men and women: 57 cases and 327 controls	Population-based study in Sihui city Incident cases identified in a highly endemic area Controls were family members of the spouse of case; no matching
Yuan *et al.* (2000) China 1987–91	Men: 668 cases and 699 controls; women: 267 cases and 333 controls	Population-based study Incident cases identified by the Shanghai cancer registry, aged 15–74 years; response rate, 84% Controls randomly selected from general population and frequency matched by sex and age (5 year groups); response rate, 96.4%

Table 2.1.4.11. Case–control studies on tobacco smoking and nasopharyngeal cancer

Table 2.1.4.13. Case–control studies on tobacco smoking and pharyngeal cancer: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Jussawalla & Deshpande (1971) India 1968	Men and women: 223 cases and 1647 controls	Retrospective study at the Cancer Registry in Mumbai Cases of the oropharynx (185) and hypopharynx (38), histologically confirmed Controls selected among residents from the registered voters' list, matched for age, sex and religion
Elwood *et al.* (1984) Canada 1977–80	Men: 68 cases and 68 controls; women: 19 cases and 19 controls	Hospital-based study at a cancer referral centre in Vancouver Incident cases of pharyngeal cancer; 95% of identified cases participated. Controls were patients with cancers unrelated to smoking, alcohol use or occupational exposure, individually matched on date of diagnosis, sex and age (± 2 years).
Brugere *et al.* (1986) France 1975–82	Men: 1000 cases	Population-based study in Paris Cases of oropharyngeal (634) and hypopharyngeal (366) cancer admitted to the head and neck department of the Institut Curie; non-squamous carcinomas and secondary cancers excluded Controls were a random subsample from a large national survey stratified by age.
Tuyns *et al.* (1988) France, Italy, Spain and Switzerland 1973–80	Men: 281 cases and 3057 controls	Population-based study in six study areas Cases of cancer of the hypopharynx, histologically confirmed; oropharynx excluded; response rate > 80% Controls drawn from the general population within a sample stratified by age and sex; response rate, 56–75%
Franceschi *et al.* (1990) Italy 1986–89	Men: 134 cases and 1272 controls	Hospital-based study Cases of pharyngeal cancer, including the junction between hypopharynx and larynx, histologically confirmed, aged < 75 years; response rate, 98% Controls were inpatients with acute conditions unrelated to tobacco or alcohol consumption, without malignant tumours, chosen on the basis of area of residence and age (± 5-year categories); response rate, 97%
Choi & Kahyo (1991) Republic of Korea 1986–89	Men: 133 cases and 399 controls; women: 19 cases and 57 controls	Hospital-based study at the Cancer Center Hospital in Seoul Cases of pharyngeal cancer, confirmed histologically or cytologically Controls excluded patients with other cancers or tobacco- and alcohol-related diseases, individually matched (3:1) on year of birth (± 5 years) and admission date (± 3 months).
Maier *et al.* (1994) Germany 1990–91	Men: 105 cases and 420 controls	Hospital-based study at the Department of Otorhinolaryngology, Head and Neck Surgery of the University of Heidelberg Cases of squamous-cell carcinoma of the oropharynx (40), hypopharynx (44) or both (21), histologically confirmed Controls were outpatients without known cancer, individually matched (4:1) for age and residential area.

Table 2.1.4.13 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
De Stefani *et al.* (1998) Uruguay 1992–96	Men: 219 cases and 427 controls	Hospital-based study in four hospitals of Montevideo Cases of squamous-cell carcinoma of the oropharynx (111), hypopharynx (97) or unspecified (11), aged 25–84 years; response rate, 93.8% Controls without diseases related to tobacco and alcohol use or non-neoplastic lesions of the oral cavity and pharynx, aged 25–84 years; frequency-matched on age, area of residence and urban/rural status; response rate, 91.0%
Franceschi *et al.* (1999) Italy & Switzerland 1992–97	Men: 364 cases and 1254 controls	Hospital-based study in major hospitals in three areas Cases of oro- or hypopharyngeal cancer, histologically confirmed, aged 32–74 years Controls were patients with acute non-cancerous illnesses unrelated to tobacco smoking or alcohol abuse, frequency-matched by age and area of residence.
La Vecchia *et al.* (1999a) Italy & Switzerland 1984–97	Men and women: 642 cases; men: 3068 controls; women: 1111 controls	Hospital-based study in a network of hospitals in the study areas Incident cases of pharyngeal cancer, aged < 75 years, histologically confirmed Controls with acute, non-neoplastic conditions unrelated to alcohol or tobacco consumption
Rao *et al.* (1999) India 1980–84	Men: 593 cases and 635 controls	Hospital-based study in Mumbai Cases of cancer of the hypopharynx Controls with infectious diseases and benign tumours, free from cancer, admitted during the same period as controls; no matching
Schlecht *et al.* (1999) Brazil 1986–89	Men and women: 217 cases and 1578 controls	Hospital-based study in three metropolitan areas Incident cases of pharyngeal cancer, histologically confirmed Controls without diagnosis of cancer or mental disorder, individually matched for sex, age and trimester of admission

Table 2.1.4.16. Case–control studies on tobacco smoking and oesophageal cancer (unspecified) or squamous-cell carcinoma of the oesophagus: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Victora *et al.* (1987) Brazil 1985–86	Men: 135 cases and 270 controls; women: 36 cases and 72 controls	Hospital-based study in eight main hospitals in southern Brazil Cases of histologically confirmed squamous-cell carcinoma of the oesophagus aged < 80 years; 90% of eligible cases Controls without disease related to alcohol or tobacco use, or upper gastrointestinal tract diseases, individually matched (2:1) by hospital, age (± 5 years) and sex
Brown *et al.* (1988) USA 1977–84	Men: 74 cases and 157 controls	Hospital-based incidence study combined with mortality study Incident cases of oesophageal cancer (NOS) identified at four hospitals in Charleston (85% squamous-cell carcinoma), aged ≤ 79 years; 85% of eligible cases participated Controls individually matched (2:1) on race, age (± 5 years), hospital and admission period; response rate, 95%; only controls without alcohol- or diet-related conditions or diagnosis of mental disorder were included.
	Men: 133 deaths and 265 controls	Mortality series: deaths from oesophageal cancer (NOS) at age ≤ 79 years Controls randomly selected and individually matched (2:1) by race, age, area of residence and year of death Cases with diagnoses and deaths with causes related to alcohol and/or diet excluded; response rate for deaths and controls combined, 94%
Nakachi *et al.* (1988) Japan 1973–85	Men: 257 cases and 257 controls; women: 86 cases and 86 controls	Population-based study in the Saitama prefecture using interviews Cases were deaths from oesophageal cancer (NOS); participation rate, 54% Controls selected from electoral roll and individually matched on sex, age (± 2 years) and neighbourhood; about 60% of first chosen controls participated.
Yu *et al.* (1988) USA 1975–81	Men: 187 cases and 187 controls; women: 88 cases and 88 controls	Population-based study in Los Angeles County Incident cases of histologically confirmed oesophageal cancer (88% squamous-cell carcinoma), identified through the local Cancer Surveillance Program, aged 20–64 years, mean, 56.5 years; 56% of eligible cases Neighbourhood controls individually matched on sex, age and race; 87% of controls were the first or the second eligible neighbour.
Ferraroni *et al.* (1989) Italy 1983–88	Men: 162 cases and 1334 controls; women: 47 cases and 610 controls	Hospital-based study in four hospitals in Milan Cases of oesophageal cancer (NOS), confirmed histologically, aged ≤ 75 years Controls with traumatic, non-traumatic orthopaedic and acute surgical conditions and ear, nose, throat, skin and dental disorders; malignant tumours, digestive tract disorders or coffee-, alcohol- or tobacco-related conditions were excluded; median age, 56 years
Li *et al.* (1989) China 1984–85	Men: 758 cases and 789 controls; women: 486 cases and 525 controls	Population-based study among residents of Linxian County using interviews Cases of cancer of the oesophageal–gastric junction (mostly squamous-cell carcinoma) or gastric cardia (mostly adenocarcinoma), aged 35–64 years, identified from all hospitals in the county; 98% of eligible cases Controls without cancer, randomly selected from population and roughly matched on age and sex; aged 35–64 years; participation rate, 100%

Table 2.1.4.16 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Rao *et al.* (1989) India 1980–84	Men: 503 cases and 634 controls	Hospital-based study at the Tata Memorial Hospital Cases with oesophageal cancer (NOS) Controls without cancer or infectious diseases
De Stefani *et al.* (1990) Uruguay 1985–88	Men: 199 cases and 398 controls; women: 62 cases and 124 controls	Hospital-based study in four main hospitals in Montevideo Cases of squamous-cell carcinoma of the oesophagus; response rate, 92% Controls without diagnosis of tobacco and/or alcohol-related diseases and individually matched (2:1) by age (± 5 years), sex and hospital
Franceschi *et al.* (1990) Italy 1986–89	Men: 288 cases and 1272 controls	Hospital-based study in two areas of northern Italy Cases of histologically confirmed oesophageal cancer (NOS), aged < 75 years; response rate, 98% Controls with traumatic or non-traumatic orthopaedic conditions, acute conditions, eye disorders and other illnesses unrelated to tobacco and alcohol consumption, matched by area of residence, hospital and age; response rate, 97%
Sankaranarayanan *et al.* (1991) India 1983–84	267 cases (207 men and 60 women) and 895 controls (546 men and 349 women)	Hospital-based study at the Regional Cancer Centre of Trivandrum Cases of oesophageal cancer (NOS) confirmed by histology (67%) or radiology (33%); 100% of eligible cases participated. Controls included 271 patients diagnosed with conditions other than cancer or precancerous lesions and 624 patients selected from those attending a teaching hospital with diagnoses of acute respiratory, gastrointestinal and genitourinary infections [no matching]
Cheng *et al.* (1992) Hong Kong SAR 1989–90	Men: 345 cases and 1378 controls; women: 55 cases and 220 controls	Hospital-based study in four general hospitals in Hong Kong using interviews Cases of histologically confirmed oesophageal cancer (85% squamous-cell carcinoma); 86.8% of all cases participated. Controls individually matched (4:1) by sex and age: 2 controls admitted to the same surgical departments; patients with tobacco- or alcohol-related cancers were excluded; 2 controls selected from private or general practice clinics in the area where case was originally referred to the physician; response rate, 95%
Negri *et al.* (1992) Italy 1984–90	Men: 244 cases and 901 controls; women: 56 cases and 302 controls	Hospital-based study in several major hospitals in the greater Milan area Cases of histologically confirmed oesophageal cancer (NOS), aged 29–74 years; median, 60 years Controls admitted for traumatic or non-traumatic orthopaedic conditions, acute surgical diseases and various other diseases; patients with cancer or digestive diseases, and diseases related to alcohol or tobacco consumption excluded; aged 25–74 years; median, 55 years
Wang *et al.* (1992) China 1988–89	Men: 204 cases and 241 controls; women: 122 cases and 155 controls	Population-based study in two major cancer hospitals in two areas Cases of oesophageal cancer (mostly squamous-cell carcinomas), aged 30–87 years (15–20% of all cases); response rate > 90% Controls selected from the population and frequency-matched on gender, age (5-year categories) and residence; response rate > 90%

Table 2.1.4.16 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Kabat *et al.* (1993) USA 1981–90	Men: 136 cases and 4544 controls; women: 78 cases and 2228 controls	Hospital-based study in 28 hospitals in 8 US cities Cases of histologically confirmed squamous-cell carcinoma of the oesophagus Controls included patients with cancers of breast, endometrium, ovary, prostate and skin, leukaemias, lymphomas and sarcomas and non-cancer diagnosis, individually matched on age (± 5 years), sex, race and hospital
Brown *et al.* (1994a) USA 1986–89	Men: 124 white and 249 black cases, and 750 white and 614 black controls	Population-based study in three areas Cases of histologically confirmed squamous-cell carcinoma of the oesophagus, aged 30–79 years; response rate, 68% Controls selected by random digit dialling and random sampling from Medicare recipients, frequency-matched on race and age; response rates, 78% and 82% for whites and blacks, respectively
Gao *et al.* (1994) China 1990–93	Men: 624 cases; women: 278 cases; 1552 controls	Population-based study in permanent residents of urban Shanghai Cases of oesophageal cancer (NOS), aged 30–74 years Controls randomly selected from the general population and frequency-matched on sex and age (5-year categories) within a larger case–control study
Hanaoka *et al.* (1994) Japan 1989–91	Men: 141 cases and 141 controls	Hospital-based study in seven university clinics Cases of histologically confirmed oesophageal cancer (NOS), aged < 85 years Controls selected from patients with diseases supposedly unrelated to alcohol or tobacco use; 54% cancer of the stomach, colon or rectum, and 18% benign gastrointestinal conditions, individually matched (1:1) by age (± 3 years), sex, hospital and area of residence
Hu *et al.* (1994) China 1985–89	Men: 170 cases and 340 controls; women: 26 cases and 52 controls	Hospital-based study at five major hospitals in north-eastern China Cases of histologically confirmed oesophageal cancer (NOS); 100% of eligible cases Controls without cancer or oesophageal diseases, individually matched (2:1) by sex, age (± 5 years), hospital and area of residence
Chen *et al.* (1995) China 1990–92	Men: 117 cases and 234 controls; women: 31 cases and 62 controls	Population-based study in Shichuan Province Incident cases of oesophageal cancer (NOS) registered in Jintang county, aged 26–88 years (mean, 61.5 years) Healthy controls from neighbourhood, individually matched (2:1) by age (± 5 years), sex and residence
Cheng *et al.* (1995) Hong Kong SAR 1989–90	Men: 30 cases and 279 controls; women: 23 cases and 128 controls	Hospital-based study in four general hospitals; cases and controls were abstainers from alcohol. Cases of histologically confirmed oesophageal cancer (NOS) Controls not matched to cases; patients with diabetes mellitus and alcohol- and tobacco-related conditions excluded
Rolón *et al.* (1995) Paraguay 1988–91	Men: 110 cases and 318 controls; women: 21 cases and 63 controls	Hospital-based study in all medical facilities of Ascunción Cases of oesophageal cancer (NOS) diagnosed by cytology, histology and radiology, aged < 75 years; 100% of eligible cases Controls with cancers thought not to be associated with smoking or alcohol (skin, prostate, leukaemia, lymphomas) and benign conditions, individually matched (3:1) by sex and age (± 5 years), hospital and admission period; 97% participation rate

Table 2.1.4.16 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Siemiatycki *et al.* (1995) Canada 1979–85	Men: 99 cases and 2238 controls	Hospital- and population-based study in Montreal Cases of cancers of the oesophagus (NOS), confirmed histologically, aged 35–70 years Controls: 533 population-based, selected from electoral list stratified by age; participation rate, 72%; 1705 patients with all other cancers
Vaughan *et al.* (1995) USA 1983–90	Men: 64 cases and 506 controls; women: 42 cases and 218 controls	Population-based study in western Washington State Cases of histologically confirmed squamous-cell carcinoma of the oesophagus, identified by the local Cancer Surveillance System; response rate, 83% Controls identified by random-digit dialling and frequency-matched on age and sex; response rate, 80%
Vizcaino *et al.* (1995) Zimbabwe 1963–77	Men: 826 cases and 3007 controls; women: 55 cases and 2231 controls	Hospital-based study in Bulawayo using interviews Incident cases of oesophageal cancer registered by the local cancer registry; 86% confirmed histologically, of whom 90% had squamous-cell carcinoma; mean age, 55.7 years; 73% of all cases participated. Controls with all other cancers unrelated to alcohol or tobacco consumption; response rate, 71%
Tavani *et al.* (1996) Italy 1984–92	Men: 22 cases and 79 controls; women: 18 cases and 72 controls	Hospital-based study in major hospitals in Milan, restricted to abstainers from alcohol Incident cases of oesophageal cancer (NOS), aged 26–74 years; 97% of eligible cases Controls without malignant, digestive or metabolic diseases or diseases known or suspected to be related to alcohol or tobacco consumption; 97% of eligible controls
Gammon *et al.* (1997) USA 1993–95	Men: 176 cases and 555 controls; women: 45 cases and 140 controls	Population-based study in three areas Cases of histologically confirmed squamous-cell carcinoma of the oesophagus, identified through population-based tumour registries, aged 30–79 years; 74% of eligible cases Controls identified by random-digit dialling or random sampling of Health Care Financing Administration rosters, frequency matched by area, age, sex and/or race, depending on study centre; response rate, 70%
Launoy *et al.* (1997) France 1991–94	Men: 208 cases and 399 controls	Hospital-based study in three university hospitals Cases of histologically confirmed squamous-cell carcinoma of the oesophagus, aged < 85 years Controls with osteoarthritis, lumbago, sciatica or eye conditions; trauma patients excluded; matched on age and hospital
Castellsagué & Muñoz (1999) Argentina, Brazil, Paraguay & Uruguay 1985–92	Men (76–84%) and women: 179 cases and 776 controls	Pooled analysis of five hospital-based studies in over 30 hospitals and clinics; study restricted to abstainers from alcohol Cases of squamous-cell carcinoma of the oesophagus; response rates, 90–99% Controls with diseases unrelated to alcohol or tobacco use, individually matched (2:1 or 3:1) on age (± 5 years), sex, hospital and residence

Table 2.1.4.16 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Castellsagué *et al.* (1999) Argentina, Brazil, Paraguay, Uruguay 1985–92	Men (76–84%) and women: 830 cases and 1779 controls	Pooled analysis of five hospital-based studies in over 30 hospitals and clinics Cases of squamous-cell carcinoma of the oesophagus; response rates, 90–99% Controls with diseases unrelated to alcohol or tobacco, individually matched (2:1 or 3:1) by age (± 5 years), sex, hospital, admission period and residence
La Vecchia *et al.* (1999b) Italy 1984–92	Men: 22 cases and 79 controls; women: 18 cases and 72 controls	Pooled analysis of two hospital-based studies in two regions in northern Italy; study restricted to abstainers from alcohol Incident cases of histologically confirmed oesophageal cancer (NOS) Controls with acute, non-neoplastic conditions; diseases related to tobacco use or alcohol abuse excluded
Shen *et al.* (1999) China 1994–95	Men: 307 cases and 307 controls; women: 242 cases and 242 controls	Population-based study Incident cases of oesophageal cancer (NOS) confirmed by X-rays or computerized tomography scan (53%) or by histology (47%); 71% of squamous-cell carcinomas; aged 30–74 years; response rate, 90.3% Controls with no history of digestive cancer, individually matched on age (± 3 years), sex and village
Lagergren *et al.* (2000) Sweden 1995–97	Men: 120 cases; women: 47 cases; 820 controls	Population-based study in the entire population of Sweden using interviews Cases of squamous-cell carcinoma of the oesophagus, born in Sweden on even dates; median age, 67 years; response rate, 73% Controls randomly selected and frequency-matched to total cases of squamous-cell carcinoma and adenocarcinoma of the oesophagus, and adenocarcinoma of the gastric cardia; participation rate, 73%
Lu *et al.* (2000) China 1995–96	Men: 198 cases and 198 controls; women: 154 cases and 154 controls	Population-based study in Lin County Cases of oesophageal cancer (NOS), confirmed by histology or cytology (87%) or X-rays or surgery (13%) Neighbourhood controls individually matched (1:1) on age (± 3 years) and sex
Zambon *et al.* (2000) Italy 1992–97	Men: 275 cases and 593 controls	Hospital-based study in three areas of northern Italy using interviews Incident cases of histologically confirmed squamous-cell carcinoma of the oesophagus, aged 39–79 years; 95% of eligible cases Controls admitted for acute illnesses unrelated to tobacco and alcohol use to major hospitals in the same areas, frequency-matched by age (± 5 years) and area of residence; malignant lesions excluded; 95% of eligible controls participated.
Pacella-Norman *et al.* (2002) South Africa 1995–99	Men: 267 cases and 804 controls; women: 138 cases and 1370 controls	Hospital-based study at 3 major hospitals in greater Johannesburg Incident cases of oesophageal cancer (NOS), 90% confirmed by histology, haematology or cytology, aged 18–74 years Controls with cancers thought to be unrelated to tobacco and alcohol use: breast, prostate, leukaemia, lymphoma, myelomas, ovary, endometrium, vulva, skin, colon, penis and others; aged 18–74 years

Table 2.1.4.17. Case–control studies on tobacco smoking and oesophageal cancer (unspecified) or squamous-cell carcinoma of the oesophagus

Reference Country and years of study	Cancer subsite	Smoking categories	Relative risk	95% CI	Comments
Victora *et al.* (1987) Brazil 1985–86	Squamous-cell carcinoma	Former smoker Current smoker	1.3 3.9	0.6–2.7 1.9–8.0	Adjusted for cachaça (local beverage) consumption, place of residence, intake of fruit and meat
Brown *et al.* (1988) USA 1977–84	Oesophagus (unspecified)	Current smoker Cigarettes/day 1–19 20–29 ≥ 30 Duration (years) 1–24 25–44 ≥ 45	1.8 0.8 2.0 2.6 1.4 1.6 1.8	1.0–3.0 0.4–1.5 1.1–3.4 1.4–4.7 0.6–2.9 1.0–2.8 1.0–3.3	Cases and controls from the incidence and mortality series were combined for the analysis. Adjusted for study series (incidence or mortality), use of local beverage and other alcoholic beverages
Nakachi *et al.* (1988) Japan 1973–85	Oesophagus (unspecified)	Men > 400 000 vs < 400 000 cigarettes smoked Women Ever-smoker vs never	 2.4 2.3	 0.99–5.7 1.02–5.2	Participation rates for both cases and controls were low. Relevant factors were not fully adjusted for except variables for matching.
Yu *et al.* (1988) USA 1975–81	Oesophagus (unspecified)	Packs/day ≤ 1 2 ≥ 3	 6.6 9.1 5.1	 2.3–19.3 2.9–29.0 1.5–16.9	Analysis restricted to directly interviewed pairs (n = 129); relevant factors were not adjusted for except variables for matching (age, sex and race).

Table 2.1.4.17 (contd)

Reference Country and years of study	Cancer subsite	Smoking categories	Relative risk	95% CI	Comments
Ferraroni *et al.* (1989) Italy 1983–88	Oesophagus (unspecified)	Former smoker Cigarettes/day < 15 15–24 ≥ 25	2.9 4.2 4.2 7.2		Adjusted for age, sex, education, social class, marital status, smoking, coffee and alcohol consumption $p < 0.01$ for all current smokers combined
Li *et al.* (1989) China 1984–85	Oesophagus (unspecified)	High-risk area Current smoker Cigarettes/day 1–9 10–19 ≥ 20 Age at starting smoking (years) ≥ 35 25–34 20–24 < 20 Low-risk area Current smoker Cigarettes/day 1–9 10–19 ≥ 20	 0.9 1.0 0.8 0.9 1.0 1.1 0.8 0.7 1.5 1.4 1.3 1.7	 0.6–1.2 0.6–1.6 0.5–1.2 0.6–1.4 0.6–1.7 0.7–1.7 0.5–1.3 0.4–1.1 1.1–2.0 0.4–2.1 0.9–2.0 1.2–2.6	Analysis included only men because of the very small number of women who smoked; cancers of the oesophagus and gastric cardia were combined in the analysis; adjusted for age

Table 2.1.4.20. Case–control studies on tobacco smoking and adenocarcinoma of the oesophagus: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Levi *et al.* (1990) Switzerland 1963–85	Men: 21 cases and 85 controls; women: 9 cases and 55 controls	Hospital-based study Cases histologically confirmed as adenocarcinoma in Barrett's oesophagus, aged 37–86 years Controls with Barrett's oesophagus without any malignant features
Kabat *et al.* (1993) USA 1981–90	Men: 173 cases and 4544 controls; women: 21 cases and 2228 controls	Hospital-based study in 28 hospitals in eight cities Cases histologically confirmed as adenocarcinoma of the distal oesophagus, gastro–oesophageal junction or cardia Controls included cancers of the breast, endometrium, ovary, prostate and skin, leukaemia, lymphomas and sarcomas and non-cancer diagnoses; individually matched on age (± 5 years), sex, race and hospital
Menke-Pluymers *et al.* (1993) Netherlands 1978–85	Men: 47 cases and 53 controls; women: 15 cases and 43 controls	Hospital-based study Cases histologically confirmed as adenocarcinoma in Barrett's oesophagus; mean age, 62 years Controls with cancer-free Barrett's oesophagus; mean age, 61 years
Brown *et al.* (1994b) USA 1986–89	Men: 174 cases and 750 controls	Population-based study in three areas Cases histologically confirmed as adenocarcinoma of the oesophagus or gastro–oesophageal junction, identified through cancer registries, aged 30–79 years Controls selected from general population by random-digit dialling and random sampling of Medicare recipients, frequency-matched on age and race
Gao *et al.* (1994) China 1990–93	Men and women: 51 cases and 1552 controls	Population-based study in the urban area of Shanghai Cases histologically confirmed as adenocarcinomas of the oesophagus, identified through Shanghai Cancer Registry, aged 30–74 years Controls randomly selected from Resident Registry, matched on age and sex
Vaughan *et al.* (1995) USA 1983–90	Men and women: 298 cases and 724 controls	Population-based study in western Washington State Cases histologically confirmed as adenocarcinomas of the oesophagus (133) or gastric cardia/gastro–oesophageal junction (165), identified through the Cancer Surveillance System of the Fred Hutchinson Cancer Research Center Controls identified by random-digit dialling, frequency-matched by age and sex

Table 2.1.4.20 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Zhang *et al.* (1996) USA 1992–94	Men: 79 cases and 62 controls; women: 16 cases and 70 controls	Hospital-based study Cases histologically confirmed as adenocarcinomas of the oesophagus (28) or gastro–oesophageal junction and gastric cardia (67) Controls were patients who had undergone gastrointestinal endoscopy.
Gammon *et al.* (1997) USA 1993–95	Men: 245 cases and 555 controls; women: 48 cases and 140 controls	Population-based study in three areas Cases histologically confirmed as adenocarcinomas of the oesophagus, identified through population-based tumour registries, aged 30–79 years; 81% of eligible cases participated. Controls identified by random-digit dialling or random sampling of Health Care Financing Administration rosters, frequency-matched by geographical area, age, sex and/or race, depending on study centre; response rate, 70%
Lagergren *et al.* (2000) Sweden 1995–97	Men: 164 cases and 681 controls; women: 25 cases and 139 controls	Population-based study Cases histologically confirmed as adenocarcinomas of the oesophagus from the entire population of Sweden; median age, 69 years; 87% of eligible cases participated. Controls randomly selected in general population, from age and sex strata (frequency-matched); participation rate, 73%
Wu *et al.* (2001) USA 1992–97	Men: 202 cases and 999 controls; women: 20 cases and 357 controls	Population-based study in Los Angeles County Cases histologically confirmed as adenocarcinomas of the oesophagus, identified by the Los Angeles County Cancer Surveillance Program; 77% of those approached participated. Controls from neighbourhood, matched on gender, race and age (± 5 years); diagnosis of oesophageal or stomach cancer excluded

Table 2.1.4.23. Case–control studies on tobacco smoking and laryngeal cancer: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility
Wynder & Stellman (1979) USA 1969–76	Men: 286 cases and 4835 controls; women, 64 cases and 4712 controls	Retrospective study conducted in six cities Cases histologically confirmed Controls with cancers not related to tobacco consumption, benign neoplasms and other non-neoplastic conditions
Burch *et al.* (1981) Canada 1977–79	Men: 184 cases and 184 controls; women: 20 cases and 20 controls	Population-based study Cases histologically confirmed, ascertained by two Ontario hospitals; response rate, 79% Neighbourhood controls individually matched (1:1) on sex, age (± 5 years) and area of residence; response rate, 78%
Graham *et al.* (1981) USA 1957–65	White men: 374 cases and 381 controls	Hospital-based study in a major cancer institution Cases histologically confirmed Controls without cancer or respiratory or digestive tract diseases, randomly selected by 5-year age groups
Herity *et al.* (1982) Ireland	Men only: 68 cases and 68 controls	Hospital-based study Controls with cancers and premalignant skin conditions considered not to be related to tobacco or alcohol consumption
Olsen *et al.* (1985) Denmark 1980–82	326 cases (276 men and 50 women) and 1134 controls	Population-based study Cases of cancer of the glottis (58%) and supraglottis (34%); aged < 75 years, 91% histologically confirmed; response rate, 96% Controls matched about 4:1 on sex and date of birth; response rate, 78%
Brownson (1987) USA 1984–85	White men: 63 cases and 200 controls	Hospital-based study Cases ascertained through the Missouri Cancer Registry, histologically confirmed Controls with colon cancer, matched about 3:1 by area and admission time period
De Stefani *et al.* (1987) Uruguay 1985–86	Men: 107 cases and 290 controls	Hospital-based study in the University Hospital in Montevideo Cases histologically confirmed, aged 30–89 years Controls with diseases not related to tobacco or alcohol consumption, admitted to the same hospital in the same time period
Tuyns *et al.* (1988) France, Italy, Spain and Switzerland 1973–80	Men: 696 cases and 3057 controls	Population-based study in six areas in four countries Cases of cancer of the endolarynx (61% supraglottic, 39% glottic and subglottic); response rate > 80% Controls drawn from the local population as a stratified sample by sex and 10-year age group; response rate, 56–75%

Table 2.1.4.23 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility
Falk *et al.* (1989) USA 1975–80	Whie men: 151 cases and 235 controls	Population-based study Cases aged 30–79 years, ascertained from 56 hospitals in six counties Controls frequency-matched by area of residence, 5-year age group and ethnicity
Franceschi *et al.* (1990) Italy 1986–89	Men: 162 cases and 1272 controls	Hospital-based study in two hospitals Cases histologically confirmed, aged ≤ 75 years Controls with acute conditions unrelated to tobacco or alcohol consumption from the same hospital, matched by area of residence and age (± 5 years)
Sankaranarayanan *et al.* (1990) India 1983–84	Men: 191 cases and 546 controls	Hospital-based study in two major hospitals Cases histologically confirmed Controls with diagnosis of respiratory, genitourinary and gastrointestinal infections without cancer
Ahrens *et al.* (1991) Germany 1986–87	Men: 85 cases and 100 controls	Hospital-based study in a hospital in Bremen Cases histologically confirmed (55 incident and 30 prevalent) Controls without cancer and with diseases not related to smoking, matched on age
Choi & Kahyo (1991) Republic of Korea 1986–89	Men: 94 cases and 282 controls; women: 6 cases and 18 controls	Hospital-based study in a Cancer Center Hospital in Seoul Cases histologically confirmed Controls without cancer and tobacco- or alcohol-related diseases, matched on sex, year of birth (± 5 years) and admission time period
Zatonski *et al.* (1991) Poland 1986–87	Men: 249 cases and 965 controls	Population-based study Cases identified in Lower Silesia, histologically confirmed, aged < 65 years; response rate, 88% Controls from the same region, aged 25–64 years; response rate, 94%
Freudenheim *et al.* (1992) USA 1975–85	Men: 250 cases and 250 controls	Population-based study in three counties in New York Cases identified from pathology records of the hospitals, Caucasians only; response rate, 30% Neighbourhood controls matched on sex, race and age; response rate, 48%
López-Abente *et al.* (1992) Spain 1982–85	Men: 50 cases and 103 controls	Hospital- and population-based study in Madrid Cases of cancer of the glottis (30%) and supraglottis (54%); aged ≤ 80 years; response rate, 51% Controls matched on sex and age (± 5 years): 45 hospital controls with diseases considered not to be related to tobacco or alcohol consumption, 58 population controls from the general population selected from the electoral roll; response rate, 49%

Table 2.1.4.23 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility
Maier *et al.* (1992b) Germany 1988–89	Men: 164 cases and 656 controls	Hospital-based study in Heidelberg Cases of cancer of the glottis and supraglottis, histologically confirmed; mean age, 58.1 years Controls with no known tumorous diseases, selected randomly from outpatient clinics, matched 4:1 by age and residential area
Muscat & Wynder (1992) USA 1985–90	White men: 194 cases and 184 controls	Hospital-based study in eight hospitals in four states Cases of cancer of the glottis (48%) and supraglottis (47%), histologically confirmed Controls with conditions unrelated to tobacco-induced diseases, individually matched on hospital, age (± 5 years) and year of interview
Zheng *et al.* (1992c) China 1988–90	Men: 177 cases and 269 controls; women: 24 cases and 145 controls	Population-based study among residents of urban Shanghai Cases aged 20–75 years; response rate, 76% Controls randomly selected and frequency-matched by sex and age (5-year groups); response rate, 88%
Hedberg *et al.* (1994) USA 1983–87	Men: 185 cases and 356 controls; women: 50 cases and 191 controls	Population-based study Cases had response rate of 81%. Controls randomly selected from the population of same area by random-digit dialling and frequency-matched on sex and age (5-year groups); response rate, 75%
Sokic *et al.* (1994) Yugoslavia 1991–92	Men: 93 cases and 93 controls; women: 7 cases and 7 controls	Hospital-based study in University Clinical Center in Belgrade Cases histologically confirmed Controls with minor injuries, matched on sex, age (5-year groups) and residence
Tavani *et al.* (1994) Italy 1986–92	Men: 350 cases and 1373 controls; women: 17 cases and 558 controls	Hospital-based study in the greater Milan area Cases histologically confirmed, aged < 80 years Controls without cancer and with diseases or conditions unrelated to smoking, alcohol consumption or long-term dietary modifications, matched by hospital
Dosemeci *et al.* (1997) Turkey 1979–84	Men: 832 cases and 829 controls	Hospital-based study in an oncology treatment centre in Istanbul Cases histologically confirmed Controls with selected cancers not reported to be related to smoking or alcohol drinking (97%) or without cancer (3%)

Table 2.1.4.23 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility
Maier & Tisch (1997) Germany 1988–89	Men: 164 cases and 656 controls	Hospital-based study in two clinical departments of the University of Heidelberg Cases histologically confirmed Controls without cancer, randomly selected from outpatients, individually matched (4:1) on age and residential area
Rao *et al.* (1999) India 1980–84	Men: 427 cases and 635 controls	Hospital-based study in Mumbai Cases histologically confirmed Controls free from cancer, infectious diseases or benign tumours, admitted at the same hospital during the same period
Schlecht *et al.* (1999) Brazil 1986–89	Men and women: 194 cases and 1578 controls	Hospital-based study in three metropolitan areas in southern Brazil Cases histologically confirmed Controls without cancer or mental disorders, selected from the same or nearby hospitals, matched on sex, age (± 5 years) and admission period

Table 2.1.4.24. Case–control studies on tobacco smoking and laryngeal cancer

Reference Country and years of study	Smoking categories	Relative risk	95% CI	Comments
Burch *et al.* (1981)	Cigarettes/day			Adjusted for lifetime alcohol consumption
Canada	1–14	3.0	1.4–6.3	
1977–79	15–24	3.4	1.7–6.8	
	≥ 25	4.5	2.2–9.2	
Graham *et al.* (1981)	Cigarettes/day			Adjusted for alcohol consumption. Possible selection bias in controls
USA	1–10	2.1	$p < 0.05$	
1957–65	11–20	4.8	$p < 0.005$	
	21–39	8.8	$p < 0.005$	
	≥ 40	8.5	$p < 0.005$	p for trend < 0.005
Herity *et al.* (1982)	Tobacco consumption			Analysis restricted to abstainers from alcohol and light drinkers. Consumption of tobacco in pipes and cigars converted into the equivalent of cigarettes/day (1 oz tobacco = 25 cigarettes, 1 cigar = 7 cigarettes, 1 cheroot = 2.5 cigarettes). Smokers whose consumption was at or below the median are referred to as light smokers; those above the median consumption as heavy smokers. Possible selection bias in controls
Ireland	None or light	1.0	–	
	Heavy	4.9	2.6–9.0	
Olsen *et al.* (1985)	Tobacco/day (g)			Adjusted for age, sex and alcohol consumption. One cigarette equals 1 g; one cigar, 3 g, and a pipeful, 2.5 g of tobacco. Effects of smoking cigarettes, cigars and pipe could not be separated. The association was similar for the glottis and supraglottis.
Denmark	0–10	1.0		
1980–82	11–20	1.7		
	≥ 21	2.3		
Brownson (1987)	Cigarettes/day			Adjusted for age and alcohol consumption. Former smokers were classified as 1–19 cigarettes/day, cigar and pipe smokers as 20–40 cigarettes/day. Possible selection bias in controls. Effects of cigarette, cigar and pipe smoking could not be separated. p for trend < 0.01
USA	1–19	2.6	1.1–6.1	
1984–85	20–40	3.7	1.5–9.2	
	> 40	7.0	1.3–37.9

Table 2.1.4.28. Case–control studies on tobacco smoking and cancers of the upper aerodigestive tract: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Blot *et al.* (1988) USA 1984–85	Men: 762 cases and 837 controls; women: 352 cases and 431 controls	Population-based study in four regions Incident cases of pathologically confirmed oral and pharyngeal cancer identified through local cancer registries; aged 18–79 years; 75% of all incident cases Controls selected by random-digit dialling (aged 18–64 years) and from Health Care Financing Administration rosters (aged 65–79 years), frequency-matched by age, sex and race
Ferraroni *et al.* (1989) Italy 1983–88	Men: 43 cases and 1334 controls; women: 7 cases and 710 controls	Hospital-based study in four hospitals in Milan Cases confirmed histologically, aged ≤ 75 years Controls with traumatic, non-traumatic orthopaedic and acute surgical conditions and ear, nose, throat, skin and dental disorders included; malignant tumours, digestive tract disorders and coffee-, alcohol- or tobacco-related conditions excluded; median age, 56 years
Merletti *et al.* (1989) Italy 1982–84	Men: 86 cases and 385 controls; women: 36 cases and 221 controls	Population-based study Cases histologically confirmed as squamous invasive carcinoma Controls selected from random samples of files of residents of Turin stratified by sex and age
Talamini *et al.* (1990) Italy 1986–89	Men: 291 cases and 1272 controls; women: 45 cases and 380 controls	Hospital-based study in two areas of northern Italy; study restricted to abstainers from alcohol Cases histologically confirmed as cancer of oral cavity (183) or pharynx (153) Controls: patients from the same hospitals admitted for acute illnesses, without malignant tumours or conditions related to tobacco or alcohol consumption
Barra *et al.* (1991) Italy 1985–90	Men: 236 cases, 577 cancer controls and 1122 non-cancer controls; women: 36 cases, 446 cancer controls and 762 non-cancer controls	Hospital-based study in the Pordenone province Cases histologically confirmed Cancer controls with cancers not related to tobacco or alcohol consumption: colorectal, renal cell, prostate, thyroid, and haematological. Non-cancer controls admitted for acute illnesses, without malignant tumours or conditions related to tobacco or alcohol consumption

Table 2.1.4.28 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
La Vecchia *et al.* (1991) Italy 1987–89	Men: 89 cases and 875 controls; women: 16 cases and 294 controls	Hospital-based study in five hospitals in Milan Incident cases of histologically confirmed oral (35) or oropharyngeal (70) cancer, aged < 75 years Controls admitted for acute, non-neoplastic or digestive diseases unrelated to alcohol or tobacco consumption; aged 21–74 years
De Stefani *et al.* (1992) Uruguay 1988–90	Men: 109 cases and 273 controls	Hospital-based study in a cancer institute Cases of cancer of the mouth and pharynx Controls with diseases unrelated to tobacco or alcohol use, admitted to the same hospital during the same time period
Franceschi *et al.* (1992) Italy 1986–90	Men: 104 cases and 726 controls	Hospital-based study in the Pordenone province and the greater Milan area (Lombardy region) Cases histologically confirmed Non-cancer controls admitted to the same hospitals for acute illnesses unrelated to tobacco or alcohol consumption
Marshall *et al.* (1992) USA 1975–83	Men: 201 cases and 201 controls; women: 89 cases and 89 controls	Population-based study Cases from 20 major hospitals in three New York counties, histologically confirmed (90% squamous-cell carcinoma) Controls selected by sampling dwellings, individually matched on neighbourhood, age and sex
Zheng *et al.* (1992a) China 1988–90	Men: 115 cases and 269 controls; women: 89 cases and 145 controls	Population-based study in the urban Shanghai area, linked to the Shanghai Cancer Registry Controls randomly selected from the Shanghai Resident Registry
Day *et al.* (1993) USA 1984–85	Men: 729 cases and 785 controls; women: 336 cases and 397 controls	Population-based study in four regions Incident cases of histologically confirmed oral and pharyngeal cancer identified through local cancer registries Controls selected by random-digit dialling (aged 18–64 years) and Health Care Administration rosters (aged 65–79 years), frequency-matched by age, sex and race

Table 2.1.4.28 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Kune *et al.* (1993) Germany 1982	Men: 41 cases and 398 controls	Population-based study Incident cases of histologically confirmed squamous-cell oral and pharyngeal cancer at a general hospital in Heidelberg; mean age, 64 years Community controls from Melbourne Colorectal Cancer Study; mean age, 65 years
Mashberg *et al.* (1993) USA 1972–83	Men: 359 cases and 2280 controls	Hospital-based study in a veterans' medical centre in New Jersey Cases histologically confirmed as invasive squamous-cell carcinoma or carcinoma *in situ* Controls without evidence of cancer or dysplasia of the pharynx, larynx, lung or oesophagus
Negri *et al.* (1993) Italy 1984–92	Men: 372 cases and 1575 controls; women: 67 cases and 531 controls	Hospital-based study Cases histologically confirmed Controls: patients admitted to the same network of hospitals for acute, non-neoplastic, non-digestive conditions
Spitz *et al.* (1993) USA 1987–91	Men: 70 cases and 70 controls; women: 38 cases and 38 controls	Population-based study in Texas Cases histologically confirmed as squamous-cell carcinoma Controls selected from blood and platelet donors, matched on age, sex and ethnicity
De Stefani *et al.* (1994) Uruguay 1988–92	Men: 246 cases and 253 controls	Hospital-based study in a cancer institute Incident cases of histologically confirmed squamous-cell carcinoma of the oral cavity and pharynx, aged 40–89 years; participation rate, 100% Controls free of benign oral tumours, non-neoplastic conditions of the mouth and pharynx, digestive diseases, or diseases related to tobacco and alcohol consumption; frequency-matched by age; participation rate, 100%
Kabat *et al.* (1994) USA 1977–90	Men: 1097 cases and 2075 controls; women: 463 cases and 873 controls	Hospital-based study in 28 hospitals in eight cities Cases histologically confirmed Controls: patients with diseases unrelated to tobacco or alcohol consumption, and without history of tobacco-related cancer, matched on age, sex, race, hospital and date of interview

Table 2.1.4.28 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Muscat *et al.* (1996) USA 1981–90	Men: 687 cases and 619 controls; women: 322 cases and 304 controls	Hospital-based study Cases histologically confirmed Controls with conditions unrelated to tobacco use, identified from daily hospital admission logs, matched on sex, age, race and date of admission
Sanderson *et al.* (1997) Netherlands 1980–90	Women: 303 cases	Population-based study Cases of squamous-cell carcinoma of the oral cavity and oropharynx Controls: data from a large national survey on public health conducted by the National Central Bureau of Statistics; matched on sex and age
Lewin *et al.* (1998) Sweden 1988–91	Men: 545 cases and 641 controls	Population-based study in two areas Cases identified at weekly conferences at all ear, nose and throat departments in the study area (90%) and from regional cancer registers (10%); aged 40–79 years; 90% eligible cases Controls selected by random sampling from a population register stratified by region and age; response rate, 85%
Talamini *et al.* (1998) Italy and Switzerland 1992–97	Men: 10 cases and 79 controls; women: 22 cases and 145 controls	Multicentre hospital-based study; analysis restricted to abstainers from alcohol Cases histologically confirmed Controls admitted for acute non-neoplastic conditions unrelated to alcohol consumption or tobacco use
Rao *et al.* (1999) India 1980–84	678 cases and 635 controls (men only)	Hospital-based study in Mumbai Cases of cancer of the oral cavity and pharynx Controls with infectious diseases and benign tumours, free from cancer, admitted during the same period as controls [no matching]
Bosetti *et al.* (2000) Italy and Switzerland 1984–97	Women: 195 cases and 1113 controls	Two multicentre hospital-based studies Cases histologically confirmed Controls admitted for acute non-neoplastic conditions, frequency-matched by age and residence

Table 2.1.4.28 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Dikshit & Kanhere (2000) India 1986–92	Men: 247 cases and 260 controls	Population-based study in Bhopal Cases of oropharyngeal cancer collected by a population-based cancer registry Controls randomly selected from a group of 2500 men surveyed for tobacco habits in the general population, stratified by age
Moreno-Lopez *et al.* (2000) Spain	Men: 63 cases; women: 12 cases; 150 controls	Hospital-based study in three hospitals in the Madrid community Cases histologically confirmed Controls selected from healthy subjects with no history of cancer or oral disease, in health care centres corresponding to the hospitals
Zavras *et al*. (2001) Greece 1995–98	Men: 68 cases and 69 controls; women: 42 cases and 46 controls	Hospital-based study in three university hospitals in Athens Cases histologically confirmed Controls hospitalized for conditions unrelated to cancer, matched on age and sex

2.1.5 *Cancer of the pancreas*

(*a*) *Cohort and case–control studies*

The designs of the case–control and cohort studies are summarized in Table 2.1.5.1 and 2.1, respectively. Additional data have come from the Alpha-Tocopherol Beta-Carotene Cancer Prevention Study (Stolzenberg-Solomon *et al.*, 2001), which followed a cohort of more than 27 000 male smokers between 1985 and 1997. Pancreatic cancer cases were ascertained from the Finnish Cancer Registry, which hold records of almost 100% of all cases in Finland.

All but two of the published cohort and case–control studies (Murata *et al.*, 1996; Liaw & Chen, 1998) showed an increased risk for pancreatic cancer in ever-smokers (Tables 2.1.5.2 and 2.1.5.3). The conclusion that smoking is a cause of this cancer reached in the *IARC Monograph* on tobacco smoking (IARC, 1986) remains unchanged; smokers have about twice as high a risk for this cancer as never-smokers.

A number of cohort studies have reported associations between smoking and the subsequent development of pancreatic cancer. Pancreatic cancer was ascertained mainly by linkage to population-based cancer registries, death notification systems or pathology laboratories. Some studies only recorded smoking habits at time of enrolment; thus data on prolonged tobacco consumption were not readily available.

Several case–control studies on the relationship between smoking and pancreatic cancer have also been published since 1986. These studies were designed to measure the effect of smoking, alcohol consumption and coffee drinking. Some studies also measured the effect of certain dietary items. Two types of control group were used: hospital-based controls, mainly with conditions not thought to be associated with smoking or tobacco, or neighbourhood-matched controls selected using electoral rolls or random-digit telephone dialling. Verification of pancreatic cancers ranged from 100% (i.e. only those with histological verification were included in a study) to about 30%. However, whether or not subanalyses were carried out on cases diagnosed with histology, this made little difference to the results. Because pancreatic cancer is rapidly fatal, most studies questioned proxies for the case about the smoking characteristics of the patients. Some studies also interviewed proxies of the control patients, but again, restricting the analyses to direct interviews rather than proxy interviews made little difference to the direction of the association.

(*b*) *Factors affecting risk*

(i) *Duration and intensity*

Table 2.1.5.3 shows the results of studies that considered dose–response relationships. Most studies found clear evidence demonstrating that the risk for cancer of the pancreas increases with daily cigarette consumption and the number of years of smoking.

(ii) *Cessation*

Eight studies (Mack *et al*., 1986; Cuzick & Babiker, 1989; Bueno de Mesquita *et al*., 1991; Howe *et al*., 1991; Silverman *et al*., 1994; Ji *et al.*, 1995; Muscat *et al*., 1997; Partanen *et al*., 1997) reported on the risk of pancreatic cancer according to the number of years since quitting. Five of these studies found a decreasing monotonic trend in risk associated with the number of years for which the subjects had stopped smoking (Mack *et al*., 1986; Howe *et al*, 1991; Silverman *et al*., 1994; Ji *et al*., 1995; Partanen *et al*., 1997). A further study reported that the excess risk in former smokers disappeared after less than 10 years since quitting, but did not provide quantitative estimates (Fuchs *et al*., 1996) (Table 2.5.1.4).

(iii) *Type of cigarette*

Friedman *et al*. (1998) compared rates of pancreatic cancer development between those who reported smoking mentholated cigarettes and those who smoked non-mentholated cigarettes. The rate ratio was 0.6 for men (95% CI, 0.3–1.4) and 0.8 for women (95% CI, 0.3–1.8); the difference in risk between mentholated and non-mentholated cigarettes was not statistically significant and the confidence intervals were wide, so that no firm conclusion can be made.

Three case–control studies (Table 2.1.5.5; Bueno de Mesquita *et al*., 1991; Ghadirian *et al*., 1991; Howe *et al*., 1991) compared filter-tipped with untipped cigarettes. Ghadirian *et al*. (1991) observed an approximately twofold higher risk for pancreatic cancer in heavy smokers of untipped cigarettes than in smokers of filter-tipped cigarettes. Overall, however, there was no difference in effect.

(*c*) *Population characteristics*

(i) *Sex*

The effect of sex on risk was investigated in two case–control studies (Mack *et al*., 1986; Clavel *et al*., 1989) and four cohort studies (Akiba & Hirayama, 1990; Engeland *et al*., 1996; Fuchs *et al*., 1996; Tulinius *et al*., 1997). Relative risks were similar for men and women and no consistent evidence of an effect of sex on risk was observed.

(ii) *Ethnic group*

The role of ethnic group in the association between tobacco smoking and pancreatic cancer was investigated among African Americans and Caucasians in the USA (Silverman *et al*., 1994). No evidence of heterogeneity by ethnic group was obtained.

(*d*) *Confounding factors*

In addition to age and sex, other potential confounding factors considered in several studies included consumption of alcohol and coffee. The excess risk due to smoking remained after adjustment for some or all of these factors (Hiatt *et al*., 1988; Lyon *et al*., 1992; Zheng *et al*., 1993; Silverman *et al*., 1994; Engeland *et al*., 1996).

Five studies were carried out simultaneously in Utrecht, The Netherlands (Bueno de Mesquita *et al*., 1991), Toronto, Canada (Howe *et al*., 1991), Montreal, Canada (Ghadirian

et al., 1991), Opole, Poland (Zatonski *et al*., 1993) and Adelaide, Australia (Baghurst *et al*., 1991), as part of the Surveillance of Environmental Aspects Related to Cancer in Humans (SEARCH) programme of the IARC, to elucidate the roles of alcohol and tobacco in the development of pancreatic cancer. These were reviewed by Boyle *et al*. (1996).

Table 2.1.5.1. Case–control studies on tobacco smoking and cancer of the pancreas: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Wynder *et al*. (1973) USA 1950–64	Men: 100 cases and 200 controls; women: 42 cases and 107 controls	Hospital-based study. Cases from nine hospitals. Controls: hospitalized patients without tobacco-related disease, matched for age, sex and ethnicity
MacMahon *et al*. (1981) USA 1974–79	Men: 218 cases and 306 controls; women: 149 cases and 337 controls	Hospital-based study. Cases from 11 hospitals. Controls: hospitalized patients without tobacco or alcohol-related disease
Durbec *et al*. (1983) France 1979–80	Men: 37 cases and 100 controls; women: 32 cases and 99 controls	Cases selected in three hospitals; neighbourhood controls
Whittemore *et al*. (1983) USA 1962–66	Men: 122 cases and 781 controls	Population-based study. Cases from the University of Harvard and University of Pennsylvania. Data obtained by postal survey. Controls: randomly selected classmates
Wynder *et al*. (1983) USA 1981	Men: 153 cases; women: 122 cases; 7994 controls	Hospital-based study. Cases from 15 hospitals. Controls: hospitalized patients without tobacco-related disease
Kinlen & McPherson (1984) UK 1952–54	Men: 109 cases and 218 controls; women: 107 cases and 214 controls	Cases not specified. Controls: patients with cancers unrelated to smoking
Gold *et al.* (1985) USA 1978–80	Men and women: 201 cases, 201 hospital controls and 201 community controls	Hospital-based study in 16 hospitals; 62% cases histologically confirmed. Hospital controls: patients with heart, other circulatory and digestive diseases excluding any type of cancer; matched to cases on age, ethnicity, sex, hospital and date of admission. Community controls: selected by random-digit dialling, matched to cases on age, ethnicity, sex and telephone exchange
Hsieh *et al.* (1986) USA 1981–84	Men and women: 176 cases and 273 controls	Hospital-based study in 11 large hospitals 100% cases histologically confirmed Controls: patients with cancers of the breast, colon, stomach, uterus, benign tumours, hernia, colitis enteritis or other minor conditions

Table 2.1.5.1 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Mack *et al.* (1986) USA 1976–81	Men and women: 490 cases and 490 controls	Population-based study. Histologically confirmed cases identified by cancer registry; neighbourhood controls matched on age, sex, ethnicity and place
Wynder *et al.* (1986) USA 1981–84	Men: 127 cases and 371 controls; women: 111 cases and 325 controls	Hospital-based study in 18 hospitals in six cities. Cases: identified by histology or discharge summary. About three controls/case, matched for sex, age, ethnicity, hospital, year of admission, without tobacco-related disease
La Vecchia *et al.* (1987) Italy 1983–86	Men: 99 cases and 471 controls; women: 51 cases and 134 controls	Hospital-based study. Cases histologically confirmed. Controls admitted to hospitals for traumatic or surgical conditions, orthopaedic disorders, disorders of ear, nose and throat, skin or teeth
Clavel *et al.* (1989) France 1982–85	Men: 98 cases and 161 controls; women: 63 cases and 107 controls	Hospital-based study; 63% of cases histologically confirmed; controls had cancers and benign conditions unrelated to smoking or alcohol; two controls matched to each case by age, sex, hospital and interviewer
Cuzick & Babiker (1989) UK 1983–86	Men: 123 cases and 150 controls; women: 93 casess and 129 controls	Hospital-based study in 3 major city hospitals; 30.1% of cases histologically confirmed. Hospital controls and general practitioner controls had diseases unrelated to smoking
Ferraroni *et al.* (1989) Italy 1983–88	Men: 136 cases and 1334 controls; women: 78 cases and 610 controls	Hospital-based study. All cases histologically confirmed
Falk *et al.* (1990) USA 1979–83	Men and women: 198 cases and 209 controls	Hospital-based study in 29 hospitals; 83% cases histologically confirmed. Hospital controls matched for ethnicity, age, sex and hospital
Baghurst *et al.* (1991) Australia 1984–87	Men and women: 104 cases and 253 controls	Population-based study within the IARC SEARCH[a] programme. Controls obtained from a random sample of the electoral roll. Analysis matched by age and sex
Bueno de Mesquita *et al.* (1991) Netherlands 1984–88	Men and women: 176 cases and 487 controls	Population-based study within the IARC SEARCH[a] programme; 68% of cases histologically confirmed. Controls selected from municipal population registries
Ghadirian *et al.* (1991) Canada 1984–88	Men: 97 cases and 239 controls; women: 82 cases and 116 controls	Population-based study within the IARC SEARCH[a] Programme; 83% of cases histologically confirmed. Controls selected by random-digit dialling and from telephone directories, and matched to cases on age, sex and residence

Table 2.1.5.1 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Howe *et al.* (1991) Canada 1983–86	Men: 141 cases and 270 controls; women: 108 cases and 235 controls	Population-based study within the IARC SEARCH[a] Programme; 69% of cases histologically confirmed. Controls selected randomly from population lists in the same study area
Vioque & Walker (1991) Multinational; early 1960s to beginning of 1980s	Men and women: 108 cases and 374 controls	Hospital-based study. Data collected by the Boston Collaborative Drug Surveillance Programme in six countries: Canada, Israel, New Zealand, Scotland, USA and former West Germany; age-sex- and hospital-matched controls
Lyon *et al.* (1992) USA 1984–87	Men and women: 149 cases and 363 controls	Population-based study. Cases from the Utah Cancer Registry. Controls selected by random-digit dialling
Mizuno *et al.* (1992) Japan 1989–90	Men: 68 cases and 68 controls; women: 56 cases and 56 controls	Hospital-based study in seven hospitals. Cases and hospital controls matched on age, sex and institute. Controls: patients with benign digestive, circulatory and other disorders
Kalapothaki *et al.* (1993) Greece 1991–92	Men: 115 cases, 115 hospital controls and 115 visitor controls; women: 66 cases, 66 hospital controls and 66 visitor controls	Hospital-based study in eight major teaching hospitals. Cases (all histologically confirmed) and controls matched by hospital, gender and age. Controls: patients with fractures, appendicitis, ear, nose and throat conditions, goitre, varicose veins and sciatica
Zatonski *et al.* (1993) Poland 1985–88	Men: 68 cases and 89 controls; women: 42 cases and 106 controls	Population-based study within the IARC SEARCH[a] programme; 43.6% cases histologically confirmed
Silverman *et al.* (1994) USA 1986–89	Men: 244 cases and 1328 controls; women: 235 cases and 774 controls	Population-based study; 85% cases histologically confirmed. Controls aged 30–64 years selected by random-digit dialling, those aged 65–79 years selected by stratified random sampling from the Health Care Financing Administration's rosters. Cases and controls matched by area, age, sex and ethnicity
Gullo *et al.* (1995) Italy 1987–89	Men: 319 cases; women: 251 cases; 570 matched controls	Hospital-based study in 14 university and community hospitals. Cases and controls matched for age, sex, socioeconomic status and area; 70% cases histologically confirmed. Controls: patients with minor trauma or disorders unrelated to alcohol, coffee or tobacco consumption
Ji *et al*. (1995) China 1990–93	Men: 264 cases and 852 controls; women: 187 cases and 701 controls	Population-based study among permanent residents of 10 urban districts; cases identified by the Shanghai Cancer Registry; 37% of cases histologically confirmed. Controls randomly selected from Shanghai residents' registry

Table 2.1.5.1 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Siemiatycki *et al.* (1995) Canada 1979–86	Men: 116 cases, 1705 hospital controls with cancer and 533 population controls	All cases histologically confirmed. Control group had cancer at sites not previously demonstrated as affected by cigarette smoking
Fernandez *et al.* (1996) Italy 1983–92	Men: 229 cases and 1031 controls; women: 133 cases and 377 controls	All cases histologically confirmed. Controls: hospital patients with acute, non-neoplastic, non-digestive, non-smoking- and non-alcohol-related disorders
Lee *et al.* (1996) China, Province of Taiwan 1989–94	Men and women: 282 cases and 282 controls	Hospital-based study; 45.7% of cases histologically confirmed. Controls matched on age and sex had no history of pancreatic cancer.
Nishi *et al.* (1996) Japan 1987–92	Men and women: 141 cases and 282 controls	Population-based study. Controls matched for sex, age and place of residence selected using random-digit dialling
Ohba *et al.* (1996) Japan 1987–92	Men: 85 cases; women: 56 cases; and 282 controls	Cases: data obtained by direct interview; 41.8% of cases histologically confirmed. Controls matched on age, sex and residence randomly selected from telephone directories, data collected from self-administered questionnaires and telephone back-up
Fryzek *et al.* (1997) USA 1994–95	Men and women: 66 cases and 131 controls	Hospital-based study in five large hospitals and two teaching hospitals. Cases diagnosed by cytology. Controls selected by random-digit dialling. Cases and controls matched by age, sex, ethnicity and county of residence
Muscat *et al.* (1997) USA 1985–93	Men: 290 cases and 572 controls; women: 194 cases and 382 controls	Hospital-based study; all cases histologically confirmed. Controls without pancreatic cancer hospitalized for conditions unrelated to tobacco use. Cases and controls matched by hospital, sex, age, ethnicity and year of diagnosis
Partanen *et al.* (1997) Finland 1984–87	Men and women: 662 cases and 1770 controls	Population-based study. Cases from the Finnish Cancer Registry diagnosed 1984–87 and decedent in 1990. Cancer controls include 1014 patients with stomach, 441 with colon and 315 with rectum cancers
Mori *et al.* (1999) India 1994–96	Men and women: 79 cases and 146 controls	Hospital-based study; 100% of cases of histologically confirmed pancreatic ductal adenocarcinoma. Controls selected from healthy hospital visitors, matched to cases on sex and age
Villeneuve *et al.* (2000) Canada 1994–97	Men: 322 cases and 2452 controls; women: 261 cases and 2361 controls	Population-based study in 8 provinces, within the Canadian National Enhanced Cancer Surveillance System (NECSS); all cases histologically confirmed. Strategies for selection of controls varied by province.

2.1.6 *Cancer of the stomach*

(*a*) *Cohort studies*

A total of 29 prospective cohort studies have examined the association between smoking and stomach cancer. The details of the design of these studies are described in Table 2.1 and Table 2.1.6.1. Summary findings are presented in Table 2.1.6.2.

(i) *Intensity and duration of smoking*

Intensity (cigarettes/day), age at starting smoking and/or duration of smoking were studied in almost all of the cohorts. Sixteen cohort studies reported a statistically significant association between smoking and the risk for stomach cancer, with odds ratios ranging from 1.4 to 2.6 in current smokers (Kahn, 1966; Hirayama, 1982, 1985; Kono *et al*., 1987; Akiba & Hirayama, 1990; McLaughlin *et al*., 1990; Nomura *et al*., 1990a,b; Kneller *et al*., 1991; Kato *et al*., 1992a; Doll *et al*., 1994; McLaughlin *et al*., 1995; Nomura *et al*., 1995; Liaw & Chen, 1998; Gao *et al*., 1999; You *et al*., 2000; Chao *et al*., 2002). In eight of these studies, significant dose–response relationships were observed between intensity of smoking and the risk for stomach cancer (Kahn, 1966; Hirayama, 1985; Akiba & Hirayama, 1990; McLaughlin *et al*., 1990; Kneller *et al*., 1991; Doll *et al*., 1994; McLaughlin *et al*., 1995; Gao *et al*., 1999) and in five studies between duration of smoking and risk for stomach cancer (McLaughlin *et al*., 1990; Nomura *et al*., 1995; Liaw & Chen, 1998; You *et al*., 2000; Chao *et al*., 2002). In eight cohort studies, the increase in risk associated with smoking was statistically non-significant (Hammond, 1966; Doll & Peto, 1976; Kato *et al*., 1992b; Tverdal *et al*., 1993; Engeland *et al*., 1996; Yuan *et al*., 1996; Nordlund *et al*., 1997; Mizoue *et al*., 2000). Five studies did not find any association between smoking and stomach cancer (Guo *et al*., 1994; Murata *et al*., 1996; Chen *et al*., 1997; Tulinius *et al*., 1997; Terry *et al*., 1998).

Many studies that have tested the statistical significance of trend in risk with duration of smoking or number of cigarettes/day have included nonsmokers in the analysis. [The Working Group noted that the preferred approach is to limit testing for trend to exposed persons across gradients of exposure.]

(ii) *Smoking cessation*

Relative risks in former smokers have been examined in 16 studies and two studies have assessed the effect of number of years since quitting (Guo *et al*., 1994; Chao *et al*., 2002). The risk in former smokers ranged from 1.2 to 2.6 in men and women combined, from 0.9 to 2.2 in men and from 0.2 to 1.4 in women. Increasing number of years since cessation and younger age at cessation were associated with a significant trend in decreasing risk (Chao *et al*., 2002).

(iii) *Effect of sex*

Data for men and women were combined in five studies, seven studies presented data separated by sex, 16 studies presented results for men only and one study for women only.

Generally, the numbers of incident cases and of deaths from stomach cancer in women were small. The risks for stomach cancer associated with smoking were assessed separately for women in only seven cohort studies and, of these, only three reported significant increases in risk (Akiba & Hirayama, 1990; Gao *et al.*, 1999; Chao *et al*., 2002). In three studies, increases in risk were statistically non-significant (Hirayama, 1982; Kato *et al*., 1992a; Nordlund *et al*., 1997) and, in one study, smoking was not associated with risk for stomach cancer (Engeland *et al*., 1996).

(iv) *Bias and misclassification*

Several limitations of cohort studies should be considered. First, some studies reported a low response rate in the initial survey and a high proportion of individuals who were lost to follow-up, leading to selection bias. Second, most cohorts were followed passively and the information on smoking habits was based only on the initial survey, although many cohort members could have subsequently changed their smoking habits. Therefore, misclassification of former smokers as current smokers is possible. Thus, the risk for stomach cancer is most probably underestimated in most, if not all, cohort studies. The results of cohort studies could also be confounded by the effects of alcohol consumption. Only seven studies adjusted relative risks for alcohol consumption (Kono *et al*., 1987; Kato *et al*., 1992a; Nomura *et al*., 1995; Chen *et al*., 1997; Liaw & Chen, 1998; Mizoue *et al*., 2000; You *et al*., 2000). In most of these studies, the risk for stomach cancer in smokers was significantly different from unity.

(*b*) *Case–control studies*

Forty-five case–control studies detailed in Tables 2.1.6.3 and 2.1.6.4 have reported results regarding the influence of smoking on the risk for stomach cancer. Some very weak, early studies, although reported in Tables 2.1.6.3 and 2.1.6.4 for completeness, will not be considered further here (Wynder *et al*., 1963; Staszewski, 1969; Ames & Gamble, 1983). Twenty-three studies were hospital-based, one was a retrospective mortality study and 18 studies were population-based. In most studies, odds ratios were adjusted for variables such as sex, age, residence, socioeconomic status, income, diet and consumption of fresh fruits and vegetables. Odds ratios were adjusted for alcohol consumption in 18 studies (Hoey *et al*., 1981; Correa *et al*., 1985; Hu *et al*., 1988; You *et al*., 1988; Ferraroni *et al*., 1989; De Stefani *et al*., 1990; Lee *et al*., 1990; Jedrychowski *et al*., 1993; Kabat *et al*., 1993; Siemiatycki *et al*., 1995; Ji *et al*., 1996; Zhang *et al*., 1996; Gammon *et al*., 1997; De Stefani *et al*., 1998; Inoue *et al*., 1999; Ye *et al*., 1999; Lagergren *et al*., 2000; Zaridze *et al*., 2000).

(i) *Intensity and duration*

Thirty-one case–control studies (Haenszel *et al*., 1972; Hoey *et al*., 1981; Correa *et al*., 1985; Risch *et al*., 1985; Hu *et al*., 1988; You *et al*., 1988; De Stefani *et al*., 1990; Kato *et al*., 1990; Lee *et al*., 1990; Wu-Williams *et al*., 1990; Dockerty *et al*., 1991; Saha, 1991; Yu & Hsieh, 1991; Kabat *et al*., 1993; Hansson *et al*., 1994; Inoue *et al*., 1994;

Siemiatycki *et al*., 1995; Yu *et al*., 1995; Gajalakashmi & Shanta, 1996; Ji *et al*., 1996; Zhang *et al*., 1996; Gammon *et al*., 1997; De Stefani *et al*., 1998; Liu *et al*., 1998; Chow *et al*., 1999; Inoue *et al*., 1999; Ye *et al*., 1999; Lagergren *et al*., 2000; Mathew *et al*., 2000; Zaridze *et al*., 2000; Wu *et al*., 2001) reported a statistically significant association between smoking and the risk for stomach cancer. Most studies published after 1990 examined the effect of intensity and duration of smoking on the risk for stomach cancer. In most of them, there was a statistically significant dose–response trend between the number of cigarettes smoked daily, duration of smoking and/or age at start and the risk for stomach cancer (Hu *et al*., 1988; You *et al*., 1988; De Stefani *et al*., 1990; Kato *et al*., 1990; Lee *et al*., 1990; Wu-Williams *et al*., 1990; Yu & Hsieh, 1991; Kabat *et al*., 1993; Hansson *et al*., 1994; Gajalakashmi & Shanta, 1996; Ji *et al*., 1996; Zhang *et al*., 1996; Gammon *et al*., 1997; De Stefani *et al*., 1998; Ye *et al*., 1999; Lagergren *et al*., 2000; Mathew *et al*., 2000; Zaridze *et al*., 2000; Wu *et al*., 2001). In nine studies, no association was found between smoking and the risk for stomach cancer (Jedrychowski *et al*., 1986; Buiatti *et al*., 1989; Ferraroni *et al*., 1989; Boeing *et al*., 1991; Buiatti *et al*., 1991; Agudo *et al*., 1992; Palli *et al*., 1992; Jedrychowski *et al*., 1993; Gao *et al*., 1999).

(ii) *Smoking cessation*

Twenty-five studies examined relative risks in former smokers and several also examined the effect of cessation of smoking (De Stefani *et al*., 1990; Kabat *et al*., 1993; Hansson *et al*., 1994; Inoue *et al*., 1994; Ji *et al*., 1996; Gammon *et al*., 1997; De Stefani *et al*., 1998; Chow *et al*., 1999; Ye *et al*., 1999; Lagergren *et al*., 2000; Wu *et al*., 2001). Quitting smoking was found to decrease the risk for cancer. A significant negative trend for increasing number of years since cessation was reported in six studies (De Stefani *et al*., 1990; Hansson *et al*., 1994; Inoue *et al*., 1994; Gammon *et al*., 1997; De Stefani *et al*., 1998; Lagergren *et al*,. 2000), whereas two studies found no effect (Kabat *et al*., 1993; Ji *et al*., 1996). However, in examining temporal trends in risk with time since cessation, some studies did not exclude persons who had quit recently, among whom increased risk may reflect cessation due to smoking-attributable disease.

(iii) Subsites of stomach cancer

Several case–control studies presented studies by subsites (De Stefani *et al*., 1990; Wu-Williams *et al*., 1990; Saha, 1991; Palli *et al*., 1992; Kabat *et al*., 1993; Inoue *et al*., 1994; Zhang *et al*., 1996; Gammon *et al*., 1997; De Stefani *et al*., 1998; Ye *et al*., 1999; Zardize *et al*., 2000; Wu *et al*., 2001). In all the studies that distinguished between cancer of the gastric cardia and distal stomach, an effect of smoking was seen on the risk for cancers at both sites. Dose–response relationships were observed between number of cigarettes smoked per day, duration of smoking and time since quitting for cancers of both sites. The significant association between smoking and cancer risk persisted when relative risks were examined separately for intestinal and diffuse histological types (Kato *et al*., 1990; Ye *et al*., 1999).

(iv) *Effect of sex*

Most studies included both men and women; seven studies reported results for men only and only eight reported results for men and women separately (Haenszel *et al*., 1972; Kato *et al*., 1990; Kabat *et al*., 1993; Inoue *et al*., 1994; Ji *et al*., 1996; Liu *et al*., 1998; Chow *et al*., 1999; Inoue *et al*., 1999). The number of cases of stomach cancer in women was generally small and the increase in risk estimates was generally lower than that for men and was not statistically significant (Kato *et al*., 1990; Inoue *et al*., 1994; Ji *et al*., 1996; Liu *et al*., 1998). However, in the studies in which a sufficient number of cases of stomach cancer in women were included, the relative risks were significant and comparable with those in men (Kabat *et al*., 1993; Chow *et al*., 1999; Inoue *et al*., 1999).

(v) *Effect of ethnicity*

The only study that investigated ethnicity reported a significantly higher risk for African Americans than for Caucasians (Correa *et al*., 1985).

(vi) *Type of tobacco and type of cigarette*

The effects of black and blond tobacco were distinguished only by De Stefani *et al*. (1990, 1998). Five studies evaluated the effect of filter tips (De Stefani *et al*., 1990; Jedrychowski *et al*., 1993; Gammon *et al*., 1997; De Stefani *et al*., 1998; Chow *et al*., 1999) and one study looked at the effect of swallowing tobacco smoke (Saha, 1991). The risk associated with smoking black tobacco was higher than that for smoking blond tobacco (De Stefani *et al*., 1990, 1998). There was no clear difference in risk between smokers of filter-tipped or untipped cigarettes or whether or not smoke is swallowed.

(vii) *Bias and misclassification*

The relative risk for stomach cancer associated with smoking is most probably underestimated, particularly in hospital-based case–control studies, because of a substantial proportion of controls with smoking-related diseases. Of special concern are the studies in which prevalence of smoking was higher in controls than in cases and in which controls with smoking-associated diseases were included (Haenszel *et al*., 1976; Correa *et al*., 1985; Jedrychowski *et al*., 1986; Lee *et al*., 1990; Boeing *et al*., 1991; Agudo *et al*., 1992; Zaridze *et al*., 2000) or in which the diagnoses of hospital controls were not reported (Haenszel *et al*., 1972).

(*c*) Helicobacter pylori *infection*

A positive association between smoking and the risk for stomach cancer could be confounded by the effect of *Helicobacter pylori* infection status. A large body of evidence supports a causative role for *H. pylori* in stomach cancer. In 1994, IARC recognized *H. pylori* as a class 1 human carcinogen (IARC, 1994).

None of the available cohort studies have assessed *H. pylori* infection status. Two case–control studies investigated the interaction between *H. pylori* seropositivity and smoking in relation to the risk for stomach cancer (Zaridze *et al*., 2000; Siman *et al*.,

2001). The relative risk for stomach cancer was higher in *H. pylori*-infected men (Zaridze *et al*., 2000). These results suggest that smoking may potentiate the carcinogenic effect of *H. pylori*.

Several studies have shown that *H. pylori* infection status is not associated with smoking habit. Limburg *et al*. (2001) examined the association between seropositivity for *H. pylori* and different risk factors. The proportion of seropositive individuals was similar in nonsmokers (58%) and in smokers (61%). Moreover, the prevalence of CagA-seropositive individuals was higher in nonsmokers (32%) than in smokers (24%). Another study in China looked at the association between the prevalence of *H. pylori* infection and smoking, alcohol consumption and diet. The prevalence of *H. pylori* positivity was lower among ever-smokers than never-smokers, with an odds ratio for ever-smokers of 0.9 (95% CI, 0.7–1.0). In the highest category of smokers, who had a lifetime exposure of more than 14 235 packs, the odds ratio was 0.8 (95% CI, 0.6–1.1) (Brown *et al*., 2002).

Similar evidence has been obtained in Europe. The prevalence of seropositive subjects is similar among never- (50.9%), former (48.7%) and current smokers (45.1%). In fact, the percentage of *H. pylori* seropositivity is somewhat lower among current smokers than among never-smokers (crude odds ratio, 0.8; 95% CI, 0.7–0.9) (EUROGAST Study Group, 1993). In only one study conducted in northern England was smoking more than 35 cigarettes/day found to be associated with higher risk for *H. pylori* positivity (Moayyedi *et al*., 2002). However, it should be noted that the proportion of subjects infected was identical in all categories of low smoking intensity. Overall, there is no association between *H. pylori* infection status and smoking. Therefore, *H. pylori* is of little or no relevance with regard to potential confounding of the association between smoking and stomach cancer.

(*d*) *Precursor lesions*

According to one widely accepted model of gastric carcinogenesis, development of stomach cancer is preceded by several precursor stages, including chronic atrophic gastritis, intestinal metaplasia and dysplasia. An increase in the relative risk for developing these lesions has been shown to be associated with smoking, with a significant positive trend associated with intensity and duration of smoking. The magnitude of the association was stronger for dysplasia than for metaplasia (Kneller *et al*., 1991). You *et al*. (2000) found an increased risk for the progression of precursor lesions to dysplasia and cancer for subjects who had smoked for more than 25 years and a significant trend with increasing duration of smoking.

Overall, the results from both cohort and case–control studies are consistent with a causal role of tobacco smoking in the development of stomach cancer.

Table 2.1.6.1. Additional cohort studies on tobacco smoking and stomach cancer: main characteristics of study design

Reference Country and years of follow-up	Cohort sample	Cases/deaths identification	Comments
Kato *et al.* (1992a) Japan 1985–91	9753 male (≥ 40 years) and female (≥ 30 years) inhabitants of a mountainous area of Aichi prefecture	Death certificates	Questionnaires linked to data from another questionnaire survey conducted in 1983–84 that included information on smoking habits
Kato *et al.* (1992b) Japan 1985–89	5395 patients receiving gastroscopic examination at Aichi Centre Hospital	Linkage with gastro-endoscopic records at Aichi Cancer Centre Hospital, Aichi Cancer Registry and death certificates	Diagnoses at baseline included: atrophic gastritis (mild, moderate/severe), 'extension on the greater curvature', 'extension on the lesser curvature', gastric ulcer and gastric polyp (none with normal gastric mucosa)
You *et al.* (2000) China 1989–94	3433 subjects participating in a gastric cancer-screening study, residents in 14 villages randomly selected within Linqu County, aged 35–64 years	Cases identified by pathological examination of biopsies and endoscopic examination	Diagnosis of cohort members divided into superficial gastritis or chronic atrophic gastritis, intestinal metaplasia and dysplasia (none with normal gastric mucosa)

Table 2.1.6.3. Case–control studies on tobacco smoking and stomach cancer: main characteristics of study design

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Wynder *et al.* (1963) Slovenia, Iceland, Japan and USA Years of study not specified	Men: 367 cases and 401 controls; women: 154 cases and 252 controls	Hospital-based study Cases from Japan (51%), New York (30%), Slovenia (10%) and Iceland (9%) Controls with malignant and non-malignant diseases, individually matched by age and hospital; cancers of the respiratory and upper alimentary tract excluded
Staszewski (1969) Poland 1957–68	Men: 450 cases and 771 controls; women: 178 cases and 383 controls	Hospital-based study Cases confirmed by histopathology (72%) or surgery and/or radiology (28%) as cancer of the cardia (17%), middle part (27%), pylorus (33%) or all stomach (23%) Controls hospitalized for diseases not connected with smoking; cancers of the colon and rectum excluded
Haenszel *et al.* (1972) USA 1963–69	Men: 135 cases and 270 controls; women: 85 cases and 170 controls	Hospital-based study among Japanese Hawaiian migrants (120) and their offspring (100) Cases: 96% confirmed histologically as cancer of the cardia (6%), fundus (8%), prepylorus (10%), antrum (33%), lesser or greater curvatures (25%) or other/unknown site (18%) Controls individually matched by age, sex, hospital and time of visit; gastric ulcer, other stomach diseases and cancer of digestive system excluded
Haenszel *et al.* (1976) Japan 1962–65	Men: 526 cases and 1052 controls; women: 257 cases and 514 controls	Hospital-based study from eight hospitals in Hiroshima (247) and Miyagi (416) Cases: 98% confirmed microscopically as cancer of the cardia (9%), fundus (4%), antrum (40%), prepylorus (31%), or lesser or greater curvatures (14%); aged ≥ 35 years Controls with neoplasms, gastrointestinal, infectious and circulatory diseases and conditions affecting nervous system and sense organs; individually matched for age, sex, hospital and time of visit; gastric ulcer, other stomach diseases and cancer of digestive system excluded
Hoey *et al.* (1981) France 1978–80	Men: 40 cases and 168 controls	Hospital-based study in endoscopy department among French residents of Lyon Cases confirmed histologically; mean age, 65.4 years; 91% of eligible cases Controls with other gastrointestinal diagnoses (hiatal hernia (29%), colorectal polyps (33%), gallstones (17%) and colorectal cancer (21%)); mean age, 59.9 years

Table 2.1.6.3 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Ames & Gamble (1983) USA Years of study not specified	Men: 46 cases and 92 controls	Prospective mortality study on white coal miners Controls: deaths from other cancers (1:1) and from non-cancer/non-accidents (1:1), individually matched by age at death and year of birth (± 3 years)
Correa *et al.* (1985) USA 1979–83	Men: 264 cases and 264 controls; women: 127 cases and 127 controls	Hospital-based study in 26 counties of South Louisiana Cases: 98% confirmed histologically as cancer of the antrum/corpus (87%), cardia (6.5%) or other/unknown site (6.5%) Controls mainly with cardiovascular (20%), gastrointestinal (12%), infectious (11%) or respiratory (10%) diseases; individually matched on age (± 5 years), sex, race and hospital
Risch *et al.* (1985) Canada 1979–82	Men: 163 cases and 163 controls; women: 83 cases and 83 controls	Population-based study Cases confirmed histologically; aged 35–79 years Controls randomly selected from electoral lists, individually matched by age (± 4 years), sex, province of residence and neighbourhood; participation rate, 58%
Jedrychowski *et al.* (1986) Poland 1980–81	Men: 70 cases and 140 controls; women: 40 cases and 80 controls	Hospital- and population-based study using interviews Cases confirmed histologically Controls individually matched by age (± 5 years) and sex: hospital-based (1:1), with orthopaedic problems, heart or endocrinological disorders; obvious gastrointestinal diseases and recent dietary abnormality excluded; population-based (1:1), randomly selected from healthy participants of a medical survey on chronic chest diseases
You *et al.* (1988) China 1984–86	Men: 443 cases and 888 controls; women: 121 cases and 243 controls	Population-based study among residents of Linqu for ≥ 10 years Cases confirmed by histology (50%), endoscopy or surgery (32%) or radiological and clinical examination (17%); aged 35–64 years; 82% of eligible cases Controls randomly selected using rosters, frequency-matched by age and sex; participation rate, 100%

Table 2.1.6.3 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Hu *et al.* (1988) China 1985–86	Men: 170 cases and 170 controls; women: 71 cases and 71 controls	Hospital-based study from two hospitals in Harbin and Heilongjiang province using interviews Cases confirmed histologically; aged 25–80 years Controls with non-neoplastic diseases (chest diseases, general surgery, urological and orthopaedic diseases, trauma); individually matched by sex, age and area of residence
Buiatti *et al.* (1989, 1991) Italy 1985–87	1989 study: men: 640 cases; women: 376 cases; 1991 study: men: 597 cases; women: 326; 1159 controls (705 men and 454 women)	Population-based study among residents of four areas with varying incidence of stomach cancer using interviews Cases confirmed histologically as intestinal (55%), diffuse (23%) or mixed/unclassified (22%); mean age, 65 years; 83% of eligible cases Controls randomly selected from general population, frequency-matched on 5-year age-groups and sex; participation rate, 81%
Ferraroni *et al.* (1989) Italy 1983–88	Men: 243 cases and 1334 controls; women: 154 cases and 610 controls	Hospital-based study from four major hospitals in Milan Cases confirmed histologically; aged ≤ 75 years Controls with traumatic (38%), non-traumatic orthopaedic (15%) and acute surgical conditions (34%) and ear, nose, throat, skin and dental disorders (13%); malignant tumours, digestive tract disorders or any coffee-, alcohol- or tobacco-related conditions excluded; median age, 56 years
De Stefani *et al.* (1990) Uruguay 1985–88	Men: 138 cases and 414 controls; women: 72 cases and 216 controls	Hospital-based study from the University Hospital in Montevideo using interviews Cases confirmed histologically as cancer of the cardia (13%), corpus (9%), antrum (15%) and unclassified (63%); aged 30–89 years; 100% of eligible cases participated. Controls individually matched (1:3) by age (± 5 years) and sex; tobacco- or alcohol-related diseases or gastric conditions excluded
Kato *et al.* (1990) Japan 1985–89	Men: 289 cases and 2013 controls; women: 138 cases and 2415 controls	Hospital-based study at gastroscopy department in Aichi prefecture; self-administered questionnaire Cases confirmed histologically, mainly of diffuse (48%) or intestinal (50%) type Controls with normal gastric mucosa (3014) or atrophic gastritis (1414); other cancers, resected stomach and gastroduodenal diseases excluded 89% participation rate for cases and controls
Lee *et al.* (1990) China, Province of Taiwan 1954–88	Men: 123 cases and 478 controls; women: 87 cases and 332 controls	Hospital-based study in four major hospitals in Taipei using interviews Cases confirmed histologically; 90% of eligible cases participated. Controls from ophthalmic service, group matched by sex and age; participation rate, 96%

Table 2.1.6.3 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Wu-Williams *et al.* (1990) USA 1975–82	Men: 137 cases and 137 controls	Population-based study among white men from Los Angeles County using interviews Cases confirmed histologically as cancer of the cardia (58), fundus/body (10), antrum/pylorus (22) or other site (47); aged < 55 years; 52 % of eligible cases participated. Controls individually matched by age (± 5 years), sex and race (Hispanic white and other white)
Boeing *et al.* (1991) Germany 1985–87	Men and women: 143 cases (almost equal number of men and women) and 579 controls (slightly more women)	Hospital-based study from five hospitals in Bavaria and Hesse using interviews Cases confirmed histologically as cancer of the cardia (17%), corpus (32%), antrum/pylorus (40%) or multiple sites (11%); aged 32–80 years; 85% of eligible cases Controls: 251 visitors and 328 patients with other cancers (12%), metabolic (13%), cardiovascular (30%) and respiratory (5%) diseases, and diseases of digestive organs other than stomach (23%); matched by sex and age (± 3 years); patients with history of atrophic gastritis or intestinal metaplasia excluded; participation rate, 90%
Dockerty *et al.* (1991) New Zealand 1980–84	Men: 797 cases and 8398 controls	Cases and controls from New Zealand Cancer Registry Cases aged ≥ 20 years; 78% of all cases registered at the Registry. Controls with other types of cancer; smoking-related cancers excluded
Saha (1991) UK 8 years	Men: 81 cases and 162 controls; women: 36 cases and 72 controls	Hospital-based study at four hospitals using interviews Cases confirmed histologically as cancer of the cardia (46), body (24) or antrum (47); aged 35–89 years Controls with benign surgical conditions, individually matched by age (± 5 years), sex and social class; respiratory, upper gastrointestinal and vascular diseases excluded
Yu & Hsieh (1991) China 1976–80	Men: 52 cases and 2676 controls; women: 32 cases and 1843 controls	Population-based study among primary and middle-school staff in Shanghai using interviews for cases and self-administered questionnaire for controls Cases confirmed histologically as cancer of the lesser curvature (73%), pylorus (17%), antrum (6%) or other site (4%); 89% of eligible cases participated. Controls from 55 randomly selected schools stratified by districts; participation rate, 91%

Table 2.1.6.3 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Agudo *et al.* (1992) Spain 1987–89	Men: 235 cases and 235 controls; women: 119 cases and 119 controls	Hospital-based study in 4 regions with varying incidences of stomach cancer using a questionnaire Cases confirmed histologically mainly as intestinal (56%) or diffuse (26%) type; mean age, 65.2 years Controls with a wide variety of diagnoses; individually matched by hospital, sex, age (± 3 years) and area of residence; cancers of digestive and respiratory tracts, and chronic respiratory illnesses excluded; aged 31–88 years (mean, 65.5 years)
Hoshiyama & Sasaba (1992a,b) Japan 1984–90	Men: 251 cases and 483 controls	Population-based study among people living in Saitama Prefecture for ≥ 10 years using interviews Cases confirmed histologically as single (216) or multiple (35) cancer; 73% of eligible cases participated. Controls randomly selected from electoral roll with stratification by sex and age; participation rate, 28%
Palli *et al.* (1992) Italy 1985–87	Men: 597 cases and 705 controls; women: 326 cases and 454 controls	Population-based study using interviews Cases from study by Buiatti *et al.* (1991); histologically confirmed as cancer of the cardia (68) or other site (819); cancer of the stump (36) excluded from the analysis Controls randomly selected from 5-year age and sex strata; history of gastric surgery excluded
Jedrychowski *et al.* (1993) Poland 1986–90	Men: 520 cases and 520 controls	Hospital-based study from nine university hospitals in Poland using interviews Cases confirmed histologically as cancer of the cardia (137, of which 58% of intestinal and 20% of diffuse type) or of non-cardia (383, of which 51% of intestinal and 36% of diffuse type); aged < 75 years; 100% of eligible cases participated. Controls admitted mostly for accidents, orthopaedic problems or general surgery; individually matched by age (± 5 years); diseases of the gastrointestinal tract and other cancers excluded; participation rate, 100%
Kabat *et al.* (1993) USA 1981–90	Men: 295 cases and 4544 controls; women: 52 cases and 2228 controls	Hospital-based study in 28 hospitals of seven states using interviews Cases confirmed histologically as cancer of distal oesophagus/gastric cardia (194) or of distal stomach (153) Controls with non-tobacco-related cancers (43%) and non-cancer diagnoses (57%), including fractures, disc problems, eye problems, acute infections and trauma; matched by age (± 5 years), sex, race and hospital; cancers and other diseases of the gastrointestinal tract excluded

Table 2.1.6.3 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Hansson *et al.* (1994) Sweden 1989–92	Men: 218 cases; women: 120 cases; and 679 controls [no information on sex distribution]	Population-based study among residents of five counties in central and northern Sweden using interviews Cases confirmed histologically; aged 40–70 years (mean, 67.7 years); 74% of eligible cases Controls randomly selected from population registers, frequency-matched by sex and age strata; mean age, 67.0 years; participation rate, 77%
Inoue *et al.* (1994) Japan 1988–91	Men: 420 cases and 420 controls; women: 248 cases and 248 controls	Hospital-based study at Aichi Cancer Centre Hospital using self-administered questionnaire Cases identified through Cancer Registry database; confirmed histologically as cancer of the cardia, middle part or antrum; aged ≥ 18 years (mean, 58.0 years) Controls randomly selected from first-visit outpatients, individually matched by sex, age (± 2 years) and date of first visit (± 2 months); history of cancer or any other specific disease excluded; mean age, 57.8 years; participation rate, 98%
Siemiatycki *et al.* (1995) Canada 1979–85	Men: 251 cases and 2238 controls	Hospital- and population-based study among residents of Montreal area using interviews Cases confirmed histologically; aged 35–70 years Controls: 533 population-based, selected from electoral lists stratified by age; participation rate, 72%; 1705 hospital-based; cancers of the lung, bladder, oesophagus, pancreas, liver and kidney excluded
Yu *et al.* (1995) China 1991–93	Men: 453 cases and 453 controls; women: 258 cases and 258 controls	Population-based study among residents of Hongkou district and Nanhui county (Shanghai) using interviews Cases confirmed; aged < 80 years; 91% of eligible cases participated. Controls individually matched for age (± 3 years), sex and residence (street); participation rate, 99%
Gajalakshmi & Shanta (1996) India 1998–90	Men: 287 cases and 287 controls; women: 101 cases and 101 controls	Hospital-based study from Cancer Institute in Chennai (Madras) using interviews Cases confirmed histologically (75%) or by barium meal evidence, exploratory surgery or endoscopy (25%) Controls with cancer mainly of the penis, bone and connective tissue, skin and cervix; individually matched for age (± 5 years), sex, religion and mother tongue; cancers of the gastrointestinal tract, bladder and pancreas and smoking-related cancers excluded

Table 2.1.6.3 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Ji *et al.* (1996) China 1988–89	Men: 770 cases and 819 controls; women: 354 cases and 632 controls	Population-based study among permanent residents in Shanghai using interviews Cases identified through Shanghai cancer registry; confirmed histologically (52%) or by surgery, endoscopy, X-rays or ultrasound (48%) as cancer of the cardia (16%), distal stomach (70%) or unspecified site (14%); aged 20–69 years; 66% of eligible cases participated. Controls randomly selected, frequency-matched for age (5-year categories) and sex; participation rate, 86%
Zhang *et al.* (1996) USA 1992–94	Men: 122 cases and 62 controls; women: 40 cases and 70 controls	Hospital-based study at endoscopy department in New York using self-administered questionnaire Cases confirmed histologically as cancer of oesophagus/cardia (95) or distal stomach (67) Controls were cancer-free, with atrophic/chronic or other types of gastritis (71%) or disease-free (29%)
Gammon *et al.* (1997) USA 1993–95	Men: 477 cases and 555 controls; women: 152 cases and 140 controls	Population-based study using interviews Cases confirmed histologically as cancer of the cardia (261) or other sites (368); aged 30–79 years; 81% of eligible cases participated. Controls aged 30–65 years identified by random-digit dialling and those aged 65–79 years by random sampling of rosters; frequency-matched by age (5-year group) and sex; participation rate, 70%
De Stefani *et al.* (1998) Uruguay 1992–96	Men: 311 cases and 622 controls	Hospital-based study from four major hospitals in Montevideo using interviews Cases confirmed microscopically as cancer of the cardia (24), antrum (240), fundus (25) or of diffuse type (22); aged 25–84 years Controls mainly with eye disorders (33%), hernia (17%), osteoarticular diseases (11%) and skin (9%) and ear (7%) disorders; frequency-matched for age (10-year group), hospital, time of visit and residence; tobacco- and alcohol-related diseases and digestive tract conditions excluded; aged 25–84 years; participation rate for cases and controls, 93%
Liu *et al.* (1998) China 1986–88	Men: 20 195 cases and 52 775 controls; women: 9009 cases and 34 560 controls	Retrospective mortality study Cases aged 35–69 years Controls: death from neoplastic, respiratory and cardiovascular diseases excluded

Table 2.1.6.3 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Chow *et al.* (1999) Poland 1994–97	Men: 302 cases and 314 controls; women: 162 cases and 166 controls	Population-based study among Warsaw residents using interviews Cases from 22 hospitals in Warsaw, confirmed histologically mainly as intestinal (67%) or diffuse (14%); aged 21–79 years; 90% of eligible cases participated. Controls randomly selected from registry, frequency-matched by age (5-year categories) and sex; participation rate, 82%
Gao *et al.* (1999) China 1995	Men: 110 cases and 154 controls; women: 43 cases and 80 controls	Population-based study among Yangzhong residents using interviews Cases from Regional Cancer Registry, confirmed histologically; aged 30–79 years Controls from household registration office, individually matched for sex, age (± 2 years) and town or area of residence; participation rate for cases and controls, 100%
Inoue *et al.* (1999) Japan 1988–95	Men: 651 cases and 12 041 controls; women: 344 cases and 31 805 controls	Hospital-based study at Aichi Cancer Centre Hospital Cases from cancer registry and surgical records, confirmed histologically mainly as differentiated (46%) or non-differentiated (53%) Controls with benign tumours or non-neoplastic polyps (13%), benign and non-specific diseases (43%), or no abnormal findings (44%); cancers or past history of cancer excluded; aged ≥ 18 years
Ye *et al.* (1999) Sweden 1989–95	Men: 348 cases and 779 controls; women: 166 cases and 385 controls	Population-based study using interviews Cases confirmed histologically as cancer of the cardia (90), and distal cancer of intestinal (260) or diffuse (164) type; aged 40–79 years; 62% of eligible cases participated. Controls randomly selected from registers, frequency-matched by age and sex; participation rate, 76%
Lagergren *et al.* (2000) Sweden 1995–97	Men: 223 cases and 681 controls; women: 39 cases and 139 controls	Population-based study among people born in Sweden using interviews Cases of cardia; aged ≤ 80 years, mean 66 years; 83% of eligible cases participated. Controls randomly selected from whole population of Sweden, frequency-matched for age and sex; mean age, 68 years; participation rate, 73%
Mathew *et al.* (2000) India 1988–91	Men: 151 cases and 228 controls; women: 43 cases and 77 controls	Hospital-based study at the Regional Cancer Centre in Trivandrum using interviews Cases confirmed by histology and/or endoscopy or barium meal evidence, aged ≥ 20 years Controls selected from visitors, individually matched for age (± 5 years), sex, religion and residential area; controls with gastric complaints excluded

Table 2.1.6.3 (contd)

Reference Country and years of study	Number of cases and controls	Criteria for eligibility and comments
Zaridze *et al.* (2000) Russia 1996–97	Men: 248 cases and 292 controls; women: 200 cases and 318 controls	Hospital-based study in two cancer hospitals (cases) and two general hospitals (controls) among Moscow residents using self-administered questionnaire Cases confirmed histologically as cancer of the cardia (92) or non-cardia (356); aged < 75 years; 98% of eligible cases participated. Controls with a variety of conditions including respiratory (10%) and heart (10%) diseases, diseases of the nervous system (10%) and hypertension and stroke (9%); cancer and/or gastrointestinal diseases excluded; participation rate, 97%
Wu *et al.* (2001) USA 1992–97	Men: 492 cases and 999 controls; women: 228 cases and 357 controls	Population-based study among whites, Latino-, African and Asian Americans from Los Angeles county using interviews Cases confirmed histologically as cancer of the cardia (277) or distal stomach (443); aged 30–74 years; 56% of eligible cases participated. Controls individually matched by neighbourhood, sex, age (± 5 years) and ethnicity; diagnosis of stomach or oesophageal cancer excluded

Table 2.1.6.4. Case–control studies on tobacco smoking and stomach cancer

Reference Country and years of study	Subjects	Exposure estimates	Relative risk (95% CI)	Comments, variables adjusted for, significance, limitations of the study
Wynder *et al.* (1963) Slovenia, Iceland, Japan, USA	Men and women			No definition of smoking habit. No participation rate for cases or controls. No relative risk calculated. No consistent difference between cases and controls in terms of type or quantity of tobacco smoked
Staszewski (1969) Poland 1957–68	Men and women	Ever-smoker % of smokers % of heavy smokers[†] Index of smoking[‡]	1.6 Cases Controls 90.0 84.8 $p \leq 0.01$ 71.9 63.0 $p \leq 0.01$ 472 428 $p < 0.05$	No definition of smoking habit. No participation rate for cases or controls. The majority of cases among men were cancer of the cardia and pylorus, and among women cancer of the cardia. [†]Index of smoking ≥ 300 [‡]Index of smoking = daily amount of tobacco × years of smoking
Haenszel *et al.* (1972) USA, Hawaii 1963–69	Men and women	Any tobacco use Hawaiian Japanese Migrant Offspring ≥ 20 vs < 20 cigarettes/day	Men and women Men Women 1.5* 1.4 1.7 1.9* 1.9* 1.7 1.1 0.9 1.8 0.9	* $p < 0.05$ No definition of tobacco use. No response rate for cases or controls. Odds ratios adjusted for sex and age, and for birthplace for Hawaiian Japanese
Haenszel *et al.* (1976) Japan 1962–65	Men and women	Any tobacco use Hiroshima Miyagi Hawaii[†]	 1.1 1.3 1.4 All $p > 0.05$	Odds ratio reported for men only, probably because of low prevalence of smoking among women in Japanese populations. Same questionnaire used as in previous study. No response rate for cases or controls. Odds ratios adjusted for prefecture, occupation (farm, non-farm), age and sex. Relative risks probably underestimated because of high proportion of controls with smoking-related diseases. [†]Data from previous study

Table 2.1.6.4 (contd)

Reference Country and years of study	Subjects	Exposure estimates	Relative risk (95% CI)		Comments, variables adjusted for, significance, limitations of the study
Hoey *et al.* (1981) France 1978–80	Men	≥ 7 cigarettes/week	4.8 (1.6–14.8)		Very small study. No participation rate for controls. Significant difference between cases and controls in mean age and weekly alcohol consumption. Little information about potential confounding. Relative risk reduced to 3.8 after adjustment for wine intake, but still statistically significant [95% CI not given].
Ames & Gamble (1983) USA	Men	Current smoker	0.7 (0.2–2.0)		Very small study. Deaths from other cancers used as controls, leading to underestimation of risk
Correa *et al.* (1985) USA 1979–83	Men and women	*Cigarette smoker* Ever-smoker Former smoker Current smoker	**Whites** 1.3 (0.8–2.2) 1.0 (0.5–2.0) 1.4 (0.8–2.4)	**Blacks** 2.6 (1.4–5.0) 1.9 (0.8–4.2) 2.7 (1.3–5.3)	No response rate for cases or controls. No definition of smoking habit. High proportion of interviews with proxies. Odds ratios adjusted for age, sex, current alcohol consumption, respondent type, education and income. About 30% of controls had cardiac or respiratory diseases. No significant linear trend for no. of cigarettes/day, pack–years or age at starting smoking. Increasing risk with increasing duration of smoking for blacks only ($p < 0.05$). Relative risk for deep inhalers of 1.8 compared with nonsmokers and non-inhalers. Adjustment for vitamin C intake had no effect on relative risk [data not shown].
Risch *et al.* (1985) Canada 1979–82	Men and women	20 pack–years	1.3 (1.01–1.6)		No definition of smoking habit or smoking history. Low response rate for controls. Odds ratios adjusted for ethnicity, various foods and type of water supply.
Jedrychowski *et al.* (1986) Poland 1980–81	Men and women	Former smoker Current smoker	0.8 (0.3–2.1) 0.7 (0.4–1.2)		No definition of smoking habit. No response rate for cases or controls. Analysis performed with hospital controls only. Odds ratio adjusted for residence only. Relative risk could be underestimated because hospital controls included patients with smoking-related diseases

Table 2.1.6.4 (contd)

Reference Country and years of study	Subjects	Exposure estimates	Relative risk (95% CI)		Comments, variables adjusted for, significance, limitations of the study
You *et al.* (1988) China 1984–86	Men and women	*Cigarettes /day* < 20 ≥ 20 *p* for trend	 1.3 (0.9–1.9) 1.5 (1.0–2.1) 0.01		Analysis for men only because there were few women who smoked. Odds ratios adjusted for age, family income and alcohol drinking. Association stronger when analysis restricted to histologically confirmed cases [data not shown].
Hu *et al.* (1988) China 1985–86	Men and women	*Cigarettes/day* < 6 ≥ 6 *Duration (years)* < 14 14–25 > 25 *Age at starting smoking (years)* > 21 6–21 < 6 *p* for trend *Index of smoking*[a] < 7 ≥ 7	**Univariate** 1.0 1.8 (1.2–2.6) 1.0 1.6 (0.7–3.6) 2.3 (1.6–3.5) *p* for trend < 0.001 2.2 (1.1–4.4) 1.6 (0.8–3.2) 1.0 < 0.001 1.0 2.0 (1.4–2.9)	**Multivariate** 1.0 2.0 (1.4–2.7)	No definition of smoking status. No participation rate for cases or controls. Multivariate analysis adjusted for Chinese cabbage and alcohol consumption. Inconsistency between table and text in direction of trend for age at starting analysis, and limit of category surprisingly low.
Buiatti *et al.* (1989, 1991) Italy 1985–87	Men and women	Former smoker Current smoker Low High	0.9 (0.7–1.1) 1.0 (0.8–1.4) 1.2 (0.9–1.7)		No definition of smoking history or smoking habit. Odds ratios adjusted for age, sex, study area and place of residence, migration from the south, socioeconomic status, family history of stomach cancer and Quetelet index. Results not presented in tables. No association found for specific histological types separately.

2.1.7 *Colorectal cancer*

(*a*) *Overview*

In the last three decades, a total of 60 epidemological studies have investigated the relationship between tobacco smoke and colorectal cancer, but few were specifically designed to study the effects of tobacco smoking. Although most of the earlier studies did not show any consistent association between tobacco use and risk, several prospective cohort and case–control studies published since the late 1980s have found a significantly increased risk for colorectal cancer among smokers. Also, since the late 1980s, smoking has emerged as a risk factor for colorectal adenomas, a well-established precursor for colorectal cancer. On the basis of these new findings on smoking and colorectal cancer and adenomas, Giovannucci *et al*. (1994a,b) hypothesized that smoking may act as an initiator of colorectal cancer and that an induction period of 35–40 years may be needed to increase incidence. Giovannucci explained that if a long induction is needed for tobacco to play a role in colorectal carcinogenesis, this may explain the lack of association between smoking and colorectal cancer found in earlier cohort studies that had a short follow-up time and in case–control studies that did not obtain complete lifetime smoking histories.

The epidemiological evidence on tobacco smoke and colorectal cancer from prospective cohort and case–control studies is summarized below. Relevant information on each of the cohort studies (source of the cohort, years of follow-up, number of cases) is summarized in Tables 2.1 and 2.1.7.1 and the data obtained are reported in Table 2.1.7.2. Relevant information on case–control study design and results is summarized in Tables 2.1.7.3 and 2.1.7.4, respectively. Site-specific relative risks were presented in the majority of studies. Results for colorectal cancers combined were reported in 12 prospective cohort studies (Hammond, 1966; Garland *et al*., 1985; Wu *et al*., 1987; Giovannucci *et al*., 1994a,b; Chen *et al*., 1997; Kato *et al*., 1997; Liaw & Chen, 1998; Nordlund *et al*., 1997; Tulinius *et al*., 1997; Chao *et al*., 2000; Stürmer *et al*., 2000) and six case–control studies (Dales *et al*., 1979; Olsen & Kronborg, 1993; Boutron *et al*., 1995; Yamada *et al*., 1997; Nusko *et al*., 2000; Lam *et al*., 2001).

(*b*) *Factors affecting risk*

Virtually all the cohort and case–control studies reported risks for colorectal cancer in former and current smokers relative to never-smokers (Tables 2.1.7.2 and 2.1.7.4). Sixteen of the prospective cohort studies were conducted in the USA, 10 in Europe and three in Japan. In most studies, a small elevated risk for colon, rectal or colorectal cancer was found for smokers, but results were statistically significant in only a few studies. In these latter studies, former and/or current smokers experienced a significantly increased risk of 1.2–1.4 for colon cancer (Heineman *et al*., 1994; Chyou *et al*., 1996), rectal cancer (Akiba & Hirayama, 1990; Doll *et al*., 1994; Heineman *et al*., 1994; Chyou *et al*., 1996; Engeland *et al*., 1996) or colorectal cancer (Wu *et al*., 1987; Chao *et al*., 2000; Stürmer *et al*., 2000), relative to never-smokers (Table 2.1.7.4). Of all cohort studies, four showed a lower risk

for colorectal cancer among smokers (Hammond & Horn, 1958a,b; Williams *et al*., 1981; Garland *et al*., 1985; Kono *et al*., 1987); the result was statistically significant in one (Williams *et al*., 1981).

A total of 31 case–control studies have examined the association between active smoking and cancer of the colon and rectum (Tables 2.1.7.3 and 2.1.7.4). [The Working Group excluded from their review studies that did not present point risk estimates in association with smoking.]
